procoagulant activity, incidence of pulmonary embolism, autonomic activity, heart rate and blood pressure, and incidence of MI (Dimsdale 2008; Nakagawa et al. 2009). In the aftermath of the destruction of the World Trade Center in New York in September 2001, patients with implanted defibrillators had increased frequency of ventricular tachycardia and ventricular fibrillation episodes, even if they were geographically distant and at no risk of physical harm from the disaster (Shedd et al. 2004; Steinberg et al. 2004). Acute emotional stress can provoke a variety of supraventricular arrhythmias as well as ventricular tachycardia and fibrillation (Ziegelstein 2007).

Acute stress in the laboratory, provoked by standardized tasks such as mirror drawing, the Stroop color-word test, mental arithmetic, video games, and public speaking, results in elevation in heart rate and blood pressure and alteration in indices of cardiac autonomic regulation, with diminished parasympathetic and elevated sympathetic activation, in both healthy volunteers and patients with CAD (Blumenthal et al. 1995; Manuck and Krantz 1986; Rozanski et al. 1988, 1999; Sheps et al. 2002). In addition, coronary vasospasm and mental stress-induced platelet activation appear to be mechanisms of mental stress-induced ischemia in at least some cases (Reid et al. 2009; Yeung et al. 1991). One-third to one-half of patients with CAD experience ischemia during mental stress testing, and ischemia occurs at lower levels of rate-pressure product elevation during mental stress than during exercise stress. Most patients with mental stress-induced ischemia also have exercise-induced ischemia. Wall motion abnormality appears to be a more sensitive indicator of ischemia than ST segment depression, for unknown reasons (Strike and Steptoe 2003). Mental stress-induced ischemia is usually silent (Blumenthal et al. 1995; Rozanski et al. 1988, 1999). The technique of ecological momentary assessment has been used to demonstrate that emotional arousal, and especially anger during daily events, is associated with similar alterations in hemodynamic and autonomic state, and it has been estimated that acute emotional stress is a trigger for up to 20%–30% of acute coronary events (Muller et al. 1994). In patients with coronary disease, mental stress-induced ischemia, indicated by wall motion abnormalities on radionuclide ventriculography or echocardiography, is associated with more than a doubling in the risk of death, even after adjustment for other prognostic variables (Jiang et al. 1996; Sheps et al. 2002). Mental stress-induced myocardial ischemia in CAD patients is associated with increased QT interval variability, increasing proarrhythmic risk (Hassan et al. 2009). Genetic polymorphisms of the beta-adrenergic receptor substantially affect susceptibility to the development of mental stress-induced myocardial ischemia (Hassan et al. 2008).

Acute stress cardiomyopathy, sometimes referred to as Takotsubo cardiomyopathy or broken heart syndrome, is a rare illness occurring in the setting of sudden emotional stress or surprise. Affected individuals, who are predominantly female, experience abrupt onset of ventricular dysfunction, with characteristic ventricular apical ballooning seen on echocardiography (Tsai et al. 2009), with chest pain and/or hypotension, in the absence of atherosclerosis or CAD. Most patients recover, with improvement in ventricular function over several days to weeks (Bielecka-Dabrowa et al. 2010; Wittstein 2007; Wittstein et al. 2005). An abrupt surge in circulating catecholamines and/or sympathetic nervous system activation is believed to cause the ventricular dysfunction by provoking myocardial hypercontractility, and so-called contraction band necrosis has been reported on myocardial biopsy (Samuels 1993; Wittstein 2007; Wittstein et al. 2005). Takotsubo cardiomyopathy has also been reported as a complication of electroconvulsive therapy (ECT) (Kent et al. 2009; O'Reardon et al. 2008).

Midbrain control of vagal withdrawal and sympathetic nervous system activation during mental stress, and its relationship to cardiac events, can be demonstrated through functional brain imaging (Critchley et al. 2005; Thayer and Lane 2007).

Chronic Mental Stress

The cumulative effect of chronic or recurring emotional stressors on risk of myocardial infarction has been strikingly demonstrated in the INTERHEART study (Rosengren et al. 2004), a 52-country investigation evaluating chronic stress in more than 11,000 MI patients and more than 13,000 matched control subjects. Work stress, family stress, and general stress over the past year were each associated with significantly increased risk of MI (odds ratios > 2). The total number of stressors reported was also correlated with MI risk. Similarly, a prospective cohort study of 972 individuals after a first MI found that chronic job strain was associated with a doubling of risk for recurrent CAD events (Aboa-Eboulé et al. 2007).

Sleep Apnea

Sleep apnea is associated with hypertension and CHF (Bradley and Floras 2003a, 2003b). Two studies of chronic heart failure patients found the prevalence of obstructive sleep apnea to range from 11% to 37%, and the presence of sleep apnea increases the risk of developing heart failure. Obstructive apnea results in hypoxia, elevated intrathoracic pressure, and sympathetic nervous system activation, with increases in heart rate and blood pressure. These physiological derangements may contribute to the development of heart failure, ischemic events, and arrhythmias (Shamsuzzaman et al. 2003). A randomized trial showed

that continuous positive airway pressure for 1 month leads to improvement in the number of apnea episodes, systolic blood pressure, heart rate, left ventricular end-systolic dimension, and left ventricular ejection fraction (Kaneko et al. 2003). Central sleep apnea does not severely exacerbate negative intrathoracic pressure, but it does produce periodic sympathetic arousals and increased afterload and myocardial work (Bradley and Floras 2003b) (see also Chapter 15, "Sleep Disorders").

Low Social Support

Although social support is an omnibus term covering a variety of quantitative (i.e., how many relationships?) and qualitative (i.e., what kind of relationships?) aspects of social relationships, a preponderance of studies have shown an association between low support and coronary disease risk and prognosis. The effect of social support is moderated by socioeconomic status, depression, and cultural factors (Lett et al. 2005; H.X. Wang et al. 2006). In two trials, efforts to improve social support for post-MI patients with low social support did not improve cardiac outcomes (Burg et al. 2005; Frasure-Smith et al. 1997).

Excess Cardiovascular Disease–Related Mortality Associated With Other Psychiatric Disorders

Increased cardiovascular mortality risk is also associated with schizophrenia and bipolar disorder (Sowden and Huffman 2009). Adults with bipolar I disorder have increased rates and earlier age at onset of hypertension and CAD compared with the general population, even after controlling for demographic factors, smoking, obesity, substance use, and comorbid anxiety (B.I. Goldstein et al. 2009). The extent to which the pathophysiology of these psychiatric illnesses itself affects cardiovascular risk, as opposed to the effects of lifestyle and associated behaviors (e.g., smoking) and treatments (e.g., antipsychotic drugs, lithium, anticonvulsants), is unknown. These psychiatric disorders also have increased comorbidity with a variety of other medical disorders (C.P. Carney and Jones 2006; C.P. Carney et al. 2006).

Stress Management and Health Education Interventions in CAD Patients

A large meta-analysis of a variety of health-education and stress-reduction interventions in patients with CAD concluded that these interventions reduce the incidence of recurrent MI (29% reduction) and death (34% reduction) at 2- to 10-year follow-up. The mechanism of the effect is unclear; these analyses do not consistently demonstrate a

reduction in mental symptoms (i.e., anxiety and depression ratings are not reduced) (Dusseldorp et al. 1999). Psychoeducational programs may include varying components of health education, stress management, and supervised exercise training; and many individual reports fail to give specific details of the interventions. Successful effects on proximal targets such as systolic blood pressure, cholesterol, body weight, smoking behavior, physical exercise, and emotional distress or some combination of these mediate the beneficial effects for mortality. For recurrent MI, protective effects of psychoeducational intervention were associated with beneficial effects on systolic blood pressure, smoking behavior, physical exercise, and emotional distress. Patients who participate in psychoeducational programs are three times more likely to be successful in quitting smoking (Dusseldorp et al. 1999). Longer intervention programs with more hours of intervention and more tailoring of program content to individual needs appear to have greater long-term effect on cardiac outcomes (Linden 2000; Linden et al. 1996). Subsequent meta-analyses have been critical of the quality of individual trials and more guarded in their assessment of the benefits of psychological interventions in CAD patients, suggesting effects ranging from limited to modest benefits for anxiety and depression symptoms only (Rees et al. 2004) to reductions in cardiac and all-cause mortality and nonfatal MI associated with interventions with behavioral components (Welton et al. 2009). Psychosocial interventions including specific efforts to change targeted behaviors are most effective for reducing all-cause mortality and cardiac mortality, while improved psychosocial support has its strongest effect on reducing nonfatal MI. Psychosocial interventions with an educational component (e.g., providing information) are most effective in reducing anxiety, while interventions with a cognitive component (e.g. reframing, changing beliefs about factors leading to heart disease) are most effective for reducing depression symptoms (Welton et al. 2009). In a carefully done randomized trial, both stress management and supervised exercise training in patients with stable CAD were superior to usual care in reducing emotional distress and improving several physiological parameters associated with cardiovascular risk (Blumenthal et al. 2005).

Diagnostic Issues

Most psychiatric diagnoses are reached in a straightforward fashion in patients with heart disease, but confusion may arise because of the overlap of symptoms of heart disease with symptoms of psychiatric disorder and because treatments for heart disease may cause psychiatric side effects. The most frequent problem in psychiatric diagnosis is the attribution of symptoms of depression to the under-

lying cardiac disease or to a “normal” reaction to the illness, with a resultant underdiagnosis of depression. Generally in practice, however, an inclusive approach is appropriate, counting symptoms such as fatigue and poor sleep toward a diagnosis of depression even if those symptoms might also be attributable to the patient’s cardiac condition (Cohen-Cole and Kauffman 1993) (see also Chapter 8, “Depression”). In an analysis of the 222 patients with acute MI included in the landmark Montreal Heart Institute depression mortality study, the investigators considered the specificity of various symptoms from the depression criteria set for a diagnosis of depression. Sleep disturbance and appetite disturbance did not help to distinguish between patients who met criteria for depressive episode and those who did not (i.e., these symptoms were common in both depressed and nondepressed patients), but fatigue and especially sadness and loss of pleasure occurred almost exclusively in patients who met criteria for a major depressive episode (Lesperance et al. 1996). This finding suggests that patients who report somatic symptoms of depression should be evaluated for the presence of the cardinal mood and interest symptoms, and they should be considered depressed if these symptoms are also present. Patients with advanced heart failure often develop appetite loss and cachexia, but in the absence of loss of self-esteem, loss of interest in ordinarily enjoyable events, or depressed mood, these patients should not be diagnosed with a depressive disorder.

Paroxysmal supraventricular tachycardia (PSVT) occurs in young and middle-aged adults and may manifest with symptoms of shortness of breath, chest discomfort, and apprehension. Because these features may overlap with those of generalized anxiety symptoms and panic attacks, there is a significant risk of misdiagnosis. In a retrospective study of 107 patients with PSVT, DSM-IV (American Psychiatric Association 1994) criteria for panic disorder were met in 59 patients (67%); PSVT had been unrecognized after initial medical evaluation in 55% and remained unrecognized for a median of 3.3 years. Prior to the eventual identification of PSVT, nonpsychiatric physicians attributed symptoms to panic, anxiety, or stress in 32 (54%) of the 59 patients (Lessmeier et al. 1997). Of course, some patients may have both PSVT and an anxiety disorder, with symptomatic attacks including elements of each.

Atypical Chest Pain and Palpitations

Typical anginal chest pain in CAD occurs with exertion or after eating; is not exacerbated by palpation of the chest or by inspiration; is described as dull, pressure-like, or burning rather than sharp or stabbing; and is experienced across the precordium rather than in a pinpoint area of the left side of the chest. Many patients present for evaluation

of atypical chest pain (Sheps et al. 2004). While atypical features do not rule out a diagnosis of CAD, 40%–70% of patients with no history of documented CAD and few CAD risk factors have panic disorder, somatoform disorders, or depression (Alexander et al. 1994; Fleet et al. 2000). Patients with noncardiac chest pain demonstrate a high prevalence of anxiety disorders (approximately 40%–60%), including panic and social phobia, depression (approximately 5%–25%), and somatoform disorders (2%–15%), and a substantial portion of the remaining patients have subsyndromal symptoms of these disorders (Hocaoglu et al. 2008; Jonsbu et al. 2009; White et al. 2008). More than half of children with noncardiac chest pain have an anxiety disorder, usually panic disorder (Lipsitz et al. 2005). A small randomized trial found a benefit of 8 weeks of paroxetine treatment in noncardiac chest pain patients who did not meet criteria for panic disorder or depression (Doraiswamy et al. 2006).

In the absence of CAD, characteristics of chest pain patients predicting panic disorder include female sex, atypical chest pain quality, younger age, lower education and income, and high self-reported anxiety (Dammen et al. 1999; Huffman and Pollack 2003). Panic disorder is twice as likely in chest pain patients without CAD as in patients with CAD (Dammen et al. 1999; Fleet et al. 2000).

Psychiatric disorders are also common in patients complaining of palpitations. In one study using structured diagnostic interviews and self-report questionnaires for patients undergoing ambulatory electrocardiogram (ECG) monitoring, the lifetime prevalence of any disorder was 45%, and 25% of the patients had a current disorder. The lifetime prevalences of panic disorder and major depression were 27% and 21%, respectively, and 19% had panic disorder at the time of evaluation (Barsky et al. 1994a). Rates of anxiety, depressive, and somatoform disorders were similar in another study 15 years later (Jonsbu et al. 2009). These rates are probably somewhat higher than in the general population, because they derive from tertiary-care clinic settings. Even when a patient with palpitations has a history of panic disorder, clinical examination alone may not be sufficient to exclude significant arrhythmias. Ambulatory electrocardiographic monitoring with loop recording is the most sensitive method for identifying the presence of a specific arrhythmia in patients with palpitations (Thavendiranathan et al. 2009).

Special Issues

Heart Transplantation

Heart transplantation has been the treatment of last resort for patients with severe heart failure, and occasionally for

patients with intractable recurrent myocardial ischemia or ventricular arrhythmias, for the past three decades (see also Chapter 31, "Organ Transplantation"). Because of donor scarcity, the number of heart transplants performed annually in the United States has reached a plateau of approximately 2,100 per year. Patients eligible for heart transplantation typically have an expected survival of less than 2 years unless they receive a transplant. With transplantation, expected 5-year survival is now around 67%–73% (Organ Procurement and Transplant Network 2010). Complications can occur, and the care regimen for heart transplant patients is challenging, especially in the first few months after surgery, so transplant programs generally screen patients and exclude from candidacy those with significant relative contraindications.

These facts provide the context for the "normal" psychological experience of patients entering the process (Shapiro 1990). Patients generally fear that they are close to death or will experience a sudden catastrophic deterioration in the future and believe that a transplant is their best hope for survival. Although they may be anxious about the dangers of transplantation, they are even more often anxious about being excluded from candidacy. Consequently, the evaluation period is a time of heightened concern, and patients meeting with a psychiatrist as part of the evaluation process wonder whether they will "pass" this examination. Patients awaiting transplantation often experience depression symptoms, because they perceive themselves as helpless to fundamentally affect their own chances of survival. During the waiting period, depression is often enhanced by a sense of guilt over wishes for the death of a suitable donor. Patients sometimes describe a kind of psychological "ambulance chasing," hearing a siren and wondering whether this might signal the availability of a donor. Before, at the time of evaluation, and up to the time of receiving a transplant, patients may also display variable levels of denial of the seriousness of their illness and ambivalence about undergoing transplant surgery. This minimization or denial of illness can fluctuate and coexist with other emotional responses, including fear, depression, and anxiety. Patients who come to heart transplantation after an acute catastrophic cardiac event, without a prior chronic heart failure syndrome, are especially prone to experience a combination of denial, shock, anger, and fear all at the same time, as they must rapidly assimilate an altered view of their health status, appreciate the associated risks, and appraise the possible risks and benefits of transplantation, before having much opportunity to mourn the loss of their previous health and associated social role. If they are sedated or in a state of altered consciousness because of cardiogenic shock, medication, or metabolic disarray, their capacity to psychologically ad-

just is further reduced, with more adaptation forced on them after the fact.

Following heart transplant surgery, patients receive multiple immunosuppressive anti-rejection medications, along with vitamins; minerals; antibacterial, antifungal, and antiviral medications; and treatments as needed for hypertension, arrhythmias, fluid retention, or other conditions. Most patients are hospitalized for 10–20 days after surgery, undergoing surveillance for allograft rejection as the immunosuppressive medication doses are adjusted. (These medications are discussed in Chapter 31, "Organ Transplantation.") High doses of intravenous and then oral corticosteroids are the rule in the initial weeks after transplant surgery, and predictably they induce increased appetite, fluid retention, and mood lability. Most patients experience an initial euphoria at awakening from surgery, knowing that they have now been delivered from end-stage heart failure, but the emotional reaction depends in part on the patient's previous expectations in comparison with the state of subjective well-being in the early days after surgery. Positive feelings tend to subside as complications occur and as the patient settles into the work of rehabilitation and adjustment to the new medication regimen. One or more episodes of rejection are not uncommon in the early period after surgery; if transient corticosteroid dose increases are employed to treat rejection episodes, a medication-exacerbated emotional roller coaster may ensue.

Psychiatric complications after heart transplantation are fairly common (see Chapter 31, "Organ Transplantation," for a fuller discussion). In addition to postoperative delirium, steroid-induced mood disorders and depression not attributable to steroids occur in perhaps 20%–40% of patients in the first year after surgery. Many cases occur in the setting of medical complications, but role transitions are often difficult for the recovering patient, and stressors such as increased demand for autonomous function or the need to provide for others in the family, difficulty negotiating return to work, or financial concerns that were previously ignored often stimulate increased emotional distress (Shapiro 1990; Shapiro and Kornfeld 1989). Some heart transplant patients experience transplantation-related posttraumatic stress disorder following particularly frightening or troubling episodes during their care, appear psychologically fixated on these events and subjectively distressed, and are impaired in their daily functioning long after the transplant (Dew et al. 2001).

Left Ventricular Assist Devices

The shortage of available donors of hearts for transplantation and the large number of patients dying of CHF provided impetus even early in the era of heart transplantation for the development of artificial heart technology (D.J.

Goldstein and Oz 2000). In addition to attempting to devise a total artificial heart, researchers have developed and tested a variety of ventricular assist pumps over the past decade. To date, experience with total artificial hearts has been characterized by limited success, although they may be helpful as short-term bridges to heart transplantation (Copeland et al. 2004). Ventricular assist devices, however, have been more successful and are in more widespread use as bridges to heart transplantation or in some cases bridges to recovery after acute myocardial injury (D.J. Goldstein and Oz 2000). Early experience with use of LVADs designed to be used for periods of weeks to months as a bridge to transplantation indicated that significant neuropsychiatric issues were delirium, stroke, cognitive impairment, pain, and depressed mood. Depression seemed especially linked to frustration with ongoing limitations in function as a result of tethering to the device, and cerebrovascular and cognitive problems were associated with a history of even minor or transient cerebrovascular disease symptoms before LVAD surgery (Shapiro et al. 1996). For most patients, quality of life with LVADs was superior to that while they were in severe heart failure (Dew et al. 1998, 1999a, 1999b). Ongoing improvements in device design have reduced the mechanical problems of attachment to an external device to a considerable degree (D.J. Goldstein and Oz 2000).

The success of LVAD use as a bridge to transplantation led to study of permanent ("destination") LVAD treatment for patients with end-stage heart failure who could not receive a heart transplant (Rose et al. 1999). The REMATCH trial, a randomized clinical study providing either optimized medical therapy or LVAD therapy for patients with severe chronic heart failure, demonstrated a substantial survival benefit associated with LVADs, along with improved quality of life outcomes (Rose et al. 2001). Interestingly, somatic dimensions of quality of life were substantially better in LVAD recipients, but mental-emotional components did not differ from those of medically treated heart failure patients (Shapiro et al. 2002). Postoperative delirium was the most important psychiatric problem seen in LVAD patients in this study (Lazar et al. 2004). The success of LVAD treatment in extending survival without worsening quality of life in the REMATCH trial led to approval by the U.S. Food and Drug Administration (FDA) of destination LVAD therapy for nonexperimental use in the United States in 2002. However, quality of life in patients with LVADs is not as good as that in patients who receive heart transplants or who are able to be weaned off of mechanical assist devices (Dew et al. 1999b; Wray et al. 2007).

Ventricular assist device design has evolved over the past decade; pulsatile devices are being superseded by continuous flow systems with better durability and better as-

sociated neurocognitive outcomes and quality of life (L.W. Miller et al. 2007; Petrucci et al. 2009; Slaughter et al. 2009). In addition to their use as bridges to transplantation and as destination therapy, ventricular assist devices are also being used for "bridge to recovery," with current trials investigating the adjunctive use of the beta-adrenergic agonist clenbuterol, stem cell therapy, and other means of promoting ventricular remodeling and recovery of ventricular function (Terracciano et al. 2010). While most patients receive ventricular assist devices for chronic heart failure, and therefore have opportunity for education and consideration of their options before implantation, emergency implantation in the setting of acute cardiogenic shock has become more common. Patients in this situation may not have been able to participate in decision making, and have greater difficulty with initial emotional adjustment to living with the assist device.

Hypertension

The relationship of psychological factors to the development of hypertension has been a subject of controversy, with mixed findings in large-scale observational studies. Several cross-sectional studies found no relationship between psychological variables and risk of hypertension (Davies et al. 1999; R. Friedman et al. 2001; Hildrum et al. 2007; Licht et al. 2009). In one study comparing the blood pressure of subjects with current and past history of depression and/or anxiety and healthy control subjects, current and remitted depression were associated with lower likelihood of hypertension and lower mean systolic blood pressure, but use of TCAs, SSRIs, and noradrenergic agents increased the risk of hypertension (Licht et al. 2009). Another study found a significant association of hypertension with co-occurrence of generalized anxiety disorder and major depressive disorder, but not either disorder alone (Carroll et al. 2010).

Large-scale prospective studies with longitudinal follow-up ranging from 11 to 22 years have come to different conclusions. A 15-year prospective study of psychosocial risk factors for hypertension based on a follow-up of more than 3,000 young white and black adults from four metropolitan areas of the United States found that two components of Type A behavior—namely, "time urgency-impatience" and "hostility"—were each associated with almost double the rate of incident hypertension. In contrast, anxiety symptoms, depression symptoms, and "achievement-striving-competitiveness" (another Type A component) did not predict hypertension (Yan et al. 2003). In a Norwegian epidemiological study, high baseline depression and anxiety symptoms were both associated with low systolic blood pressure at 11-year follow-up, and the magnitude and direction of anxiety or depression symptom changes over time

were inversely associated with the magnitude of the change in systolic blood pressure. These effects were not accounted for by use of antihypertensive and antidepressant medication (Hildrum et al. 2008). However, 22-year follow-up of a population-based cohort of 3,310 normotensive persons without chronic diseases from the National Health and Nutrition Examination Survey I (NHANES I) Epidemiologic Follow-up Study found that combined symptoms of depression and anxiety ("negative affect") were associated with increased risk for hypertension. The risk for treated hypertension was increased in both men and women and was most pronounced (more than threefold) in black women (Jonas and Lando 2000). A review (Rutledge and Hogan 2002) of 15 prospective studies of psychological traits affecting the development of hypertension, with sample sizes varying from 78 to 4,650 subjects and follow-up for 2.5–21 years, found small but significant effects of anger, anxiety, depression, and other variables, with an overall magnitude of effect suggesting an 8% increase in prospective hypertension risk associated with a high level of one or more of the psychological variables. A smaller number of studies separately reported the effect of psychological factors on hypertension in African Americans and in women. In African Americans, the same psychological predictors appeared to be associated with hypertension. In women, the results were equivocal.

The main psychiatric consequence of hypertension seems to be long-term neurocognitive impairment and increased risk of dementia (Frishman 2002). Treatment that successfully controls blood pressure reduces the risk (Forre et al. 2002; Guo et al. 1999; Launer et al. 1995; Vinyoles et al. 2008). In patients older than 60 years, adherence to antihypertensive therapy is associated with better blood pressure control and better cognitive function (Vinyoles et al. 2008). White-coat hypertension, defined as repeatedly high blood pressure at visits to the doctor's office, with normal ambulatory and self-measured blood pressure, is associated with increased long-term risk of stroke but not of heart disease (Angeli et al. 2005). Behavioral treatments appear to have a modest effect at best on hypertension (Linden and Moseley 2006; Perez et al. 2009), but combined treatments may help in paroxysmal hypertension, especially if paroxysmal episodes of high blood pressure are linked to panic or anxiety (Pickering and Clemow 2008).

Congenital Heart Disease

The prevalence of psychiatric disorders in adult survivors of congenital heart disease has not been extensively studied. The existence of this clinical population depends largely on advances in pediatric cardiac surgery over the past three decades. Lifetime rates of mood and anxiety disorders may be as high as 50% (Kovacs et al. 2009), but some

investigators have not found elevated rates of psychiatric symptoms (Cox et al. 2002; Geyer et al. 2006). Sexual dysfunction is common in men who have had surgery for congenital heart disease (Vigl et al. 2009).

Psychological maladjustment is common in children after surgery for congenital heart disease (Latal et al. 2009). Overall IQ scores are typically in the normal range but lower than healthy control subjects, and subtle neuropsychological deficits are common (Forbess et al. 2002; Miatton et al. 2007). For cyanotic conditions, but not for acyanotic lesions, delayed repair appears to exacerbate intellectual impairment (Newburger et al. 1984). Other common psychological problems among children and young adults with congenital heart disease include concerns about exclusion from participation in peer group activities such as sports and gym class, problems with appearance (short stature, cyanosis, drug side effects on appearance), concerns about attractiveness, capacity to develop intimate relationships, exclusion from work, and fears about mortality (Kendall et al. 2001).

Treatment Issues

Psychotherapy

Psychological reactions to the experience of heart disease include feelings of anxiety and sadness as well as concerns about survival and well-being and their effects on social roles, relationships, and the impact on loved ones. Denial is nearly universal as an initial reaction to illness, and it can be helpful in staving off depressed and anxious mood or hurtful because of nonadherence to the treatment program. Conversely, preoccupation with disease can lead to abnormal illness behavior, unnecessary disability, and impaired quality of life. Few systematic studies of psychotherapy have been reported that specifically targeted psychological symptoms or psychiatric disorders in heart patients. As was described previously, a larger number of studies have described stress management or health education effects on cardiac outcomes in cardiac rehabilitation settings; meta-analyses of these studies do show beneficial effects on cardiac outcomes and suggest that reducing emotional distress and changing health-related behaviors may be correlated with better cardiac disease outcomes (Dusseldorp et al. 1999; Linden et al. 1996; Welton et al. 2009).

The ENRICH trial tested the effects of a CBT intervention versus usual care in patients who had a recent MI and either low social support and/or major depression or minor depression with a history of prior major depression in a randomized trial. Patients in the intervention arm participated in either individual or group therapy sessions; treatment

was manualized; and therapist adherence to treatment methods was assessed during the trial. Most patients received 6–10 therapy sessions. The trial demonstrated a modest benefit of the CBT intervention on measures of social support and depression. However, the improvement on these measures seen in the usual-care group was higher than expected, so that the effect of treatment, although statistically significant, was of small magnitude (Writing Committee for the ENRICHD Investigators 2003).

As described previously, the Recurrent Coronary Prevention Project tested the effect of group Type A behavior modification in reducing the impact of Type A behavior pattern on mortality and recurrent infarction in a cohort of post-MI patients (M. Friedman et al. 1986). In retrospect, although the term was not used at the time, this was clearly a cognitive-behavioral psychotherapy intervention. The intervention had a strong beneficial effect on Type A behavior as rated using a videotaped structured interview for the assessment of Type A behavior.

Interpersonal psychotherapy (IPT) of depression focuses on present-day interpersonal problems linked to depressed mood, such as interpersonal disputes, grief after object loss, interpersonal deficits, and social role transitions. One such role transition may occur with the change in social role imposed by development of a chronic or acute medical illness (Klerman et al. 1984). Therefore IPT would seem to be readily applicable to the treatment of patients who experience depression after the onset or exacerbation of heart disease. However, the only published controlled trial of interpersonal therapy for depression in patients with CAD, the CREATE trial (Lesperance et al. 2007), found no added benefit of interpersonal therapy compared with clinical management alone.

An innovative collaborative care model was successful in reducing depression symptoms and improving health-related quality of life in patients with depression following coronary bypass surgery in a recent randomized controlled trial (Rollman et al. 2009). Patients met criteria for at least mild depression through screening with the 9-item Patient Health Questionnaire (PHQ-9). This trial intervention included having a nurse perform telephone monitoring of patient status with education about depression, provision of self-help materials, and encouragement of exercise and treatment adherence. Depending on patient preference and response to initial supportive interventions, referral to a mental health specialist or pharmacotherapy by the patient's primary care physician was coordinated by the psychiatric study nurse, with support by a supervising study psychiatrist. Patients who received pharmacotherapy generally received an SSRI, but treatment was open and could be adjusted according to patient response to try other categories of medication.

Psychopharmacological Treatment

Common adverse cardiac effects of psychiatric drugs are shown in Table 18–2 (see also Chapter 38, “Psychopharmacology”).

Antidepressants

Antidepressants must be used in therapeutically effective doses in cardiac patients with depression, and it is counterproductive to use inadequate doses out of fear of side effects or prolongation of metabolism. Unless the patient has severe right heart failure resulting in hepatic congestion, ascites, and jaundice, it is unlikely that metabolism of oral psychotropic medication (except for lithium) will be substantially impaired because of heart disease.

TCAs cause orthostatic hypotension, cardiac conduction delay (bundle branch block or complete atrioventricular nodal block), and, in overdose, ventricular arrhythmias (ventricular premature depolarization, ventricular tachycardia, and ventricular fibrillation). QRS interval prolongation results from interference with phase 1 depolarization (slow Na^+ channel activity) of the action potential across the membrane of the specialized conduction tissue of the ventricle. Prolongation of the QT interval is predominantly caused by prolongation of the QRS interval, and ventricular tachycardia or fibrillation can occur if marked prolongation of the QT interval (over 500 msec) results in the R-on-T phenomenon. Nortriptyline and desipramine tend to cause less orthostatic hypotension than tertiary amine tricyclic drugs and are better tolerated by patients with cardiac disease (Roose and Glassman 1989; Roose et al. 1986, 1987, 1989). Cardiac pacemakers can obviate the risk of heart block associated with TCAs. More commonly problematic, however, is orthostatic hypotension, which can result in syncope and falls.

TCAs have quinidine-like effects on cardiac conduction and are classified as Type 1A antiarrhythmic agents. Drugs of this class have been shown to increase rather than decrease mortality in post-MI patients with premature ventricular contractions (CAST Investigators 1989; CAST II Investigators 1992; Morganroth and Goin 1991), an effect believed to be mediated by episodic myocardial ischemia (Lynch et al. 1987). Consequently, TCAs should generally not be used as first-line agents for treatment of depression in ischemic heart disease patients. This is not to say that they should never be used, however, because their efficacy may offset the risk for selected patients. Consideration should be given to the totality of the clinical situation, including the severity of depression, past treatment responses, concomitant medications, and ECG (Glassman et al. 1993).

SSRIs have little to no cardiac effect in healthy subjects. The most commonly observed effect is slowing of heart rate,

TABLE 18-2. Selected cardiac side effects of psychotropic drugs

Drug/class	Cardiac effects
Lithium	Sinus node dysfunction and arrest
SSRIs	Slowing of heart rate; occasional sinus bradycardia or sinus arrest
TCAs	Orthostatic hypotension; atrioventricular conduction disturbance; Type IA antiarrhythmic effect; proarrhythmia in overdose and in setting of ischemia
MAOIs	Orthostatic hypotension
First-generation antipsychotics	Orthostatic hypotension (especially low-potency drugs); QT interval prolongation; torsade de pointes
Second-generation antipsychotics	Variable; QT interval prolongation; ventricular arrhythmias; metabolic syndrome
Clozapine	Above plus orthostatic hypotension; myocarditis
Carbamazepine	Type IA antiarrhythmic effects; AV block; hyponatremia
Cholinesterase inhibitors	Decreased heart rate

Note. AV = atrioventricular; MAOIs = monoamine oxidase inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

generally by a clinically insignificant 1–2 beats/minute. Occasional cases of sinus bradycardia or sinus arrest, with light-headedness or syncope, have been reported (Roose et al. 1994, 1998a, 1998b). The combination of beta-adrenergic blockade and serotonin reuptake inhibitors may result in additive slowing of heart rate with increased risk of symptoms. In addition, some SSRIs (fluoxetine, paroxetine, fluvoxamine) inhibit metabolism through the cytochrome P450 (CYP) 2D6 pathway responsible for metabolism of many beta-blockers. Therefore, the blood level and effect of beta-adrenergic blockers may be increased.

In patients with preexisting heart disease, the effects of SSRIs on cardiac function have been evaluated in several studies (Sheline et al. 1997). Some studies using fluoxetine and paroxetine in mixed groups of stable patients with ischemic and nonischemic heart disease demonstrate that ejection fraction may actually improve to a small extent in patients with preexisting ventricular dysfunction. The effects on heart rate are similar to those seen in patients who are free of cardiac disease, and no blood pressure, cardiac conduction, or arrhythmia effects have been noted (Roose et al. 1994, 1998a, 1998b). The SADHART study, as described previously, was a double-blind, placebo-controlled, randomized trial examining the effect of sertraline in patients with major depression immediately after an acute coronary syndrome. Sertraline had no effect on heart rate, blood pressure, arrhythmias, ejection fraction, or cardiac conduction, and adverse events were rare. All patients in SADHART began medication within 30 days of the index acute coronary event (Glassman et al. 2002). Sertraline was effective for treatment of depression in those patients with a prior history of depression, but it did not differ from pla-

cebo in response rate for those patients with no prior history of depression. Other prognostic factors associated with response to sertraline were onset of depression before the index cardiac event and more severe depression (Glassman et al. 2006).

The CREATE trial (Lesperance et al. 2007) was a 12-week randomized controlled trial utilizing a two-by-two factorial design to compare citalopram (20–40 mg/day) with placebo treatment, while simultaneously comparing clinical management with and without interpersonal psychotherapy, for treatment of depression in 284 patients with stable coronary disease. The effect of citalopram on depression symptoms and remission rate was significant. Compared with subjects in the placebo group, those receiving citalopram had a 3.3-point larger drop in Hamilton Depression Rating Scale scores and a higher likelihood of response (53% vs. 40%) and remission (36% vs. 23%). In a study in CHF patients, treatment of depression with citalopram was not more effective than placebo treatment; a high response rate was observed in both treatment groups (Fraguas et al. 2009).

Mirtazapine treatment (30–45 mg/day) of depression in patients who had had an acute coronary syndrome was evaluated in a randomized placebo-controlled trial as a part of the MIND-IT trial (Honig et al. 2007). This study enrolled 94 patients and employed several measures of depression at 8 and 24 weeks. Findings were mixed, but mirtazapine was superior to placebo on some measures at both follow-up assessments. Mirtazapine was well tolerated by the patients in this trial, with no effects on heart rate, blood pressure or electrocardiographic parameters, and no difference from placebo in the rate of major adverse cardiac events.

A randomized double-blind, placebo-controlled trial of controlled-release paroxetine for depression treatment in 28 patients with chronic heart failure found paroxetine superior to placebo in reducing Beck Depression Inventory symptoms. No blinded observer rating of treatment response was obtained. The paroxetine dose was 12.5–25 mg/day. Paroxetine treatment was generally well tolerated, although one patient in the active treatment arm died of CHF (Gottlieb et al. 2007).

The cardiovascular effects of other antidepressants have been less fully studied, especially in patients with cardiac disease. Bupropion appears to have few cardiovascular effects in small studies but may increase blood pressure occasionally (Roose et al. 1991). The serotonin–norepinephrine reuptake inhibitor venlafaxine behaves as an SSRI at low doses and displays a noradrenergic effect at higher doses. The main cardiovascular effect of this dual action is a tendency to increase blood pressure in a dose-dependent fashion at a dosage of 150 mg/day or higher. There may be a diminution of this hypertensive effect of venlafaxine with its extended-release formulation. The effect on patients with preexisting heart disease or hypertension has not been evaluated. Clinical experience with mirtazapine in patients with hypertension has also demonstrated instances of worsening hypertension, but the frequency of this adverse effect is unknown. Monoamine oxidase inhibitors (MAOIs) cause hypotension and orthostatic hypotension; dietary indiscretions resulting in high circulating levels of tyramine cause hypertensive crises. Consequently, there has been little interest in use of MAOIs in patients with heart disease. Sympathomimetic agents increase blood pressure in patients on MAOIs, though hypertensive crises are actually infrequent. Caution with the use of intravenous pressors (epinephrine, isoproterenol, norepinephrine, dopamine, dobutamine) is required (Krishnan 1995).

Antipsychotics

Antipsychotics are used in cardiac disease patients with comorbid schizophrenia, schizoaffective disorder, bipolar disorder, and other psychotic disorders and in the management of delirium in acute cardiac care settings, such as after cardiac surgery or in ICU management of pulmonary edema, arrhythmias, or acute MI. Although first-generation antipsychotic medications are losing primacy as agents of choice for management of chronic psychosis because of their extrapyramidal side effects, they continue to play a role in management of acute psychotic symptoms in delirium. In part this is because of the availability of parenteral formulations for haloperidol, few cardiovascular effects, and extensive experience with use of intravenous haloperidol in the critically ill (see Chapter 5, “Delirium”).

For chronically psychotic patients with heart disease, the choice of antipsychotic is based on side-effect profile. The principal cardiovascular effects of antipsychotic agents are orthostatic hypotension and QT interval prolongation. Orthostatic hypotension secondary to antipsychotic drugs is related to their alpha-adrenergic receptor-blocking effect, seen especially with the low-potency antipsychotic agents such as chlorpromazine and often accompanied by sedative effects. There are few data about the frequency or clinical significance of orthostatic effects of antipsychotic drugs in patients with heart disease. More attention has been paid to the less common but much more dramatic and dangerous side effect of cardiac arrest secondary to ventricular tachyarrhythmias in patients on antipsychotic drugs. The characteristic tachyarrhythmia is torsade de pointes, a polymorphic tachycardia with the appearance of “twisting of the points” of the QRS complex. QT prolongation as a result of antipsychotic agents, unlike that caused by TCAs, appears to be an effect of impaired repolarization of the ventricular conduction tissue at the end of systole, specifically an effect on the so-called potassium rectifier channel. The QT interval normally is less than 450 msec. Because the normal QT interval is dependent on heart rate, evaluation customarily adjusts for heart rate to yield a corrected QT interval (QTc). QTc greater than 500 msec greatly increases the risk of torsade de pointes. Thioridazine is the agent most commonly associated with torsade and sudden cardiac death, and sertindole was withdrawn in the United States because of its QT prolongation effects and the rate of sudden cardiac deaths observed overseas. Intravenous haloperidol is frequently employed in delirious open-heart surgery patients, and although it does have the potential to prolong the QT interval, its use in dosages up to 1,000 mg/24 hours has been reported without complications (Tesar et al. 1985). The one exception appears to be aripiprazole, which has not been reported to cause QTc prolongation even in overdose (Young et al. 2009). Clearly, electrocardiographic monitoring is important in ICU settings, and patients with a QTc interval greater than 450 msec should be closely monitored. A QTc interval over 500 msec is generally considered a contraindication to use of haloperidol and other QT-prolonging agents.

In considering the use of drugs that may prolong the QT interval, risk factors for torsade should be reviewed, including female sex, familial long QT syndrome; family or personal history of sudden cardiac death, syncope, or unexplained seizure; arrhythmias; personal history of hypertension; other medications that prolong the QT interval or that may interfere with metabolism of other QT-prolonging agents; valvular heart disease; and bradycardia. Laboratory values of particular importance are magnesium and

potassium levels. Class IA and III antiarrhythmic drugs, dolasetron, droperidol, tacrolimus, levomethadyl acetate, other antipsychotic agents, many antibiotics ("floxacin"), and antifungal agents may increase the risk of torsade de pointes (Al-Khatib et al. 2003; Glassman and Bigger 2001; Moss 2003; Roden 2008).

A large cohort study taking advantage of statewide Medicaid prescription data found that antipsychotic drug use was associated with doubling of sudden cardiac death risk; the increase in the absolute risk of sudden cardiac death associated with antipsychotic drug use was about 0.15%, meaning that one extra death would occur for every 666 persons treated for 1 year with antipsychotic drugs (Ray et al. 2009). It seems clear that this risk would be higher in patients with preexisting cardiac disease maintained on antipsychotic agents. For elderly patients receiving antipsychotic drugs for agitation or behavioral disturbance (e.g., psychotic symptoms in dementia), it is now clear that the risk of death associated with antipsychotic drugs is substantially higher. In the past several years, several studies (Gill et al. 2007; Kales et al. 2007; Liperoti et al. 2005; Rochon et al. 2008; Schneider et al. 2005; Suh and Shaw 2005; P.S. Wang et al. 2005) have drawn attention to the mortality risk associated with antipsychotic drug use in elderly patients with behavioral disturbance, and an FDA black-box warning was applied to all first- and second-generation antipsychotic agents. Studies have been conducted primarily in nursing home populations over short time frames (typically, one to several months) and demonstrate an increased absolute risk of death of about 1.9%, implying a number needed to harm of about 50. Most of these deaths were attributed to either cardiovascular or infectious causes. None of these studies directly address treatment of delirium, but the psychiatrist venturing to treat delirium or acute psychotic symptoms in patients with heart disease must be guided by an appreciation of these risks.

Of course, polymorphic ventricular tachycardia can also occur in the absence of long QT interval. Brugada syndrome is a rare disorder also characterized by history of syncope and risk of sudden death due to polymorphic ventricular tachyarrhythmias. In contrast to the defect in potassium channel-mediated ventricular repolarization underlying antipsychotic-induced prolongation of the QT interval, in Brugada syndrome the conduction abnormality is mediated by a sodium channel, prolonging ventricular depolarization, particularly in the right ventricle. ECG demonstrates an RSR' pattern and ST segment elevation in the right precordial leads, resembling right bundle branch block. Lithium has been reported to provoke Brugada syndrome, and drugs that interfere with the sodium channel, prolonging the depolarization phase of the action potential, including phenothiazines, tricyclic anti-

depressants, and carbamazepine, might also increase risk (Laske et al. 2007).

Second-generation antipsychotic agents also increase cardiovascular disease risk indirectly through promotion of the metabolic syndrome (dyslipidemia, obesity, hypertension, and impaired glycemic control). Olanzapine and clozapine may be most likely, and aripiprazole and ziprasidone least likely, to induce metabolic syndrome. In the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, olanzapine and quetiapine were associated with a slight increase, and risperidone, ziprasidone, and perphenazine with a slight decrease, in the 10-year risk of heart disease (Bobes et al. 2007; Correll et al. 2006, 2009; Daumit et al. 2008; Newcomer et al. 2007).

Myocarditis has been estimated to occur in 0.01%–1.0% of patients treated with clozapine, generally within the first few weeks of treatment (Merrill et al. 2005). Cardiomyopathy has also been reported, with onset up to a few years after starting clozapine, even without prior acute myocarditis (Mackin 2008).

Anxiolytics

Benzodiazepines have no specific cardiac effects. Reduction of anxiety tends to reduce sympathetic nervous system activation and, therefore, to slow heart rate, reduce myocardial work, and reduce myocardial irritability. Before the introduction of beta-blockers to acute coronary care, benzodiazepines were widely used for prophylaxis of infarct extension and arrhythmias in acute coronary syndrome patients, but this practice has largely been abandoned. Lorazepam can be given by intramuscular (or intravenous) injection; for most other benzodiazepines this route should be avoided because of poor absorption. Oxazepam, lorazepam, and temazepam do not undergo Phase I hepatic metabolism and may be easier for patients with heart failure to tolerate. Buspirone has no cardiovascular effects.

Stimulants

Stimulants are often useful for treating of depressed, medically ill patients, particularly those with pronounced apathy, fatigue, or psychomotor slowing. A review (Wilens et al. 2005) of several trials of stimulant treatment of attention-deficit/hyperactivity disorder (ADHD) in adults concluded that treatment increases systolic and diastolic blood pressure by about 5 mm Hg, but the doses that would be employed for ADHD treatment would typically be higher than would be used in cardiac patients. At dosages of 5–30 mg/day, dextroamphetamine and methylphenidate are well tolerated by heart disease patients, including patients with cardiac arrhythmias and angina (Masand and Tesar 1996), and have no effects on heart rate and blood pressure. Clinical response generally occurs

within days rather than weeks. The safety of a long-term treatment that raises blood pressure by 5 mm Hg has been questioned (Nissen 2006), and arrhythmia/sudden cardiac death risk associated with stimulants might be increased in children and adolescents (Gould et al. 2009) or if there is unrecognized structural heart disease (Nissen 2006), but a 10-year review of Florida Medicaid data (Winterstein et al. 2007) did not find increased mortality in children treated with stimulants for ADHD, and a recent Cochrane review did not find substantial evidence for cardiovascular harm from stimulant treatment (Candy et al. 2008). In view of the lack of consensus on the cardiovascular risks of stimulants, cardiology consultation may be prudent before prescribing stimulants for patients with heart disease.

Lithium

Lithium occasionally causes sinus node dysfunction and even sinus arrest (Mitchell and Mackenzie 1982). There are no studies of the use of lithium in patients with heart disease. Generally, even in patients with heart disease with reduced cardiac output, lithium can be safely used by adjusting the dosage downward. Because renal function is sometimes impaired in advanced heart failure, lithium dosing requires further reduction. Caution is necessary for patients taking ACE inhibitors, angiotensin II receptor blockers, and diuretics, especially thiazides, and for those on salt-restricted diets. In patients with acute CHF exacerbations and acute coronary syndromes, rapid electrolyte and fluid balance shifts can occur; lithium is best avoided during such episodes because of the difficulty managing fluctuations in lithium level as cardiac therapy is adjusted.

Other Mood Stabilizers

Valproic acid and lamotrigine have no cardiovascular effects. Carbamazepine resembles TCAs in having a quinidine-like Type IA antiarrhythmic effect and may cause atrioventricular conduction disturbances.

Cholinesterase Inhibitors and NMDA Receptor Antagonists

The elderly are prone to co-occurrence of dementia and heart disease, and treatments for dementia, including cholinesterase inhibitors (donepezil, rivastigmine, galantamine) and *N*-methyl-D-aspartic acid (NMDA) inhibitors (memantine), may be used in patients with concurrent heart disease. The procholinergic effect of cholinesterase inhibitors may cause vagotonic effects, including bradycardia or heart block. For memantine, hypertension is the only cardiac effect described by the manufacturer on the basis of premarketing controlled trials.

Electroconvulsive Therapy

ECT leads to an initial sympathetic discharge, with tachycardia and hypertension, followed by a parasympathetic reflex response, with instances of bradycardia and arrhythmia. Asystole can occur rarely but can be prevented by premedication with atropine. Excessive sympathetic response may evoke myocardial ischemia; for the elderly or those with known coronary disease, monitoring the ECG is essential, and treatment with intravenous beta-blockers is sometimes required. Takotsubo cardiomyopathy has been reported after ECT; a case of successful reintroduction of ECT after prior Takotsubo cardiomyopathy response to ECT has also been reported (Kent et al. 2009; O'Reardon et al. 2008). Cardiac effects of ECT are discussed further in Chapter 40, "Electroconvulsive Therapy." ECT has been used safely in patients with ischemic heart disease, heart failure, and heart transplants. Acute MI or recent malignant tachyarrhythmias are relatively strong contraindications.

Cardiac–Psychiatric Drug Interactions

A few drug interactions between psychotropic and cardiovascular drugs are worth noting (Table 18–3). Many psychotropic drugs lower blood pressure; their interaction with antihypertensive medications, vasodilators, and diuretics may potentiate hypotension. TCAs and antipsychotic drugs that prolong the QT interval may interact with antiarrhythmic agents such as quinidine, procainamide, moricizine, and amiodarone and result in further QT prolongation or atrioventricular block. Although SSRIs may increase risk of bleeding, most do not appear to have a clinically significant effect on the international normalized ratio (INR) in patients treated with warfarin. The largest INR effects occur with fluoxetine and fluvoxamine (Holbrook et al. 2005; Sansone and Sansone 2009). In patients undergoing CABG, SSRIs do not increase bleeding risk or hospital mortality, even when administered along with warfarin, antiplatelet therapies, and nonsteroidal anti-inflammatory agents (Kim et al. 2009).

Drug Interactions: Cytochrome P450 Issues

CYP 2D6 is responsible for the metabolism of many beta-blockers, carvedilol, and antiarrhythmic agents; this metabolic pathway is inhibited by haloperidol, fluoxetine, and paroxetine, with resulting elevation of blood levels of CYP 2D6 substrates. Conversely, amiodarone is a 2D6 inhibitor and can elevate blood levels of amitriptyline, nortriptyline, clomipramine, codeine, desipramine, fluoxetine, and risperidone. CYP 3A4 is responsible for metabolism of alprazolam, midazolam, triazolam, zolpidem, buspirone, carbamazepine, and haloperidol and of calcium channel blockers, cyclosporine, many statin agents, and tacrolimus.

TABLE 18-3. Selected psychotropic drug interactions with cardiovascular drugs

Psychotropic agent	Cardiovascular agent	Effect
SSRIs	Beta-blockers	Additive bradycardic effects
	Warfarin	Increased bleeding risk, especially with paroxetine and fluoxetine, despite little effect on INR
MAOIs	Epinephrine, dopamine	Hypertension
Lithium	Thiazide diuretics	Increased lithium level
TCAs	Type IA antiarrhythmic agents, amiodarone	Prolonged QT interval, increased AV block
Lithium	ACE inhibitors, angiotensin II receptor blockers	Increased lithium level
Phenothiazines	Beta-blockers	Hypotension

Note. ACE=angiotensin-converting enzyme; AV=atrioventricular; INR=international normalized ratio; MAOIs=monoamine oxidase inhibitors; SSRIs=selective serotonin reuptake inhibitors; TCAs=tricyclic antidepressants.

The 3A4 system is inhibited by amiodarone, diltiazem, verapamil, grapefruit juice, and nefazodone, and to a lesser degree by fluoxetine and sertraline. The combination of nefazodone and haloperidol might increase the risk of ventricular arrhythmias, because increased haloperidol levels may result in greater QT prolongation. Carbamazepine and St. John's wort are inducers of CYP 3A4 activity. An evolving reference listing for CYP interactions is available on the World Wide Web (Flockhart 2009), and these interactions are also reviewed in Chapter 38, "Psychopharmacology."

Lung Disease

Kathy L. Coffman, M.D.

James L. Levenson, M.D.

IN THIS CHAPTER, we review psychiatric aspects of the major pulmonary disorders, as well as lung transplantation and the use of psychiatric drugs in pulmonary patients.

Common Pulmonary Disorders

Asthma

Asthma is the most common chronic disease in the United States, affecting 5%–7% of the population, or approximately 17 million people (American Lung Association 2000; Barnes and Woolcock 1998). In this chapter, we focus on asthma in adults (see Chapter 34, “Pediatrics,” for discussion of asthma in children). Mortality has risen steadily since the early 1980s. Age-adjusted mortality of asthma varies among ethnic groups: Puerto Ricans, 40.9 per million; non-Hispanic blacks, 38.1 per million; Cuban Americans, 15.8 per million; non-Hispanic whites, 14.7 per million; and Mexican Americans, 9.2 per million (National Center for Health Statistics 2000).

Comorbidity With Psychiatric Disorders

Many investigators have assessed psychiatric comorbidity in asthma. Asthma patients have double the rate of anxiety and mood disorders as those without asthma (Rosenkranz and Davidson 2009). Nearly half of asthma patients at tertiary care centers have major depressive disorder (Van Lieshout et al. 2009). A study of 230 outpatients with asthma found that almost half had a positive screen for depressive symptoms (Mancuso et al. 2000). Goodwin et al. (2003a) found that asthma was associated with significantly elevated odds ratios of anxiety disorders, including panic, so-

cial phobia, generalized anxiety, and specific phobias. Youths with asthma have almost twice the prevalence of comorbid DSM-IV (American Psychiatric Association 1994) anxiety and depressive disorders compared with control youths (Katon et al. 2007).

Anxiety disorders are more frequent in patients with asthma for several reasons (ten Thoren and Petermann 2000). Anxiety increases risk for asthma, and asthma increases risk for anxiety. Anxiety is increased by asthma attacks, chronic sensations of breathlessness, and anticipation of attacks in response to certain triggers. Respiratory distress causes a wide array of anxiety symptoms (panic attacks, generalized and anticipatory anxiety, phobic avoidance), and audible wheezing aggravates social anxiety. Prospective epidemiological studies indicate that the primary risk factor for development of panic disorder in young adulthood is history of asthma as a child (Goodwin et al. 2003b). An additional reason for frequent anxiety is that many of the drugs used to treat asthma have anxiety as a potential side effect.

Asthma sometimes may be mistakenly diagnosed as an anxiety disorder, especially panic disorder, and some anxiety disorders (panic, social anxiety) may be mislabeled as asthma. This differentiation can be difficult because shortness of breath, palpitations, sweating, chest pain, lightheadedness, fear of losing control, and even fear of dying can represent either asthma or panic anxiety. When the diagnosis is unclear, a negative methacholine inhalation challenge test indicates no airway hyperresponsiveness and, therefore, a diagnosis other than asthma (Schmaling et al. 1999). Of course, as noted earlier, patients can and often do have both asthma and an anxiety disorder.

Psychological Factors in Asthma

Psychosomatic theories about asthma proposed by French and Alexander in 1939–1941 postulated that the central conflict involved unconscious dependency issues with the mother and fear of separation. However, these theories have little empirical support (Greenberg et al. 1996). No particular personality type is more susceptible to development of asthma. Asthma was once regarded as a classic psychosomatic disorder, and it is still widely believed that psychological factors (particularly anxiety) play an important role in the precipitation and aggravation of asthma.

Several psychosocial factors appear to increase the risk for development of asthma. One prospective study showed that subjects with low health-related quality of life had a higher likelihood of developing asthma 12 years later and had a higher prevalence of depression, difficulty relaxing, and sleep disturbances than did those who did not develop asthma (Lander et al. 2009). Risk of adult-onset asthma increases with increasing adversity in childhood independent of early-onset anxiety and depressive disorders, although both predict adult-onset asthma (Scott et al. 2008; Turyk et al. 2008).

Depression and anxiety are associated with worse medical outcomes in asthma. A prospective study found that a higher number of depressive symptoms correlated with an increased severity of asthma, lower quality of life, worse health outcomes, and increased risk of hospital admission due to asthma (Eisner et al. 2005). Another study reported an apparent dose-response relation between depressive symptoms and days of health-impaired quality of life in asthma patients in the past month. Depressive symptoms also were associated with more disability, life dissatisfaction, inadequate social supports, and increased risk behaviors in asthmatic patients (Strine et al. 2008). Youths with asthma and comorbid depressive disorders have significantly higher health care use and costs than do those with asthma alone (Richardson et al. 2008).

Similar to panic disorder, patients with asthma have a significant association between catastrophic cognitions and more asthma symptoms such as irritability, panic and fear, and rapid breathing (De Peuter et al. 2008; Giardino et al. 2002). Perceived discomfort, rather than actual bronchoconstriction, predicts use of bronchodilators (Schmalting et al. 1999). However, those with alexithymia have difficulty expressing emotions and perceiving physical symptoms and are at higher risk for near-fatal asthma attacks because they underestimate the severity of asthma exacerbations and delay seeking treatment (Serrano et al. 2006). In asthmatic adults, affective denial on the Levine Denial of Illness Scale was inversely correlated with adherence to inhaled asthma medications as monitored with a microelectronic monitor. Those with higher scores on the informa-

tion avoidance subscale had suboptimal compliance with inhaled asthma medication. (McGann et al. 2008). Patients with difficult-to-control asthma were found to have significantly higher external locus of control scores, which may have interfered with adherence to the medical regimen, leading to a higher admission rate (Halimi et al. 2007). Asthmatic children with avoidant coping have poorer psychological functioning, and quality of life of both the patient and the mother was lower (Marsac et al. 2007). These studies may indicate that cognitive therapy and interventions focused on coping skills may affect outcomes with asthma patients because overreaction and underreaction to symptoms may affect quality of life and survival.

Psychological distress may provoke asthma attacks. A 27% increase in severity of asthma symptoms was reported in patients surveyed in New York City 5–9 weeks after the September 11, 2001, terrorist attacks (Centers for Disease Control and Prevention 2002), and posttraumatic stress disorder (PTSD) was a significant predictor of asthma symptom severity (Fagan et al. 2003).

Recent evidence is accumulating that witnessing or being a victim of physical or sexual abuse may be a risk factor in asthma morbidity (Kashiwagi et al. 2008; Subramanian et al. 2007). Among Puerto Rican children, the odds of having asthma were doubled if they had a history of physical or sexual abuse, but neighborhood violence and other stressful life events did not correlate with asthma (R. T. Cohen et al. 2008). Psychological factors and psychosocial problems in hospitalized asthma patients were a more powerful predictor of which patients required intubation than any other examined variable (e.g., smoking, infection, prior hospitalization) (LeSon and Gershwin 1996). Several psychological factors in asthma patients may be associated with asthma deaths. A case-control study involving 533 cases showed an increased risk of death associated with health behaviors such as poor adherence with follow-up visits and poor inhaler technique. Three independent psychosocial factors appeared to increase the odds of death: psychosis, financial problems, and learning difficulties. Two factors associated with reduced risk were sexual problems and prescription of antidepressant drugs. Surprisingly, factors such as bereavement, domestic abuse, family problems, and social isolation did not correlate with risk of asthma death (Sturdy et al. 2002).

Psychophysiological Mechanisms Mediating Asthma

From a physiological perspective, the vagus nerve is thought to mediate airway reactivity to emotion (Isenberg et al. 1992; B. D. Miller et al. 2009). The upper airways innervated by cholinergic neurons may be more affected by suggestion and emotion than are smaller airways (Lehrer et al. 1986). Research has shown that various emotions and

types of stress can increase respiratory resistance in asthma (Ritz et al. 2000).

Acute and chronic stress has been reported to be correlated with several physiological measures in asthma patients, including increased salivary chromogranin A (Hoshino et al. 2008), decreased salivary alpha-amylase and cortisol (Wolf et al. 2008b), and increased interleukin 4 (IL-4), IL-5, and interferon-gamma, leading to an increase in asthma symptoms (Marin et al. 2009), decreased expression of beta₂-adrenergic receptor messenger ribonucleic acid (mRNA) and glucocorticoid receptor mRNA (G.E. Miller and Chen 2006), and other indices of anti-inflammatory response (G.E. Miller and Chen 2006; G.E. Miller et al. 2009). The clinical significance of these findings is not yet clearly established.

Psychological factors also may influence asthma through behavioral mechanisms. A large U.S. population-based study concluded that "Any degree of poor mental health appears to increase one's risk for asthma" (Chun et al. 2008). Psychological morbidity is associated with high levels of denial and delays in seeking medical care (D.A. Campbell et al. 1995; Miles et al. 1997), poor medication adherence (Cluley and Cochrane 2001; Put et al. 2000; Smith et al. 2006), and increased risk for smoking (Strine et al. 2008; M. O. Van De Ven et al. 2009). Psychopathology in persons with severe asthma is associated with increased hospitalization and outpatient and emergency department visits independent of asthma severity (Jones et al. 2008; Schneider et al. 2008; ten Brinke et al. 2001).

Interventions With Asthma Patients

In view of high levels of anxiety and depression in asthmatic patients, screening may be useful (Schneider et al. 2008). Screening and management of psychological symptoms in asthmatic patients may decrease the rate of clinic visits, hospitalization, and mortality and increase productivity at work (N. Schmitz et al. 2009). The Geriatric Depression Scale (GDS) may be more accurate in diagnosing depression than the short-form Center for Epidemiologic Studies Depression Scale (CESD-SF) because the CESD-SF is confounded by physical symptoms, unlike the GDS (Mancuso et al. 2008).

Many psychosocial adjuvant interventions have been studied in asthma, including cognitive-behavioral therapy (CBT), biofeedback, psychoeducation, hypnosis, stress management, symptom perception, and yoga (Kern-Buell et al. 2000; Lehrer et al. 2002, 2008; Yorke and Shuldhham 2005). Patient education programs may reduce anxiety and improve self-management. Patient diaries of asthma attacks can be useful in determining triggers of attacks and the effect of the illness on social and academic development and family life (Weiss 1994). However, systematic

reviews have concluded that the evidence base is not strong enough to draw any firm conclusions about the role of psychotherapeutic interventions in children (Yorke and Shuldhham 2005) and adults (Yorke et al. 2006a) with asthma. In children with asthma, there have been many studies of family therapy (e.g., S.M. Ng et al. 2008), and a systematic review has been somewhat more supportive (Yorke and Shuldhham 2005).

Although psychotropic drugs are frequently prescribed in asthma, the evidence base is very limited. Studies of antidepressant treatment in asthma patients have included small open trials of bupropion (Brown et al. 2007) and sertraline (Smoller et al. 1998) and a small randomized controlled trial of citalopram (Brown et al. 2005). No clinical trials of pharmacotherapy for anxiety in asthma have been reported.

Cystic Fibrosis

In the United States, cystic fibrosis (CF) affects more than 18,000 children younger than 18 years (1 in 2,500 births). CF is the most common hereditary disease in white children, and it is also seen in other races. Survival improved from a median age of 12 years in 1966 to 40 years by 2001 (Jaffe and Bush 2001), so adults living with CF are a relatively recent and growing population. (See also Chapter 34, "Pediatrics," for a discussion of CF in children.) More patients who did not develop lung problems until their 20s are receiving a diagnosis of CF (Wideman 2004).

Psychological Factors in Cystic Fibrosis

Several authors have described growing up with CF from a child's perspective. Knowing the key issues involved can enhance effectiveness of therapeutic interventions (Christian and D'Auria 1997; Hains et al. 1997; Llewellyn 1998).

Depression is more frequent in children and teenagers with CF than in healthy children and adversely affects family functioning (Quittner et al. 2008). Treatment adherence is challenging in both younger children and teenagers and may be influenced by psychological characteristics of the patients, as well as by caregiver and family traits (Szyndler et al. 2005; Ward et al. 2009; White et al. 2009). Having a child with CF is extremely stressful for parents, and anxiety and depression are common in caregivers (Hayes and Savage 2008; Ward et al. 2009).

In adults with CF, as with other chronic diseases, anxiety and depression are common and adversely affect treatment adherence and quality of life (Havermans et al. 2008; Quittner et al. 2008). One study showed that levels of anxiety and depression were not dependent on the severity of lung disease but on the CF patients' estimations of their disease and their level of perceived support (Wargnies et al. 2002). However, another study found that adults with CF

did not have significant levels of depression, anxiety, or any other psychopathology, although lower anxiety correlated with better pulmonary function (D.L. Anderson et al. 2001). Adults with CF are resilient and have survived a disease to which others have succumbed.

Treatment adherence in adults with CF is better in those who cope via optimistic acceptance and hopefulness and worse in those who use avoidant strategies (J. Abbott et al. 2001). Additional potential stressors include chronic pancreatitis leading to malabsorption and the development of diabetes (Collins and Reynolds 2008) and chronic pain (Palermo et al. 2006). With CF patients living longer, patients are getting married, and their partners experience significant stress (Delelis et al. 2008). Infertility is common in adults with CF, but some are having children. Although disability is common, one study found that about half of subjects were working an average of 32 hours per week despite an average forced expiratory volume in 1 second of 31.9% (Burker et al. 2004b).

Interventions With Cystic Fibrosis Patients

Several psychological interventions in CF have been studied in clinical trials, including cognitive and behavior therapies; genetic counseling; biofeedback; and educational interventions to promote independence, adherence, knowledge, and quality of life. Overall, some evidence indicates that psychological interventions improve emotional outcomes in CF patients, but there have been no consistent benefits for lung function (Glasscoe and Quittner 2008). Novel interventions have included an interactive computer game to counter isolation and improve coping with the CF regimen (Duff et al. 2006) and weekly telemedicine for terminal CF patients for psychological support (Wilkinson et al. 2008). Finally, the CF care team may struggle with end-of-life care for terminal CF patients and have difficulty discussing death and dying, saying good-bye, and asking patients about their wishes regarding active or palliative care (Chapman et al. 2005). The psychiatrist can assist both patients and team members in better handling these issues (see Chapter 41, "Palliative Care").

Cystic Fibrosis and Lung Transplantation

Lung transplantation is the treatment of last resort for CF patients. Although CF patients on a waiting list for transplantation may experience a sense of displacement, disorder, and life being in limbo (Macdonald 2006), they have been reported to have lower levels of anxiety, be more likely to be working, and use more functional coping methods compared with other end-stage lung disease candidates (Burker et al. 2000). CF patients awaiting lung transplantation have better psychological quality of life if they use more active coping and less disengagement (Taylor et al.

2008). Nevertheless, neuropsychological deficits and depression are common (Crews et al. 2000).

Chronic Obstructive Pulmonary Disease

Almost 16 million Americans have chronic obstructive pulmonary disease (COPD): 14 million with chronic bronchitis and 2 million with emphysema. COPD ranks fourth as a cause of death in the United States after heart disease, cancer, and stroke. Cigarette smokers are 10 times as likely to die of COPD as nonsmokers.

COPD results in progressive declines in arterial oxygen, with carbon dioxide increasing late in the course of the disease. Hypoxia causes confusion, disorientation, altered consciousness, muscle twitching, tremor, and seizures. Mild hypoxia can be accompanied by irritability, mental slowing, and impairment of memory with poor reasoning and perseveration. Prolonged hypoxia can result in permanent memory deficits or dementia—that is, hypoxic encephalopathy. Chronic or severe hypoxia can also lead to extrapyramidal symptoms, pseudobulbar palsy, or visual agnosia. Patients with hypercapnia and respiratory acidosis may be lethargic and have auditory and visual hallucinations (Lishman 1987).

Comorbidity With Psychiatric Disorders

Psychiatric disorders are three times as prevalent in COPD patients as in the general population, with almost twice the rates of anxiety and depression in women as in men (Laurin et al. 2007). The Patient Health Questionnaire–9 appears to be a valid screening instrument for depression in COPD patients (Lamers et al. 2008). Both the World Health Organization Quality of Life–BREF instrument and the St. George's Respiratory Questionnaire have been shown to be reliable and valid in COPD patients (Liang et al. 2008).

Nicotine dependence is the most commonly associated psychiatric condition in COPD patients. More than 80% of COPD cases are associated with tobacco smoking (Tashkin et al. 2001). Alcohol abuse aggravates COPD because of a higher rate of severe community-acquired pneumonia, particularly aspiration pneumonia (Ewig and Torres 1999). Sexual dysfunction is also common in COPD (Ibanez et al. 2001). COPD patients have a high prevalence of hypogonadism, so checking testosterone levels may be prudent (Arver and Lehtihet 2009).

Major depression is also very common in patients with COPD, partly because of an increased prevalence in smokers (Aydin and Ulusahin 2001; Omachi et al. 2009; Yohannes et al. 2000). In one study, depression was found in 42% of the patients (Yohannes et al. 2000), yet only about one-fifth of COPD patients with major depression receive antidepressants. This is a worldwide phenomenon; depression was found to be very common in COPD in a popula-

tion-based study in China (T.P. Ng et al. 2009) and in clinic patients in the Netherlands (van den Bemt et al. 2009) and in Wales (Lewis et al. 2007). A recent national multidisciplinary workshop concluded that although depression is very common in COPD, it remains underdiagnosed and ineffectively treated (Maurer et al. 2008).

Anxiety is also common in COPD (Aydin and Ulusahin 2001; Lewis et al. 2007; Yohannes et al. 2000). Like depression, anxiety disorders remain underdiagnosed and undertreated in COPD (Lewis et al. 2007; Maurer et al. 2008). As many as 44% of patients with severe COPD may have panic disorder, and the incidence of depression was linked to severity of panic symptoms (Potoczek et al. 2008). One group found that the prevalence of panic disorder was at least 10 times higher than in the general population and was due to increased sensitivity to inspiratory loads (Livermore et al. 2008). Whereas anxiety symptoms are linked to dyspnea, depressive symptoms are linked to dyspnea and decreased exercise capacity (Funk et al. 2009).

Cognitive dysfunction has long been recognized to be very common in hypoxemic COPD patients and is improved by supplemental oxygen. Most studies have been cross-sectional (e.g., Ozge et al. 2006), but a recent large population-based longitudinal cohort study found that COPD is associated with significant cognitive decline over time (Hung et al. 2009). Neuropsychological impairments in flexible problem solving and information sequencing have been observed (Emery et al. 2008). Anterior cerebral hypoperfusion has been identified on single photon emission computed tomography in hypoxemic COPD patients (Antonelli Incalzi et al. 2003).

Psychological Factors in COPD

As with other medical illnesses, measurement of physical symptoms in COPD may be confounded by psychological symptoms, and vice versa. Psychological distress in COPD amplifies dyspnea, usually without causing changes in objective pulmonary functions.

Depression and anxiety in COPD patients have led to lower exercise tolerance (Withers et al. 1999), noncompliance with treatment (Bosley et al. 1996), and increased disability (Aydin and Ulusahin 2001). Depression may adversely affect rehabilitation and contribute to difficulty ceasing tobacco use (Borson et al. 1998). Depression results in worse respiratory-specific and overall physical health-related quality of life (Cully et al. 2006; Omachi et al. 2009), is a risk factor for more COPD exacerbations and hospitalizations (Xu et al. 2008), and appears to be an independent predictor of mortality (Fan et al. 2007; Stage et al. 2005). Chronic steroid use may exacerbate depression, emotional lability, or irritability, which further strains interpersonal relationships. Anxiety has been found to be a

risk factor in COPD for poorer health outcomes, smoking, and rehospitalization (Gudmundsson et al. 2005, 2006). Factors found to increase dropout in pulmonary rehabilitation include less confidence in treatment, lower fat-free mass, living alone, and smoking (M.J. Fischer et al. 2009).

Dependence on supplemental oxygen can be socially stigmatizing. Some cannot accept the need for oxygen because of denial about the illness. Others become psychologically dependent on oxygen, exceeding the amount prescribed, posing a risk of carbon dioxide retention, which leads to lethargy.

Interventions With COPD Patients

Psychotherapeutic, psychopharmacological, and rehabilitation intervention trials in COPD have been reviewed in detail elsewhere (Brenes 2003; Puhan et al. 2009). The first priority in the rehabilitation of patients with COPD is smoking cessation. Other interventions include pharmacotherapy, physical therapy, psychosocial interventions, nutritional therapy, and, for those who are hypoxemic, long-term oxygen therapy surgery. A small fraction of patients may benefit from bilateral lung volume reduction surgery (Wurtemberger and Hutter 2001).

The goals of treatment are to relieve symptoms, improve physical functioning via rehabilitation, and improve patients' coping skills (Small and Graydon 1992). Patients with dyspnea may avoid all activity and become homebound. Exercise may help build endurance and help patients learn to pace themselves. A treatment plan with realistic and attainable goals and rewards can counteract helplessness (Dudley et al. 1985). Pulmonary rehabilitation in COPD can increase patients' sense of control over their illness (Lacasse et al. 2002) and improves anxiety and depression (Coventry and Hind 2007).

Rose et al. (2002) reviewed 25 published studies of psychological treatments for reduction of anxiety in patients with COPD. Evidence is insufficient to recommend a specific psychological treatment for anxiety in COPD, but relaxation techniques are useful in motivated patients (Rose et al. 2002). Pharmacological treatments for anxiety and depression are discussed later in this chapter (see section "Psychopharmacology in Pulmonary Disease"). Although depression clearly appears associated with worse medical outcomes in COPD, a large retrospective study did not find that guideline-concordant treatment for depression reduced hospitalization or mortality in COPD (Jordan et al. 2009).

The evidence for the efficacy of CBT in COPD has been limited (Coventry and Gellatly 2008), but a recent randomized controlled trial found that both CBT and psychoeducation improved quality of life in COPD patients with depression or anxiety (Kunik et al. 2008).

Sarcoidosis

Sarcoidosis is characterized by noncaseating granulomatous involvement of lymph nodes, lymphatic channels in the lung, and other tissues. Sarcoidosis affects black patients more frequently than white patients in the United States (40 per 100,000 vs. 5 per 100,000). In Europe, Swedish and Danish patients have high prevalence rates (American Lung Association 2000). Onset of the illness is usually between ages 20 and 40. Diagnosis may be delayed by failure to recognize the slowly progressive symptoms until characteristic findings are recognized on a chest X ray. The disease often follows a relapsing and remitting course, with recovery in 80% of patients, but about 5% die from sarcoidosis. Patients often have a dry cough, shortness of breath, fatigue, and weight loss. Lesions can affect the skin, bones, joints, skeletal muscles, and heart. Fatal complications include progressive respiratory impairment, infection, cardiac disease, and renal failure.

Central Nervous System Sarcoidosis

Sarcoidosis may affect the central nervous system (CNS) in 5% of patients. Neurosarcoidosis may cause brain lesions, involve cranial nerves (especially VII), and cause peripheral neuropathies (and rarely choreoathetosis). Indirect evidence for the diagnosis comes from cerebrospinal fluid and magnetic resonance imaging (Stoudemire et al. 1983). Pituitary involvement may result in diabetes insipidus or the syndrome of inappropriate antidiuretic hormone secretion (SIADH), hypercalcemia, hyperprolactinemia, menstrual cycle changes, or hypogonadism (Bullman et al. 2000; Delaney 1977; Mino et al. 2000; Sharma 1975). There have been many case reports of neurosarcoidosis causing cognitive deficits, delirium (Mathews 1965; Silverstein et al. 1965), seizures (Thompson and Checkley 1981), dementia, mania, and psychosis (Hook 1954; Sabaawi et al. 1992; Suchenwirth and Dold 1969; Zerman 1952). Psychotic symptoms generally remit rapidly with steroids.

Psychological Factors in Sarcoidosis

Sarcoidosis rarely has been investigated from the psychological standpoint. A large study of members of the Dutch Sarcoidosis Society found that perceived stress was high and related to depressive symptoms, suggesting that addressing stress and depressive symptoms should be part of sarcoidosis management (De Vries and Drent 2004). In addition, psychiatric comorbidity was reported in 44% of Italian sarcoidosis patients, with major depression in 25%, panic disorder in 6.3%, bipolar disorder in 6.3%, generalized anxiety disorder in 5%, and obsessive-compulsive disorder in 1.3% (Goracci et al. 2008). Although sarcoidosis patients reported a higher magnitude of stressful life

events, they had a lower capacity for coping with stress, possibly as a result of alexithymic characteristics (Yamada et al. 2003).

Quality of life in sarcoidosis patients has been related to objective pulmonary function measures (Güneyliolu et al. 2004), arthralgia, breathlessness, decreased exercise capacity, and fatigue (Michielsen et al. 2007). Depression is common and also associated with poorer quality of life (Yeager et al. 2005). Hoitsma et al. (2003) found that 72% of patients had pain, including arthralgia (53.8%), muscle pain (40.2%), headache (28%), and chest pain (26.9%), suggesting that pain management may be beneficial. Fatigue appears to be particularly problematic, yet a recent review found no clear relation between fatigue and clinical parameters of sarcoidosis (De Vries and Drent 2008). Longitudinal prospective studies of fatigue and its relation with depression are needed in this population (de Kleijn et al. 2009).

Pulmonary Fibrosis

The etiology of idiopathic pulmonary fibrosis is unknown, but the prevalence is approximately 3–5 per 100,000. Pulmonary fibrosis also may be caused by inhalation of a variety of agents (especially via occupational exposure), radiation, and rheumatological disorders, especially systemic sclerosis. There has been a recent shift in the view of idiopathic pulmonary fibrosis as solely an inflammatory condition to a primary fibrotic disease because of abnormal wound healing involving profibrogenic growth factors. This has led to a shift from use of anti-inflammatory medications to use of antifibrotic agents without significant effect on disease progression or quality of life (Abdelaziz et al. 2005; Allen and Spiteri 2002; Antoniu 2006).

Psychological factors have received surprisingly little attention in idiopathic pulmonary fibrosis. As with other chronic lung diseases, dyspnea, the subjective sense of breathlessness, is the most important factor in determining quality of life in idiopathic pulmonary fibrosis (De Vries et al. 2001; Martinez et al. 2000). Other important domains contributing to quality of life include disease symptoms, dependence, employment and finances, exhaustion, family, medical therapy, mental and spiritual well-being, mortality, sexual relationships, social participation, and sleep (Swigris et al. 2005). Poor sleep has been documented to be an important influence on emotional and physical functioning (Krishnan et al. 2008; Mermigkis et al. 2009).

Because median survival rates after diagnosis with idiopathic pulmonary fibrosis are less than 5 years, and current therapeutic options do not prolong survival, the goal is to find interventions that allow patients to be more active, be less anxious and depressed, have more control over the illness, and have improved quality of life (Swigris

et al. 2008). A review of pulmonary rehabilitation for interstitial lung disease found only five studies. Although there was no indication that physical training improved survival, dyspnea was reduced and quality of life improved in all participants (Holland and Hill 2008). One small study specific to idiopathic pulmonary fibrosis patients showed similar results (Jastrzebski et al. 2008).

Because of lack of improvement in survival in idiopathic pulmonary fibrosis patients with medical therapy, lung transplantation remains the best treatment for end-stage idiopathic pulmonary fibrosis. Idiopathic pulmonary fibrosis is second only to COPD as an indication for lung transplantation; however, survival may be lower than for other lung diseases. Double lung transplant may offer higher 1- and 5-year survival but raises ethical questions because of the organ shortage.

Tuberculosis

The incidence of tuberculosis had been declining for more than 70 years but began to rise again in the United States, Western Europe, Asia, and Africa. Causes for this trend include the rise of AIDS, increasing substance abuse and homelessness, and the failure to fund public health systems. About one-third of the world's population, more than 2 billion people, is estimated to be infected with tuberculosis. About 14 million have active infection, 1.7 million deaths occur per year, and nearly 9.2 million new cases are diagnosed per year in the world (World Health Organization 2008). See Chapter 27, "Infectious Diseases," for a discussion of CNS tuberculosis.

Psychiatrists may be asked to make capacity determinations in patients who are nonadherent with tuberculosis treatment (O'Dowd et al. 1998). Evidence on behavioral interventions (other than direct observation) for improving long-term treatment adherence is limited, but several approaches may prove fruitful to foster adherence with tuberculosis and AIDS regimens (Munro et al. 2007). One survey of tuberculosis detainees showed that 81% had drug or alcohol abuse, 46% were homeless, and 28% had mental illness (Oscherwitz et al. 1997). Because alcoholic and drug-addicted patients are more susceptible to tuberculosis, access to adequate substance abuse treatment may be essential to achieving recovery from tuberculosis and preventing relapse (Sylla et al. 2007).

Psychiatrists also must be attuned to neuropsychiatric symptoms such as mania and psychosis during treatment with isoniazid (Alao and Yolles 1998), probably related to its being a weak but irreversible inhibitor of monoamine oxidase. No dietary restrictions are required, but it can interact with other drugs. Predisposing factors for psychiatric side effects of isoniazid include alcoholism, diabetes, hepatic insufficiency, old age, slow acetylation, and family

and personal history of mental illness (Djibo and Lawan 2001). Pyridoxine deficiency also may play a role in the etiology of isoniazid-related psychosis. Psychiatric side effects also occur with several other tuberculosis drugs, most frequently with cycloserine, as well as with fluoroquinolones and ethionamide.

Psychiatric disorders are common in patients with tuberculosis, and psychiatric side effects are among the most common side effects resulting in withdrawal of one or more drugs from the treatment regimen in multidrug-resistant tuberculosis (Törün et al. 2005). In a Peruvian study of patients with multidrug-resistant tuberculosis, baseline levels of depression declined from 52.2% to 13.3% during multidrug-resistant tuberculosis treatment, whereas anxiety increased slightly from 8.7% to 12%. The incidence of psychosis during treatment was 12%. Psychiatric comorbidity did not contraindicate multidrug-resistant tuberculosis treatment or require discontinuation of cycloserine, except in one case (Vega et al. 2004). However, in a large U.S. study of patients who received treatment for multidrug-resistant tuberculosis, psychiatric disorder was an independent predictor of mortality (Franke et al. 2008).

Hyperventilation

Hyperventilation is a common presenting complaint in emergency departments leading to psychiatric consultation (Nguyen et al. 1992). These patients briefly experience an increase in the rate and depth of breathing and may have dizziness or syncope from the respiratory alkalosis and cerebral vasoconstriction that result. Symptoms of blurred vision, carpopedal spasm, myoclonic jerks, or paresthesias may frighten the patient or relatives and result in an emergency department visit.

The incidence of hyperventilation syndrome may be as high as 6%–11% in the general population (Lachman et al. 1992), especially in children, and hyperventilation syndrome may be recurrent. Medical illnesses that may be confused with hyperventilation syndrome include angina, arrhythmia, asthma (Demeter and Cordasco 1986; Kashiwagi et al. 2008), carbon monoxide poisoning (Skorodin et al. 1986), diabetic ketoacidosis (Treasure et al. 1987), pulmonary emboli (Hoegholm et al. 1987), epilepsy, hypoglycemia, ingestion of salicylates (Rognum et al. 1987), Meniere's disease, tetany (Hehrmann 1996), and vasovagal syncope. Neurological causes of hyperventilation also have been reported, including thalamic infarct (Scialdone 1990), Cheyne-Stokes breathing (Liippo et al. 1992), and traumatic vestibular hyperreactivity after whiplash injury (A.J. Fischer et al. 1995).

Medications reported to cause central hyperventilation include carbamazepine, salicylates, and topiramate. Central hyperventilation resolves promptly within a day or

two after discontinuation of these drugs (Lasky and Brody 2000; Mizukami et al. 1990).

Psychiatric disorders to consider in hyperventilation syndrome include conversion disorder, histrionic personality disorder, hypochondriasis, the respiratory subtype of panic disorder, phobic disorders, and substance abuse (Abrams et al. 2006; Araki and Honma 1986). Hyperventilation syndrome also has occurred as part of mass psychogenic illness (Araki and Honma 1986). Estimates of the overlap between hyperventilation syndrome and panic disorder are between 35% and 83% (Cowley and Roy-Byrne 1987; de Ruiter et al. 1989; Hoes et al. 1987). The relation between hyperventilation syndrome and panic disorder is controversial.

Various treatments for hyperventilation syndrome have been used over the years, such as antidepressants (Saarijarvi and Lehtinen 1987), beta-blockers (L.L. Van De Ven et al. 1995), intravenous sedatives (Hirokawa et al. 1995), breathing retraining (DeGuire et al. 1992, 1996; Pinney et al. 1987), grief therapy (Paulley 1990), group therapy (Fensterheim and Wiegand 1991), and hypnosis (Conway et al. 1988).

Although having patients with acute hyperventilation rebreathe into a brown paper bag is a traditional technique used in the emergency department, it is dangerous and potentially fatal when mistakenly applied to patients with hypoxia or myocardial ischemia (Callahan 1989).

Vocal Cord Dysfunction

Vocal cord dysfunction (VCD) is a respiratory syndrome frequently confused with asthma, although they often occur together (Newman et al. 1995). It is not unusual for VCD to be misdiagnosed as steroid-resistant asthma (Thomas et al. 1999). VCD also may co-occur with hyperventilation syndrome. The syndrome of VCD was first described 200 years ago by Osler (Brugman 2003), yet it is still not well understood. The disorder may present in childhood, adolescence, or adulthood. Patients may appear in severe respiratory distress yet have relatively normal blood gas levels, or respiratory alkalosis from hyperventilation, only rarely presenting with hypoxemia. Unlike in asthma, wheezing in VCD will be loudest over the larynx and more pronounced in the inspiratory phase, but the chest is otherwise clear. Also unlike asthma, VCD attacks typically have rapid onset and equally rapid resolution. VCD may lead to frequent emergency department visits and hospitalizations, high doses of (ineffective) asthma medications, and unnecessary intubation or tracheotomy (Bahrainwala and Simon 2001; Ibrahim et al. 2007).

The differential diagnosis of VCD includes angioedema; asthma; factitious disorder; hyperventilation syndrome; iatrogenic, inflammatory, neoplastic, or neurological disorders

(e.g., spasmodic dysphonia and laryngeal nerve injury); obsessive-compulsive disorder; personality disorder (dependent, histrionic, or mixed); PTSD; school phobia; and somatization disorder (Brugman 2003; Koufman and Block 2008; Lacy and McManis 1994). A multidisciplinary approach has been recommended, including specialists in allergy, psychiatry, pulmonary medicine, neurology, otolaryngology, and speech therapy (Nacci et al. 2007). Viewing the vocal cords via laryngoscopy allows a definitive diagnosis (Arndt and Voth 1996). Comorbid conditions in World Trade Center workers with VCD included acid reflux disease and allergic rhinitis (de la Hoz et al. 2008).

In most patients, VCD appears not to be a primary psychiatric disorder but rather a conditioned response, which may result in secondary anxiety. The onset of VCD is typically preceded by allergy, asthma, gastric reflux, irritant exposure (Perkner et al. 1998), or a dyspneic episode in athletes (Newsham et al. 2002). The psychiatric literature reflects referral bias capturing only part of the VCD spectrum. Psychiatrists are most likely to see those patients with VCD who develop panic attacks and phobic symptoms. Case reports and retrospective case series note strong dependency needs and fears of separation in patients with VCD and its acute precipitation following psychosocial stress.

Formal psychological testing in VCD patients at a tertiary-care center found high rates of conversion disorder and hypochondriasis, but a quarter had no evidence of any psychopathology. Comorbidities included asthma (65%), gastroesophageal reflux disease (51%), and history of abuse (38%) (Husein et al. 2008). Another study of tertiary-care VCD patients found that most had a history of childhood sexual abuse (Freedman et al. 1991), but this has not been replicated (Brugman 2003).

No empirically proven treatment for VCD is available, although antipanic pharmacotherapy, biofeedback, cognitive therapy, relaxation techniques, and speech therapy have been reported as helpful (Andrianopoulos et al. 2000; Brugman 2003; Earles et al. 2003). Benzodiazepines can be used to terminate a severe episode of VCD (Hicks et al. 2008).

Lung Cancer

Lung cancer is the most common cause of cancer death in the United States and the world (see also Chapter 23, "Oncology"). Smoking tobacco is the primary cause of most lung cancers (Strauss 1998). About 30% of all cancer mortality in the United States is due to lung cancer; it is the number one cancer diagnosis in men and the second most frequent cancer in women. Because 45% of patients present late with stage III disease, the 5-year survival rate is abysmally low: about 15% (Pearman 2008).

There has been a burgeoning literature on biological, psychological, and social aspects of lung cancer. Some studies and reviews indicate that psychological factors alter the incidence, course, or mortality of lung cancer (e.g., Chida et al. 2008; Faller and Bulzebruck 2002), whereas other studies do not support this association (e.g., Akechi et al. 2009). Some apparent associations disappear when other factors are adequately controlled (Nakaya et al. 2008). Publication bias, confounding by other clinical and demographic variables, and differences in study methods and patient populations make this literature difficult to interpret.

Symptoms of psychological distress are common in lung cancer. One study showed that newly diagnosed lung cancer patients had frequent insomnia (52%), loss of libido (48%), loss of interest in or ability to work (33%), concerns about their families (29%), and poor concentration (19%) (Ginsburg et al. 1995). Depression and anxiety are more frequent in patients with lung cancer than in those with breast cancer (Brintzenhofe-Szoc et al. 2009). In one study, type of lung cancer influenced the rate of depression (i.e., more frequent in small-cell cancer than in non-small-cell cancer); however, the most important risk factor was functional impairment (Hopwood and Stephens 2000). Suicide rates in cancer patients are twice those in the general population in the United States, with lung cancer having the highest standardized mortality ratio among cancers of various organs. Risk is highest in the first 5 years after diagnosis (Misono et al. 2008).

In patients with lung cancer, distress and quality of life vary depending on pretreatment psychosocial characteristics (e.g., Barlesi et al. 2006; Boehmer et al. 2007; Visser et al. 2006), specific chemotherapy agents given (e.g., Gralla and Thatcher 2004), cognitive and other side effects of chemotherapy and radiation (e.g., Whitney et al. 2008), marital relationship (Carmack Taylor et al. 2008; Zhang and Siminoff 2003), coping style (e.g., Wong and Fielding 2007), pain management (Akechi et al. 2001), and sexual functioning (Goodell 2007). Psychological distress is high in newly diagnosed lung cancer patients (Mohan et al. 2006), indicating the need for psychological support at the time of diagnosis (Lheureux et al. 2004). Management of symptoms associated with lung cancer such as anorexia, delirium, dyspnea, fatigue, and pain can improve quality of life (Bedor et al. 2005; Tishelman et al. 2005; Von Roenn and Paice 2005). Fatigue is more common at diagnosis with lung cancer than with most other cancers: 50% of those with inoperable non-small-cell cancer reported severe fatigue (Stone et al. 2000). Dyspnea is a subjective symptom even in lung cancer and is greater in patients with anxiety, fatigue, and poor coping (Henoch et al. 2008).

Given the high rate of dyspnea in lung cancer patients, one might expect that many patients would cease tobacco use. However, this is not the case, despite evidence that continued smoking after lung cancer diagnosis decreases treatment efficacy, increases complications, increases risk of recurrence and occurrence of another primary tumor, and decreases survival time. Lung cancer patients who are not ready to quit smoking or who are likely to relapse are more likely to be depressed, be fatalistic, have greater nicotine dependence, have less self-efficacy, have less education, and have relatives at home who also smoke (Schnoll et al. 2002; Walker et al. 2004).

Refusal of treatment for lung cancer is multifactorial, including distrust of medical authority, faith, fatalism, minimization of threats, and self-efficacy. Understanding the sources of resistance to treatment recommendations may help improve communication and engender trust during delivery of lung cancer care (Sharf et al. 2005). Denial is more often seen in lung cancer patients who are less educated, elderly, and male (Vos et al. 2008) but is not always maladaptive. Psychological factors also may influence response to treatment in other ways. Psychological distress influences chemotherapy-induced nausea (Takatsuki et al. 1998) and its response to treatment (Tsavaris et al. 2008).

Lung Transplantation

Indications and Contraindications

The first lung transplant was performed in 1963, but it was 20 years before the first successful operation in 1983 (Ochoa and Richardson 1999) (see also Chapter 31, "Organ Transplantation"). The most common indication is COPD (including α_1 -antitrypsin deficiency), which accounts for about 45% of lung transplants (Hosenpud et al. 1998). Transplants are also performed for those with CF, idiopathic pulmonary fibrosis, Eisenmenger's syndrome, primary pulmonary hypertension, and several other pulmonary diseases (Etienne et al. 1997).

Exclusion criteria vary from one transplant center to another. Psychiatric factors that are considered to be absolute contraindications to lung transplantation include active alcoholism, drug abuse or cigarette use, severe psychiatric illness, and noncompliance with treatment (Aris et al. 1997; Paradowski 1997; Snell et al. 1993).

The four main approaches to lung transplantation are 1) single-lung transplantation, 2) bilateral sequential transplantation, 3) heart-lung transplantation, and 4) single-lobe donation from living donors (Arcasoy and Kotloff 1999). Living donor donation has been controversial because of the uncertainty regarding risks to the donor (Barr et al. 1998).

Medical and Surgical Outcomes

Patient survival in the United States at 1 year and 5 years after lung transplant is currently 83.8% and 52.3%, respectively. For comparison, the corresponding survival figures after heart transplant are 87.7% and 73.9% (United Network for Organ Sharing 2008). Some diagnoses confer better survival. Survival after lung and heart–lung transplant in CF may be as high as 90% at 1 year and 78% at 5 years (Haloun and Despins 2003).

For patients with CF and idiopathic pulmonary fibrosis, there appears to be increased survival relative to the natural history of the underlying illness. However, for patients with COPD, no survival advantage has been documented, although transplant improves quality of life and functional ability. Exercise capacity improves, with about 80% of recipients reporting no limitations in activity within 1 year of transplant. Quality of life remains stable for the first few years if the course is uncomplicated, but those who develop bronchiolitis obliterans show a sharp decline in quality of life. Despite improvements in exercise tolerance and quality of life, 40% or fewer of lung transplant recipients return to work. This finding may be a result of employer bias, a fear of losing health insurance or disability benefits, or a change in priorities after a life-threatening illness (Estenne and Hertz 2002; Paris et al. 1998).

Early complications after lung transplantation include primary graft failure, stenosis of the anastomosis, and a higher rate of infectious complications than in other solid organ transplantation (Christie et al. 1998; Kramer et al. 1993).

Psychological Factors and Quality of Life

One-quarter of patients awaiting lung transplantation may meet criteria for at least one anxiety or mood disorder (Parekh et al. 2003). Screening for depression among lung transplant candidates showed mild to moderate depressive symptoms in 56% (Najafizadeh et al. 2009). Patients showed more anxiety and depression the longer they were on the transplant list and expressed distress from wearing a beeper and fears that the transplant would come too late (Vermeulen et al. 2005). In both pre- and post-lung transplant patients, higher social support was associated with higher quality of life and lower depressive symptoms (Archonti et al. 2004). Candidates that used maladaptive coping styles (avoidance, disengagement, low solicitation of support, and rumination and venting emotions) were more likely to show emotional distress and disability and may benefit from psychotherapy and interventions to improve coping (Burker et al. 2004a).

About 37% of patients awaiting lung transplant have moderate to severe cognitive impairment that does not differ by specific disease. Higher partial pressure of oxygen

(PO_2) values correlated with better executive function and attention, and lower partial pressure of carbon dioxide (PCO_2) values correlated with better executive function and attention and verbal memory. Verbal memory correlated with distance walked in 6 minutes (Parekh et al. 2005).

Most lung transplant recipients report significant improvement in general health, anxiety, depression, self-esteem, social functioning, and quality of life (Limbos et al. 2000), reaching a level equal to that of healthy control subjects, despite exercise capacity 30%–40% of normal (Tegtbur et al. 2004). Some recipients do experience emotional distress and disability, and their likelihood of doing so is influenced by coping style (Burker et al. 2005; Myaskovsky et al. 2003), PTSD (Köllner et al. 2003), social support (Myaskovsky et al. 2003), and pulmonary complications (Goetzmann et al. 2005), especially bronchiolitis obliterans (Goetzmann et al. 2006a, 2006b; Künsebeck et al. 2007). Social support also influences adherence with treatment posttransplant (Teichman et al. 2000). Patients became less compliant the further from the time of transplant, suggesting that periodic reeducation after transplantation may improve adherence. Quality of life in most patients begins to decline after 3–4 years (Vermeulen et al. 2003), with depressive symptoms increasing significantly in those with bronchiolitis obliterans (Fusar-Poli et al. 2007).

Psychological Interventions

Pretransplant assessment of affect (anxiety and depression), cognitive beliefs (sense of coherence and optimism), and social support may identify vulnerable candidates who may benefit from psychotherapy. Because depression affects adherence with immunosuppressants, treatment of depression is imperative. Telephone-based cognitive therapy and coping skills training have been shown to improve anxiety, depression, stress, optimism, social support, vitality, and quality of life (Blumenthal et al. 2006; Napolitano et al. 2002). A small randomized controlled trial in lung transplant candidates awaiting transplantation showed that a brief psychological intervention—quality-of-life therapy—was superior to supportive therapy in improving mood, social intimacy, and quality of life (Rodrigue et al. 2005). Although many transplant centers warn against having pets because of concerns about infection, one study found that more than half of the lung recipients owned pets and had significantly better life satisfaction, quality of life, and social support with no higher frequency of somatic complications than did those without pets (Irani et al. 2006).

Terminal Weaning

Patients with end-stage pulmonary disease caused by amyotrophic lateral sclerosis, COPD, CF, idiopathic pulmonary fibrosis, lung cancer, or other diseases may request

terminal weaning. The term *terminal weaning* has been viewed by some as an oxymoron for several reasons. Although terminal implies that the withdrawal of ventilator support will inevitably end in death, patients do not always die shortly after discontinuation of ventilator support. In one study, 8% of patients survived and were discharged (M.L. Campbell 1994), although prediction has improved since then. The phrase “discontinuation of ventilator support” or “withdrawal of mechanical ventilation” is preferable when talking with the patient, family, and other health care professionals (Apelgren 2000; Daly et al. 1993).

Ethicists and legal experts concur that competent patients, or their surrogate decision makers when patients are not competent, have the right to refuse treatment, regardless of whether it is “lifesaving,” and that there is no moral difference between not initiating treatment and withdrawing treatment in response to the patient’s request. The patient or surrogate must be made aware that death is the expected outcome when ventilator support is discontinued and should make the decision only after due deliberation (Daly et al. 1993).

The patient’s goals should guide the process of withdrawing ventilator support (J. Anderson and O’Brien 1995). If the patient shows ambivalence about terminal weaning, or it is unclear whether the patient has sufficient mental capacity to make a well-thought-out decision, a psychiatrist should be consulted. The first step in evaluation is to explore why the patient has requested discontinuation of ventilator support. Depression, delirium, and concerns about burdening the family require different interventions. In difficult cases, involvement of the hospital’s ethics committee, chaplain, social worker, and legal counsel may be helpful. A brief delay (days) after the decision has been made to withdraw ventilator support may reassure staff and family that the patient made a decision that was not based on temporary frustration or discomfort.

Patients should be told that the weaning process may be stopped at any time if they wish. Evidence-based guidance is available (M.L. Campbell 2007). Withdrawal of the ventilator may follow the withdrawal of pressors, antibiotics, and enteral feeding (Brody et al. 1997). In a conscious patient, a gradual decrease in fraction of inspired oxygen (FIO_2), with decreased positive end-expiratory pressure (PEEP) and decrease in respiratory rate over several hours has been advocated (Grenvik 1983).

Adjunctive medication may alleviate distress. Opiates have been used to decrease anxiety, coughing, gasping, pain, or the sensation of shortness of breath and to provide sedation (Wilson et al. 1992). Documentation of the physician’s intent in administering opiates is important to show that the medication is being used as a comfort measure and not to hasten death. One protocol suggests giving a bolus of 5–

10 mg morphine intravenously followed by a drip of 2.5–5.0 mg/hour of morphine. Benzodiazepines may decrease anxiety and prevent myoclonus or twitching that may be unsettling to the family (Faber-Langendoen 1994). Phenobarbital may control twitching not relieved by benzodiazepines. Low-dose haloperidol may be used intravenously for anxiety not relieved by benzodiazepines or for delirium. One group observed that because opioids and sedatives decrease oxygen requirements, these drugs may prolong life, instead of hastening death (Bakker et al. 2008). Charting should include advance directives, code status, documentation of medications given and time of initiation of the ventilator withdrawal process, and whether the patient was extubated (Kirchhoff et al. 2004). The family should be educated prior to the procedure that the medications are used to prevent the patient from having physical distress and awareness of bodily events and may induce euphoria.

Psychiatric Side Effects of Pulmonary Drugs

Psychiatric side effects of pulmonary drugs are shown in Table 19–1 and noted in the following psychiatric syndrome sections. The adverse psychiatric effects of systemic corticosteroids are reviewed in Chapter 25, “Rheumatology,” and the effects of antibiotics are reviewed in Chapter 27, “Infectious Diseases.” Isoniazid and other drugs for tuberculosis were discussed earlier in this chapter. There have been reports of suicidality with montelukast and other leukotriene antagonists but insufficient data to prove that a causal relation exists (Manalai et al. 2009). In children, a variety of adverse psychiatric effects of montelukast have been reported, including nightmares and other sleep disorders, anxiety, and aggression (Wallerstedt et al. 2009).

Psychopharmacology in Pulmonary Disease

Anxiety

Anxiety in pulmonary patients may be caused by symptoms of lung disease such as breathlessness, bronchospasm, excessive secretions, or hypoxia, so the first step in treatment of anxiety is optimization of management of the patient’s respiratory illness. Many drugs used to treat pulmonary disease may themselves cause anxiety (see Table 19–1). Theophylline can cause anxiety, nausea, tremor, and restlessness, especially at higher doses. Beta-adrenergic bronchodilators used in treatment of asthma or other obstructive lung disease can cause marked anxiety, tachycardia, and tremor, particularly in patients who overuse

TABLE 19-1. Psychiatric side effects of common pulmonary drugs

Anticholinergics	Auditory and visual hallucinations, anxiety, confusion, delirium, depersonalization, amnesia, paranoia
Antileukotrienes	Anxiety
Beta-agonists (selective)	Anxiety in susceptible patients
Beta-agonists (nonselective)	Anxiety, psychosis
Corticosteroids (inhaled)	None
Corticosteroids (systemic)	Depression, mania
Cycloserine	Agoraphobia, anxiety, depression, psychosis
Isoniazid	Amnesia, anxiety, depression, hallucinations, mania, psychosis
Theophylline	Anxiety, delirium, insomnia, mutism, restlessness, tremor

Source. Adapted from "Drugs That May Cause Psychiatric Symptoms" 2008.

their inhalers. Nonprescription asthma preparations contain nonselective sympathomimetics, which are even more likely to cause anxiety. At high doses, they may cause psychosis and seizures.

In anxious pulmonary patients with hypercapnia, buspirone is preferred for treatment of anxiety, but it may have a slow onset of action (Craven and Sutherland 1991). Buspirone may improve exercise tolerance and dyspnea, can be used safely in patients with sleep apnea (Mendelson et al. 1991), and can be combined with theophylline and terbutaline (Kiev and Domantay 1988).

In COPD patients who do not retain carbon dioxide, prudent doses of benzodiazepines may decrease breathlessness. In elderly or debilitated patients, shorter-acting benzodiazepines with no active metabolites, such as alprazolam, lorazepam, and oxazepam, are preferred. Zolpidem does not alter respiratory drive in COPD patients, but rebound insomnia or withdrawal similar to that with triazolam may result. Diazepam has no effect on breathlessness and may decrease exercise tolerance. Although some have advocated promethazine to decrease breathlessness and increase exercise tolerance in COPD, this drug is a phenothiazine and can cause akathisia, extrapyramidal effects, and neuroleptic malignant syndrome. Selective serotonin reuptake inhibitors (SSRIs) also may be helpful in treating panic symptoms and do not have pulmonary side effects. If panic does not respond to these measures, then neuroleptics may be effective in low doses. Beta-blockers should not be used for anxiety in asthma patients because of resulting bronchoconstriction.

Depression

When choosing an antidepressant, the side-effect profile and cytochrome P450 (CYP) interactions with pulmonary drugs should be considered. Among the SSRIs, sertraline,

citalopram, and escitalopram have the lowest risk of interactions with pulmonary drugs, and SSRIs may decrease dyspnea and even increase arterial oxygen concentration in some patients (Ciraulo and Shader 1990; Smoller et al. 1998).

Many pulmonary patients may be taking other medications that can prolong the QT interval, so reviewing the electrocardiogram is prudent when considering treatment with a tricyclic antidepressant. In elderly patients or in patients with COPD or sleep apnea, nortriptyline or desipramine is preferred over the more sedating tertiary amines, which may cause delirium or hypotension. Protriptyline may be helpful in sleep apnea by increasing respiratory drive, but the half-life is very long (54–92 hours), three to four times longer than that of nortriptyline, with no evidence of greater efficacy compared with other tricyclics for sleep apnea (DeVane 1998).

Psychosis

Pulmonary patients may have primary psychotic disorders, such as bipolar disorder or schizophrenia, or may become psychotic because of medications such as beta-agonists, cycloserine, isoniazid, or corticosteroids. The incidence of steroid psychosis is dose related, seen in fewer than 1% of patients taking 40 mg or less of prednisone per day compared with 28% taking 80 mg daily (Boston Collaborative Drug Surveillance Program 1972).

Typical neuroleptics such as haloperidol at high doses may cause akathisia, laryngospasm, and paradoxical intercostal muscle movements that may cause restlessness and interfere with breathing. Tardive dyskinesia sometimes affects the diaphragm and other muscles used in breathing and in severe cases can result in respiratory insufficiency. For chronic treatment, newer drugs with lower incidence of extrapyramidal side effects may be preferred.

TABLE 19–2. Drug interactions between pulmonary and psychotropic drugs

Pulmonary drug	Psychotropic drug	Adverse effect
Isoniazid	TCAs	MAOI effect of isoniazid
Rifampin	Donepezil	Decreased donepezil effect
Rifampin	Diazepam	Induced diazepam metabolism
Rifampin	Valproate	Decreased valproate level
Rifampin	TCAs, MAOIs	Induced TCA, MAOI metabolism
Sympathomimetic drugs ^a	TCAs, MAOIs	Hypertensive crisis
Theophylline	Alprazolam	Decreased benzodiazepine effect
Theophylline	Carbamazepine	Decreased carbamazepine level
Theophylline	Clozapine	Increased theophylline level
Theophylline	Fluvoxamine	Increased theophylline level
Theophylline	Lithium	Reduced lithium level 20%–30%

Note. MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant.

^aEpinephrine, ephedrine, pseudoephedrine.

Drug Interactions Between Psychotropic and Pulmonary Drugs

The psychiatrist should consider potential interactions when prescribing psychotropic medications to patients with pulmonary disease (Table 19–2). Theophylline levels may be reduced by 50%–80% by tobacco smoking. Nicotine gum does not have this effect. Polycyclic aromatic hydrocarbons in tobacco smoke may induce CYP isoenzymes 1A1, 1A2, and perhaps 2E1. If a patient quits smoking when admitted to the hospital, CYP1A2 induction rapidly declines, which can lead to increased effects of substrates, including caffeine, clozapine, fluvoxamine, olanzapine, tacrine, and theophylline. Likewise, when discharged patients resume smoking, these medications may need dosage adjustment. Inhaled corticosteroids are also influenced by smoking and may reach higher levels more quickly.

Alcohol can reduce clearance of theophylline as much as 30% for up to 24 hours. Most pulmonary medications do not affect lithium levels, except theophylline, which can lower lithium levels by 20%–30%. Patients with chronic pulmonary disease may develop right-sided heart failure and may receive diuretics that raise or lower lithium levels depending on choice of diuretic. Theophylline preparations administered concurrently with electroconvulsive therapy can prolong seizure duration, especially if the theophylline level is higher than the accepted therapeutic range, even if the level is below that typically associated with seizures (Peters et al. 1984).

Rifampin is a CYP3A4 substrate and so may compete with many psychotropic drugs, including the antidepres-

sants amitriptyline, imipramine, fluoxetine, sertraline, bupropion, venlafaxine, and trazodone. Rifampin may compete through the same site with anticonvulsants (e.g., carbamazepine, tiagabine, and valproate) and with benzodiazepines, zolpidem, and haloperidol. Montelukast sodium may have similar interactions to those of rifampin because of metabolism via CYP3A4 and CYP2C9.

Fluvoxamine can increase sildenafil exposure by 40% and prolong the half-life by 19% ($P=0.9034$). Fluvoxamine can boost sodium nitroprusside-induced venodilation by 59% (Hesse et al. 2005).

Conclusion

In this chapter we have summarized the treatment of psychiatric conditions often seen in patients with lung disease. Diseases affecting the lungs occur across the life span. Some diseases, such as asthma and cystic fibrosis, often begin in childhood and may affect childhood developmental stages. Sarcoidosis may manifest in early to middle life, disrupting career and family life. Comorbid psychiatric conditions are also prevalent in conditions that begin between midlife and senescence, such as chronic bronchitis, emphysema, and pulmonary fibrosis. Hyperventilation syndrome and vocal cord dysfunction can have biological or psychological origins that need to be identified for effective treatment. Ultimately, the psychological aspects of lung disease determine to a large extent the quality of life and outcomes of patients with lung disease, including those with lung cancer and those that undergo lung trans-

plantation. Finally, with the polypharmacy often required for treatment of lung disease, the psychiatrist must be aware of the ever-present risks of adverse interactions between pulmonary drugs and psychotropics.

Gastrointestinal Disorders

Catherine C. Crone, M.D.

Christopher R. Dobbelstein, M.D.

GASTROINTESTINAL (GI) DISORDERS cover a wide range of illnesses that span from mouth to anus and include the liver, pancreas, and gallbladder. Some disorders are uncommon, whereas others such as gastroesophageal reflux disorder (GERD), peptic ulcer, and irritable bowel syndrome (IBS) are common. Physical and psychological distress caused by GI disorders results in high rates of health care use, billions of dollars in annual health care costs, lost productivity, and reduced quality of life (QOL). Additionally, an interrelation between the brain and the gut adds to the complexity of care for many of these patients. Psychiatrists often encounter patients with concurrent GI disorders, and their presence may need to be factored into clinical evaluation and subsequent care plans. In this chapter, which is organized according to organ or GI region, we cover several GI disorders, both structural and functional in origin.

Functional Gastrointestinal Disorders

Patients often present to health care providers with various forms of GI distress that are found to lack specific structural or physiological etiologies. These represent *functional GI disorders*, a broad spectrum of symptom-defined diagnoses (e.g., globus, functional heartburn, functional dyspepsia, cyclic vomiting syndrome) with pathophysiology that is still not fully understood (Drossman 2006). A complex connection exists between the brain and the gut, with bidirectional communication pathways that involve the autonomic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Disruptions along these pathways can result in functional GI problems.

The existence of the brain-gut axis is also thought to help explain how psychosocial factors, personality styles, and comorbid psychiatric disorders can influence the onset and course of various functional GI disorders, such as IBS, functional dyspepsia, and functional nausea and vomiting. Among patients with functional GI disorders, premorbid histories of traumatic events, particularly sexual and physical abuse, are often present. Neuroticism, hostility, maladaptive coping, and emotional hypersensitivity are personality traits that are commonly observed. Comorbid psychiatric syndromes, particularly depression, anxiety, and somatization, are also frequently noted.

Psychotropic medications and psychotherapy have had a role in the treatment of many functional GI disorders, although their mechanism of action is not truly known. For example, antidepressants can provide analgesic and autonomic effects in addition to their anxiolytic and antidepressant activities.

Because of the need for consistency in diagnosis of functional GI disorders, the Rome Criteria were developed and refined through an iterative consensus process. The most recent—Rome III Criteria—involved the work of clinicians and researchers from 18 countries around the world (Drossman 2006).

Oropharyngeal Disorders

Rumination Syndrome

Rumination syndrome involves repeated and effortless regurgitation of small amounts of food from the stomach, which are subsequently rechewed, reswallowed, or expelled (Papadopoulos and Mimidis 2007). This behavior is com-

mon among infants and developmentally disabled individuals but also can appear in children and adults of normal intelligence (Olden 2001). The problem is often mistaken for bulimia, GERD, or upper GI motility disorders, such as gastroparesis (Papadopoulos and Mimidis 2007). Nausea, heartburn, abdominal discomfort, weight loss, and bowel changes often accompany rumination syndrome. Limited case series suggest that comorbid psychiatric disorders, including bulimia nervosa, may be present in up to 20%–30% of patients (Malcolm et al. 1997; Olden 2001). Rumination also can develop following a stressful life event (Attri et al. 2008). Adults primarily seek out care because of societal discomfort with their behavior. Diagnosis is made by clinical assessment rather than invasive testing. Treatment centers on behavior therapy, including habit reversal, biofeedback, and relaxation techniques (Attri et al. 2008).

Burning Mouth Syndrome

Burning mouth syndrome is a chronic pain condition characterized by a persistent oral burning sensation without accompanying evidence of mucosal disturbance (Sardella 2007; Scala et al. 2003). Symptoms typically persist throughout the day, intensify late in the day, and may be relieved by eating or drinking. Xerostomia and dysgeusia often accompany the syndrome (Scala et al. 2003). Personal stressors, fatigue, or acidic foods worsen the burning sensation for most patients. The syndrome mainly affects middle-aged to elderly women, and the prevalence in the United States is estimated to be 0.7%–1.7% (Klasser et al. 2008). Onset of symptoms is usually spontaneous, although up to a third of patients may attribute onset to illness, medications, or dental procedures (Grushka et al. 2002; Klasser et al. 2008). Potential triggering medications include angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, antiretroviral agents, hormone replacement therapy, sertraline, fluoxetine, venlafaxine, and clonazepam (Levenson 2003; Salort-Lorca et al. 2008). The underlying mechanism behind the syndrome is unknown, but some evidence suggests a neuropathic origin (Sardella 2007; Scala et al. 2003). Comorbid psychiatric disorders, including anxiety, depression, and hypochondriasis, have been identified in 40%–60% of patients, although it is unclear whether these are secondary to the condition itself (Bogetto et al. 1998). Clinical trials, most of which were small but some of which were placebo-controlled, reported partial or full remission of symptoms with oral or topical clonazepam, oral or topical capsaicin, amisulpride, paroxetine, sertraline, alpha-lipoic acid, and cognitive therapy (Bergdhal et al. 1995; Femiano and Scully 2002; Gremeau-Richard et al. 2004; Grushka et al. 1998; Maina et al. 2002; Mínguez Serra et al. 2007; Yamazaki et al. 2009; Zakrzewska et al. 2005). Recent case re-

ports also noted success with olanzapine and electroconvulsive therapy (Sudas et al. 2008; Ueda et al. 2008).

Xerostomia

Xerostomia is a subjective complaint of dry mouth that may be associated with reduced saliva production. Among sampled populations, xerostomia has been found to be present in up to 30%; its presence predisposes patients to dental caries and oropharyngeal *Candida albicans* infections (Guggenheimer and Moore 2003). Adequate saliva production is needed to facilitate taste, speech, and swallowing. Patients with xerostomia may report accompanying difficulties with altered taste, dysgeusia, or dysphagia (Friedlander and Mahler 2001). Common causes include medications, autoimmune disorders (e.g., Sjögren's syndrome), radiation therapy, anxiety, depression, and other medical conditions (e.g., diabetes, HIV) (Guggenheimer and Moore 2003). Psychotropic medications (especially anticholinergic drugs) are often linked to xerostomia; included in this group are all antidepressants, benzodiazepines, typical and atypical antipsychotics, carbamazepine, and lithium (Clark 2003; Friedlander et al. 2004; Guggenheimer and Moore 2003). Interventions include medication change, avoidance of caffeine and alcohol, sips of water, ice chips, sugarless gum or candy, saliva substitutes, acupuncture, and cholinergic agents (e.g., pilocarpine, bethanechol) (Masters 2005; Schatzberg et al. 2007).

Dysphagia

Successful swallowing of liquids or foodstuffs requires a coordinated sequence of voluntary and involuntary neuromuscular contractions that moves a bolus from mouth to pharynx, to the esophagus, and finally to the stomach. Circumstances that interfere with this series of movements lead to dysphagia, which is estimated to affect 7%–10% of adults older than 50 years, with higher rates in hospitalized and nursing home patients (Spieker 2000). Dysphagia contributes to significant morbidity and mortality by causing malnutrition, esophageal rupture, aspiration, and aspiration pneumonia (Spieker 2000). Neurological disorders (i.e., cerebrovascular accident, multiple sclerosis, myasthenia gravis, Parkinson's disease) commonly cause dysphagia (Lind 2003). Medications also contribute to dysphagia by producing xerostomia, sedation, pharyngeal weakness, dysphagia, or reflux (Palmer et al. 2000). Several patients have reported dysphagia from antipsychotic-induced dystonia, parkinsonism, and tardive dyskinesia (Dziewas et al. 2007; Nieves et al. 2007). With some, the dysphagia was the only sign of an underlying movement disorder (O'Neil and Remington 2003). Acute dystonia responds to intravenous diphenhydramine or benztropine, whereas dysphagia from drug-induced parkinsonism does not (Dziewas et al. 2007;

Garlow et al. 2006; O'Neil and Remington 2003). Rather, treatment requires discontinuing medication, lowering the dose, or switching to another agent (Dziewas et al. 2007). Tardive dyskinesia is also managed through these steps, but clonazepam is another option (Nieves et al. 2007; O'Neil and Remington 2003). Rarely, dysphagia is a manifestation of neuroleptic malignant syndrome or serotonin syndrome (Passmore et al. 2004; Shamash et al. 1994).

Globus Hystericus

Globus is the sensation of having a lump or mass in the throat that does not interfere with actual swallowing. Globus pharyngeus or hystericus represents a common benign disorder responsible for 4% of ear, nose, and throat referrals (Caylakli et al. 2006). Its course is variable, with most patients improving over time. The etiology of globus is unknown and may be multifactorial; various causes have been proposed, including cricopharyngeal spasm, lingual tonsil hypertrophy, thyroid nodules, cervical osteophytes, iron deficiency anemia, GERD, anxiety, and depression (Caylakli et al. 2006; Finkenbine and Miele 2004; Park et al. 2006). In one study of more than 100 patients who received a diagnosis of psychogenic globus, further evaluation detected physiological abnormalities in most patients (Leelamanit et al. 1996). A similar study in a smaller population yielded similar findings (Ravich et al. 1989). Treatment in those without evidence of physiological abnormalities primarily involves reassurance and psychotherapy, although antidepressants (e.g., tricyclic antidepressants [TCAs], monoamine oxidase inhibitors) have been reported to be effective for some cases (Bishop and Riley 1988; S.R. Brown et al. 1986; Finkenbine and Miele 2004). The role of anxiolytics is unclear, except for those with globus secondary to panic disorder (Finkenbine and Miele 2004).

Upper Gastrointestinal Disorders

Gastroesophageal Reflux Disorder

GERD is defined as a "condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications" (Vakil et al. 2006, p. 1903). When no reflux esophagitis is seen endoscopically but the patient is still symptomatic, it is called *nonerosive reflux disorder*. Chest pain identical to that of myocardial ischemia can be caused by GERD and is referred to as *reflux chest pain syndrome*, the most common cause of noncardiac chest pain (NCCP) (Cannon et al. 1994; Vakil et al. 2006). GERD adversely affects QOL and productivity (Camilleri et al. 2005; Moayyedi and Talley 2006). GERD is common in Western Europe and North America (prevalence = 10%–20%) but rare in the rest of the world (Dent et al. 2005).

The underlying mechanism of GERD is uncertain, but most experts believe that the increased frequency of transient lower esophageal sphincter relaxations is the most common cause (Moayyedi and Talley 2006). Higher frequency of transient lower esophageal sphincter relaxations increases exposure to gastric refluxate (Dent et al. 1980). However, the degree of esophageal injury present correlates poorly with the amount of acid exposure (Avidan et al. 2002). Esophageal mucosal hypersensitivity may play a role for some patients who show no evidence of macroscopic mucosal damage or abnormal reflux. These patients may experience pain even when a normal amount of acid contacts their esophagus (Rodriguez-Stanley et al. 1999). Central factors beyond mucosal hypersensitivity also may play a role. Prolonged stress leads to hypervigilance, increased symptom reporting, and health-care-seeking behavior. For example, GERD patients with a history of physical/sexual abuse are more likely to seek evaluation of their symptoms than are GERD patients without a history of abuse (Mizyed et al. 2009).

A study of NCCP patients that used esophageal evoked potentials showed that three subpopulations exist: 1) those with mucosal hypersensitivity (reduced pain threshold to electrical stimulus but normal cortical processing), 2) those with central factors (e.g., hypervigilance) mediating hypersensitivity (reduced pain threshold but delayed cortical processing), and 3) those without any esophageal hypersensitivity. They postulated that each group would need a different treatment strategy, with the first needing antinociceptive medications and the second needing psychotherapy (Hobson et al. 2006). It also should be noted that a large population-based study found that antidepressants (clomipramine and selective serotonin reuptake inhibitors [SSRIs]) are associated with an increased risk of reflux esophagitis (van Soest et al. 2007).

Several studies have shown higher prevalence of reflux symptoms among psychiatric patients (Mizyed et al. 2009). A case-control study comparing psychiatric inpatients with nonpsychiatric control subjects found that reflux symptoms were significantly more prevalent among the psychiatric patients, even after the study controlled for psychotropic drug use and smoking (Avidan et al. 2001). A population-based case-control study of more than 65,000 subjects found that individuals with anxiety had a 3.2-fold increased risk of severe reflux, those with depression had a 1.7-fold increased risk, and those with both anxiety and depression had a 2.8-fold increased risk (Jansson et al. 2007). A smaller population-based case-control study failed to show that anxiety and depression were risk factors for GERD (Eslick and Talley 2009).

Psychological stress influences the pathophysiology of GERD and plays a role in how patients respond to treat-

ment. Several studies have shown that acute and chronic stress affects both subjective and objective outcomes in GERD (Mizyed et al. 2009). A small study found that experimentally induced stress increased reflux symptoms but did not increase objective measures of acid reflux (Bradley et al. 1993). A larger study showed similar results (Wright et al. 2005). Fass et al. (2008) compared 46 GERD patients with confirmed abnormal esophageal acid exposure with 10 control subjects; they found that GERD patients showed esophageal hypersensitivity to acid, and this hypersensitivity increased during experimental stress. Some studies have shown that patients with nonerosive reflux disorder are more likely than patients with erosive esophagitis to have psychological symptoms, but others disagree (Nojkov et al. 2008; Wu et al. 2007).

Regarding treatment response, one study showed that patients who had more severe GERD symptoms in association with psychological distress responded well to proton pump inhibitors (Nojkov et al. 2008). This finding is in contrast to two other studies that showed that depressed and anxious GERD patients were less likely to respond to proton pump inhibitors (K.J. Lee et al. 2009; Wiklund et al. 2006). Another study showed that patients with major depression reported less relief of GERD symptoms after anti-reflux surgery, despite having physiologically equivalent results (Kamoliz et al. 2003).

Noncardiac Chest Pain

As previously noted, GERD can cause chest pain indistinguishable from that of cardiac ischemia and is the most common cause of NCCP (Cannon et al. 1994; Fass and Dickman 2006; Vakil et al. 2006). The annual prevalence in the general population is approximately 25% (Fass and Dickman 2006). Because NCCP usually persists over time and causes significant functional impairment, patients often continue to seek urgent medical care despite normal cardiac test results (Fass and Dickman 2006). Evidence suggests that NCCP is sometimes caused by esophageal hypersensitivity. Some patients experience chest pain during esophageal balloon distention, sensing the balloon at lower pressures than those felt by control subjects (Rao et al. 1996). Whether this is due to peripheral or central abnormal neural processes is currently under investigation, but treatment with visceral analgesics (such as TCAs, trazodone, or SSRIs; see below) has proven to be helpful (Chahal and Rao 2005; Fass and Dickman 2006). Psychiatric disorders, including panic disorder, other anxiety disorders, and major depression, tend to be more prevalent among NCCP patients compared with the general population (Fass and Dickman 2006). Compared with control subjects, NCCP patients tend to monitor more and use more problem-

focused coping, behaviors associated with higher levels of anxiety and depression (Fass and Dickman 2006).

Functional Heartburn

Functional heartburn has been defined as burning retrosternal discomfort or pain in the absence of evidence that gastroesophageal acid reflux is the cause of the symptom and absence of histopathology-based esophageal motility disorder (Drossman 2006). Compared with control subjects, patients with functional heartburn have more somatization and lower pain thresholds during intraesophageal balloon distention (Shapiro et al. 2006). They also tend to have more atypical symptoms, more comorbid IBS, and more anxiety than do patients with GERD (S. Lee et al. 2009).

Treatment of GERD, Noncardiac Chest Pain, and Functional Heartburn

Case reports and a small study that used experimental stressors suggested a possible role for biofeedback and relaxation training for reduction of GERD symptoms (Gordon et al. 1983; McDonald-Haile et al. 1994). Cognitive therapy also has been proposed as a treatment for NCCP, and a method for conducting it has been described in detail (Salkovskis 1992). A randomized controlled trial in which this approach was used for NCCP showed that it was successful at decreasing the frequency of NCCP, even at 12-month follow-up. This effect, however, may have been mediated by the significant improvement in anxiety in these patients (van Peski-Oosterbaan et al. 1999). Another trial showed similar effects (Klimes et al. 1990). Hypnotherapy was effective for NCCP in a small randomized controlled trial that compared 12 hypnotherapy sessions with supportive therapy. Chest pain intensity but not frequency declined with hypnotherapy (Jones et al. 2006).

TCAs have been used to treat NCCP for many years, but it is unclear whether they exert their effect locally, as a visceral analgesic, or on the central nervous system (Fass and Dickman 2006). A small retrospective study of patients who received TCAs for NCCP reported that 81% had response or remission (Prakash and Clouse 1999b). Cannon et al. (1994) found that imipramine decreased chest pain in patients with normal coronary angiograms, although it did not reduce esophageal sensitivity to balloon distention. A small placebo-controlled trial found that trazodone reduced distress from esophageal symptoms, but it did not influence manometric parameters or actual symptoms (Clouse et al. 1987). Like TCAs, SSRIs also may have peripheral or central effects on NCCP, but their clinical utility remains unclear. A randomized placebo-controlled trial of sertraline for NCCP patients without major depression,

panic disorder, or drug or alcohol abuse or dependence showed that sertraline was significantly helpful in decreasing subjective chest pain (Varia et al. 2000). On the contrary, compared with placebo, paroxetine failed to reduce pain scores significantly in NCCP patients without major depression or panic disorder (Doraiswamy et al. 2006). However, it should be kept in mind, as noted earlier, that antidepressants also can increase the risk of GERD.

Nausea and Vomiting

Hyperemesis Gravidarum

Nausea and vomiting of pregnancy affect up to 80% of pregnant women during their first trimester. When nausea and vomiting are severe and accompanied by ketonuria and weight loss, it is considered hyperemesis gravidarum (Bottomley and Bourne 2009; Gill and Einarson 2007). With an incidence rate of 0.5%–2%, hyperemesis gravidarum is the most common reason for hospitalization during the first trimester of pregnancy (T.M. Goodwin 2008). The etiology is unknown but may involve hormonal, infective, anatomical, and psychological factors (Bottomley and Bourne 2009; Kim et al. 2009). Although in the past, hyperemesis gravidarum was ascribed to psychological conflicts (e.g., ambivalence about pregnancy), there is a lack of evidence for this viewpoint (Kim et al. 2009). Rather, it appears that hyperemesis gravidarum causes significant emotional distress and reduced QOL (Gill and Einarson 2007). Some women will consider terminating the pregnancy to seek relief.

Management of hyperemesis gravidarum requires maintenance of adequate intravenous hydration and prevention of serious complications (e.g., Wernicke's encephalopathy, renal impairment, and Mallory-Weiss tears) (Chiossi et al. 2006; T.M. Goodwin 2008). Medications that have been effective include phenothiazines, metoclopramide, serotonin type 3 receptor (5-HT₃) antagonists, mirtazapine, benzodiazepines (diazepam), and vitamin B₆ (Bottomley and Bourne 2009; Gill and Einarson 2007; Gulclu et al. 2005; Tasci et al. 2009). Treatment-resistant cases may require corticosteroids. Ginger has shown some benefits for nausea and vomiting of pregnancy, but no data are available for hyperemesis gravidarum (Boone and Shields 2005; Borrelli et al. 2005). See also Chapter 33, "Obstetrics and Gynecology."

Chemotherapy-Induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting affect 70%–80% of patients, influenced by specific type of chemotherapy, dose, schedule, route of administration, and patient-specific factors (Naeim et al. 2008). Severe chemotherapy-induced nausea and vomiting cause marked impairment in daily functioning and QOL and contribute to decisions to

discontinue chemotherapy prematurely. Patients develop nausea and vomiting acutely within 24 hours after chemotherapy, or they develop a delayed response that may last for days (Feeney et al. 2007; Navari 2009). Risk factors for chemotherapy-induced nausea and vomiting include female gender, younger age, history of motion sickness or pregnancy-induced nausea, comorbid anxiety or depression, and low alcohol intake (Lohr 2008). Treatment typically relies on 5-HT₃ antagonists, dexamethasone, and neurokinin-1 antagonists (Lohr 2008; Naeim et al. 2008). A significant number of patients experience breakthrough or treatment-resistant chemotherapy-induced nausea and vomiting, requiring other adjunctive therapies. Lorazepam, metoclopramide, haloperidol, droperidol, and cannabinoids may be added (Lohr 2008). A few case reports (Pirl and Roth 2000; Srivastava et al. 2003) and Phase I and II trials support a role for olanzapine in both acute treatment of and prophylaxis against chemotherapy-induced nausea and vomiting (Navari et al. 2005, 2007; Passik et al. 2004). Two small open trials reported beneficial effects with gabapentin (Guttuso et al. 2003; Lohr 2008). A Cochrane review of 11 randomized trials concluded that acupuncture point stimulation reduced incidence of acute vomiting but not acute or delayed nausea (Ezzo et al. 2006). Electroacupuncture had the greatest effect. Acupressure studies are suggestive of benefits for acute nausea and delayed chemotherapy-induced nausea and vomiting (J. Lee et al. 2008).

Anticipatory Nausea and Vomiting

Anticipatory nausea and vomiting are conditioned responses to settings and circumstances primarily associated with actual episodes of nausea and vomiting. This condition is well recognized in the oncology literature, in which 10%–44% of patients may be affected, but anticipatory nausea and vomiting can develop with other causes of nausea and vomiting, such as pregnancy, gastroparesis, or cyclic vomiting syndrome (Aapro et al. 2005). Factors predictive of anticipatory nausea and vomiting include female gender, age younger than 50 years, susceptibility to motion sickness, nausea and vomiting after the last chemotherapy session, anxiety, hostility, depression, and subjective severity of and accompanying physical distress associated with the last chemotherapy session (Matteson et al. 2002). Expectations of experiencing nausea and vomiting also influence the likelihood of developing anticipatory nausea and vomiting (Hickok et al. 2001; Montgomery and Bovbjerg 2003). Compared with other types of nausea and vomiting, anticipatory nausea and vomiting do not respond to standard antiemetic agents. Benzodiazepines may be able to reduce the incidence of anticipatory nausea and vomiting, but behavioral interventions have proven to be the most effective approach (Matteson et al. 2002). Progressive muscle

relaxation, systemic desensitization, hypnosis, and cognitive distraction with video games have been used in both adult and pediatric patient populations (Figuerola-Moseley et al. 2007; Mundy et al. 2003; Redd et al. 2001).

Functional Nausea and Vomiting

Functional nausea and vomiting refer to chronic nausea and vomiting without apparent cause. This condition was once referred to as “psychogenic” vomiting, but no evidence shows a direct link between psychiatric disorders and chronic unexplained nausea and vomiting (Olden and Chepyala 2008; Talley 2007). According to Rome III criteria, functional nausea and vomiting are divided into three specific conditions: chronic idiopathic nausea, functional vomiting, and cyclic vomiting syndrome (Olden and Chepyala 2008; Talley 2007). *Chronic idiopathic nausea* involves nausea that occurs several times a week, which is not usually accompanied by vomiting. *Functional vomiting* refers to unexplained vomiting that occurs at least once a week, is not cyclical, and lacks an organic basis. The epidemiology and pathophysiology of chronic idiopathic nausea and functional vomiting are currently unknown (Olden and Chepyala 2008). Two studies indicated that functional vomiting is often associated with a history of physical or sexual abuse or comorbid panic disorder (Olden and Crowell 2005; Olden et al. 2003). Management of chronic idiopathic nausea is purely symptomatic, and prokinetic and antiemetic medications are used. For functional vomiting, treatment requires nutritional support and reassurance (Olden and Chepyala 2008). A small retrospective study of patients with functional vomiting found significant benefit with low-dose TCAs, with half experiencing complete symptom remission (Prakash et al. 1998).

Cyclic vomiting syndrome is characterized by recurrent stereotypical bouts of severe nausea and vomiting. Once recognized only in children, cyclic vomiting syndrome also occurs in adults, primarily between ages 20 and 40 years (Abell et al. 2008; Sonje and Levenson 2009). Among children, the prevalence ranges from 0.03% to 1.9%. The syndrome typically manifests early in childhood and then either resolves in late childhood or adolescence or progresses to migraine headaches (Dulude et al. 2008; Sonje and Levenson 2009). The prevalence in adults is unknown, and the syndrome often goes undiagnosed for several years.

Cyclic vomiting syndrome consists of four phases: prodromal, emetic, recovery, and interepisode or well. During the prodromal phase, patients experience nausea, abdominal pain, pallor, lethargy, and anorexia lasting minutes to hours, followed by vomiting (emetic phase), which can persist for days. Recovery phase begins when vomiting ceases and hunger and food tolerance resume. Between episodes, patients are often symptom free or may have dyspeptic nau-

sea. The clinical presentation of cyclic vomiting syndrome may be accompanied by fever, chills, sweating, diarrhea, neutrophilia, tachycardia, and elevated blood pressure, mimicking acute abdomen from other causes (Pareek et al. 2007). For many, certain triggers can set off an episode; triggers include infections, lack of sleep, psychologically stressful events (positive and negative), onset of a menstrual period, fasting, and certain foods. The pathogenesis of cyclic vomiting syndrome is unknown but may involve autonomic nervous system dysfunction, GI dysrhythmia, mitochondrial gene mutations, HPA axis defect, ion channelopathies, and chronic cannabis abuse (Abell et al. 2008). Comorbid migraine headache and family history of migraines are common. A higher-than-expected rate of psychiatric comorbidity (anxiety, panic attacks, depression) has been noted, but it is unclear if this represents a reaction to the stress of cyclic vomiting syndrome or an actual contributing factor (Abell et al. 2008; Fleisher et al. 2005; Tarbell 2008). Treatment is empirical and requires lifestyle adjustments, education, stress management, and reassurance, along with medications for prophylactic and acute use (Li et al. 2008). Prophylaxis primarily entails TCAs (amitriptyline), cyproheptadine, or propranolol (Chepyala et al. 2007; Li et al. 2008; Namin et al. 2007; Prakash and Clouse 1999a). L-carnitine, coenzyme Q10, low-estrogen contraceptives, anticonvulsants, and prokinetic agents also have been used. Acute periods of nausea and vomiting may require intravenous fluids, antiemetics, triptans, benzodiazepines (for sleep induction and anxiolysis), opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), proton pump inhibitors, and histamine H₂-blockers.

Gastroparesis

Gastroparesis is a clinical disorder of delayed gastric emptying without evidence of mechanical obstruction. Symptoms are variable but often include nausea, vomiting, early satiety, abdominal bloating, and pain. Symptom severity does not necessarily correlate with the magnitude of delayed gastric emptying present (Khoo et al. 2009; Stapleton and Wo 2009). The prevalence of gastroparesis may be increasing in the United States and is responsible for causing reduced QOL, impaired nutrition, and interference with oral medication absorption (Khoo et al. 2009; Stapleton and Wo 2009). Gastroparesis may be idiopathic or associated with various conditions such as diabetes or other metabolic disturbances, surgery, chronic renal failure, connective tissue disorders, and neuromuscular disorders (Khoo et al. 2009; Patrick and Epstein 2008). Diabetes mellitus is considered to be the most common cause, although idiopathic gastroparesis has been nearly as common in some series (Hasler 2008). Most patients with idiopathic gastroparesis are young to middle-aged women, many with a his-

tory of acute gastroenteritis and/or viral syndrome (Patrick and Epstein 2008). Gastroparesis can also be caused by medications including opiates, TCAs, and lithium (Hasler 2008). The natural course of gastroparesis is one of relapsing and remitting symptoms (Khoo et al. 2009). Management may involve dietary changes, nutritional supplements, prokinetic agents (e.g., metoclopramide, domperidone, erythromycin, cisapride), antiemetics, botulinum injection, or paced gastric neurostimulation (Hasler 2008; Khoo et al. 2009). Metoclopramide is often prescribed but is increasingly recognized as a potential cause of tardive dyskinesia (Kenney et al. 2008). Although counterintuitive, TCAs were noted to be useful in a small group of diabetic patients with chronic vomiting unresponsive to prokinetic agents (Sawhney et al. 2007).

Dyspepsia and Peptic Ulcer Disease

Dyspepsia is characterized by chronic or recurrent pain or discomfort centered in the upper abdomen and may include early satiety and upper abdominal fullness (Talley et al. 2005a). Bloating and nausea also may occur but do not make the diagnosis by themselves (Talley et al. 2005a). *Functional dyspepsia*, as defined by the Rome III criteria, consists of “the presence of symptoms thought to originate in the gastroduodenal region, in the absence of any organic, systemic, or metabolic disease that is likely to explain the symptoms” (Tack et al. 2006b, p. 1466). The annual prevalence of dyspepsia in the United States and other Western countries is approximately 25%; if frequent heartburn is included, prevalence approaches 40% (Talley et al. 2005a). Approximately half of those with dyspepsia seek health care for their symptoms (Tack et al. 2006b).

The four major causes of dyspepsia are peptic ulcer disease, GERD, malignancy, and functional dyspepsia. Peptic ulcer disease is the cause of approximately 10% of all upper GI symptoms, and *Helicobacter pylori* is the main cause of peptic ulcer disease not resulting from NSAIDs (American Gastroenterological Association 2005). As the prevalence of *H. pylori* has dramatically declined in most of the Western world, so has the prevalence of peptic ulcer disease and gastric adenocarcinoma (Talley et al. 2005b). A meta-analysis of risk factors for serious peptic ulcer disease in North America showed that 48% of the risk was attributable to *H. pylori*, 24% was from NSAIDs, and 23% was from cigarette smoking (Kurata and Nogawa 1997). Risk factors differ in different parts of the world (Rosenstock et al. 2003). Tobacco is a risk factor for both gastric and duodenal peptic ulcer, and it delays duodenal ulcer healing (Kato et al. 1992; Reynolds et al. 1994; Rosenstock et al. 2003). Alcohol use in moderation has been shown to have either negligible or even protective effects on risk of peptic ulcer and gastritis, and it may improve or hinder the eradication of

H. pylori, depending on the circumstances (Baena et al. 2002; Namiot et al. 2008; Taylor et al. 2005). Heavy drinking, however, increases the risk of peptic ulcer disease and gastritis (Levenstein 2000).

Evidence suggests an association between psychiatric disorders and increased risk of peptic ulcer disease. An epidemiological study of more than 43,000 subjects showed that all mood and anxiety disorders were significantly associated with peptic ulcer disease (especially generalized anxiety disorder and panic disorder), but alcohol and nicotine dependence mediated a portion of this association but not all of it (R.D. Goodwin et al. 2009). Intellectual and developmental disabilities predispose people to *H. pylori* infection, perhaps as a result of maladaptive behaviors. Their rate of infection is approximately twice that in the general population, and eradication is much more difficult (Kitchens et al. 2007).

Psychological factors have been postulated to play a role in causing peptic ulcer disease since the nineteenth century. Franz Alexander studied psychological factors' influence on GI disorders in the 1930s and included peptic ulcer disease as a classic psychosomatic disease in his 1950 book, *Psychosomatic Medicine: Its Principles and Applications* (Weiner 1991). Since then, numerous studies have confirmed that stressful life events, and perhaps personality characteristics, play a role in peptic ulcer disease (Levenstein 2000; Weiner 1991). Throughout history and in many different countries, both manmade and natural disasters have been associated with spikes in hospitalizations for peptic ulcer (Levenstein 2000). Case-control studies comparing patients with peptic ulcer disease with patients without peptic ulcer disease have noted greater likelihood of neuroticism, anxiety, guilt, stressful life events, and the perception of being under greater stress in reaction to life events in those with peptic ulcer disease (Christodoulou et al. 1983; Feldman et al. 1986). In a classic study, Weiner et al. (1957) successfully predicted which men in a large cohort of army draftees would have duodenal ulcers by combining psychological criteria with the biological criterion of high baseline pepsinogen secretion.

The prospective, longitudinal, population-based Alameda County Study identified various psychological risk factors for peptic ulcer disease, including depression, hostility, and lack of social connectedness (Levenstein et al. 1995). Adjustment for smoking, alcohol use, and other physiological variables weakened but did not eliminate these risk factors (Levenstein et al. 1995). The association between stress and peptic ulcer disease may be mediated by several factors. Lower socioeconomic status predisposes people to both stress and *H. pylori*; painful medical conditions are stressful and are associated with NSAID use; and smoking and heavy alcohol use are common in people ex-

periencing stress. Despite all these potential mediators, a direct link between stress and peptic ulcer disease is still evident (Levenstein 2000).

Sometimes the association between psychological characteristics and peptic ulcer disease does not represent a causal relation (Jess and Eldrup 1994). One prospective case-control study concluded that the anxiety and neuroticism in peptic ulcer disease patients with *H. pylori* were caused by the duodenal ulcer, not vice versa (Wilhelmsen and Berstad 2004).

Given the consistent literature on the role of life stressors, personality, and psychopathology in the pathogenesis of peptic ulcer disease, it is not surprising that psychotherapeutic and psychopharmacological approaches have been investigated for treatment of peptic ulcer disease. Many of these studies were performed in the 1950s–1970s, before acid suppression and *H. pylori* eradication became the standard treatment. Randomized controlled trials of group psychotherapy have not found it helpful (Löf et al. 1987; Wilhelmsen et al. 1994). TCAs were studied in the past and found to decrease gastric acid secretion and improve peptic ulcer healing (Andersen et al. 1984; Ries et al. 1984). Results were not consistent, however, and TCAs are no longer considered first-line therapy for peptic ulcer disease.

Functional Dyspepsia

Up to 70% of patients with dyspepsia have functional dyspepsia, and it negatively affects QOL (Talley et al. 2005b). The underlying pathophysiology remains unclear, but several possible mechanisms have been considered, one of which is hypersensitivity to gastric distention or acid exposure (Talley et al. 2005a). Functional brain imaging studies suggest that in patients with functional dyspepsia with gastric hypersensitivity, actual afferent input to the brain is increased (Vandenbergh et al. 2005; Vandenbergh et al. 2007). Functional brain imaging studies have also shown that the brains of patients with functional dyspepsia are different from those of control subjects at rest. Additionally, they have shown that endogenous pain modulation differs between functional dyspepsia patients and control subjects, regardless of whether patients have visceral hypersensitivity, and anxiety appears to play a role in this pain modulation (Van Oudenhove et al. 2010).

Many studies have shown that comorbidity between functional dyspepsia and psychiatric disorders, especially anxiety disorders, is high. Currently, it is unclear whether this reflects a causal relation between the two, a common predisposition, or anxiety-induced increased health-care-seeking behavior (Tack et al. 2006b). Case-control studies have reported that patients with functional dyspepsia have greater anxiety and depression, higher levels of other psy-

chopathology, increased life stress, and reduced health-related QOL compared with healthy control subjects and duodenal ulcer patients (Haag et al. 2008; Haug et al. 1995). Various psychological factors also have been found to influence functional dyspepsia, such as history of abuse, sleep dysfunction, somatization, and other life stressors (Haug et al. 1995; Gathaiya et al. 2009; Talley et al. 2005a).

In general, both clinicians and questionnaire-based computer models do a poor job of distinguishing between functional and organic dyspepsia; thus, endoscopy must be used to distinguish between the two (Moayyedi et al. 2006). Reassurance and education are often all that are required to treat functional dyspepsia, but management can be difficult and requires frequent follow-ups (Talley et al. 2005a). Patients are often started on drugs that provide acid suppression, but at least 40% of patients fail to respond to medication (Monkemuller and Malfertheiner 2006; Talley et al. 2005b). Of patients with functional dyspepsia, 35% have been found to respond to placebo. Those with stable symptom patterns were less likely to respond, whereas those with inconsistent symptoms were more likely to respond (Talley et al. 2006).

Although psychotherapy and antidepressants are often used to treat functional dyspepsia, the benefits of these approaches are not yet established (American Gastroenterological Association 2005). Some empirical support exists for group therapy that uses relaxation techniques (Bates et al. 1988), cognitive therapy (Haug et al. 1994), psychodynamic-interpersonal psychotherapy (Hamilton et al. 2000), and hypnotherapy (Calvert et al. 2002). However, a Cochrane review including these studies concluded that “there is insufficient evidence to confirm the efficacy of psychological interventions for non-ulcer dyspepsia” (Soo et al. 2005, p. 6). Antidepressants may be prokinetic at the levels of both the enteric and the central nervous systems (Monkemuller and Malfertheiner 2006). However, small randomized controlled trials in healthy volunteers (Bouras et al. 2008; Choung et al. 2008) and patients with functional dyspepsia (Mertz et al. 1998) have provided little support that TCAs or mirtazapine would be helpful in functional dyspepsia, and a larger randomized controlled trial comparing venlafaxine with placebo also was not supportive (van Kerkhoven et al. 2008). The National Institute of Diabetes and Digestive and Kidney Diseases is currently conducting a randomized controlled trial to determine whether amitriptyline or escitalopram is helpful in treating functional dyspepsia. This study also aims to characterize the mechanism by which these medications may work, since gastric emptying, gastric accommodation, and gastric hypersensitivity will be measured (Talley et al. 2010).

Upper Gastrointestinal Bleeding and Serotonergic Medications

Abnormal bleeding associated with SSRIs is thought to be the result of depletion of platelet serotonin. Under normal circumstances, serotonin is released from platelets, promoting platelet aggregation, a necessary step in hemostasis. Because serotonin is not synthesized by platelets, the acquisition of adequate levels of serotonin depends on platelet receptor reuptake from plasma. This process is blocked by SSRIs and possibly by other antidepressants with moderate to high affinity for serotonin receptors (e.g., clomipramine, serotonin-norepinephrine reuptake inhibitors). Several case-control studies have sought to establish a particular link between SSRIs and increased risk of upper GI bleeding (de Abajo and García-Rodríguez 2008; de Abajo et al. 1999; Helin-Salmivaara et al. 2007; Kurdyak et al. 2005; Lewis et al. 2008; Opartny et al. 2008; Schalekamp et al. 2008; Tata et al. 2005; X. Vidal et al. 2008). Despite differences in study design and antidepressants, most studies suggest that there is a two- to threefold increased risk of hemorrhage (Dalton et al. 2006; Loke et al. 2008; Opartny et al. 2008). The absolute effect in healthy adults has been considered to be moderate, comparable with that of low-dose NSAIDs, but the risk is considered significantly greater among patients at increased risk for upper GI hemorrhage (i.e., patients who are elderly or who have concurrent NSAID use, thrombocytopenia, or history of upper GI bleeds) (Weinrieb et al. 2005; Yuan et al. 2006). For these patients, closer monitoring and greater care in selecting antidepressants and NSAIDs are suggested.

Lower Gastrointestinal Disorders

Inflammatory Bowel Disease: Ulcerative Colitis and Crohn's Disease

Inflammatory bowel disease (IBD) is a chronic relapsing and remitting bowel disorder that involves inflammation of the intestinal mucosa. Common symptoms include diarrhea, fever, and abdominal pain but also can involve bleeding, anorexia, weight loss, and fatigue (Irvine 2008). Ulcerative colitis and Crohn's disease are the two forms of IBD, which differ according to the extent of mucosal damage and GI tract involvement. For ulcerative colitis, the mucosal layer from rectum to colon may be affected, whereas Crohn's disease involves transmural inflammation of any portion of the GI tract. Complications of IBD result in bowel obstruction, perforation, malnutrition, fistulas, and ulcerations, along with increased risk for colon cancer.

The peak incidence for IBD onset ranges from ages 15 to 30 years; a second peak for Crohn's disease is between

ages 50 and 80 years. Extraintestinal manifestations of IBD may be present in up to 40% of patients. Most often, this entails musculoskeletal, skin, or eye involvement. Less common is involvement of the cardiac, pulmonary, neurological (i.e., thromboembolism, sensorineural hearing loss), hematological, or renal systems (Williams et al. 2008).

Epidemiology of IBD

The incidence and prevalence of IBD are greatest in developed countries, including the United States, Canada, and Western Europe. In the past, less developed countries showed low incidence and prevalence rates for IBD, but this has changed over the past decade. Eastern Europe, South America, and Asia have shown progressive increases in their incidence of IBD. This increase is thought to be at least partly a result of the changes brought by modernization and development (e.g., diet, hygiene, pathogen exposure). Currently, prevalence rates for IBD range from 37 to 246 cases per 100,000 persons for ulcerative colitis to 26 to 199 cases per 100,000 persons for Crohn's disease (Mikocka-Walus et al. 2008b). Incidence rates for ulcerative colitis vary from 0.5 to 24.5 per 100,000 person-years, and rates for Crohn's disease vary from 0.1 to 16 per 100,000 person-years (Lakatos 2006). In the United States, IBD is estimated to affect approximately 1.5 million people (Shanahan and Bernstein 2009).

Pathophysiology of IBD

The underlying pathophysiology of IBD is not completely understood but appears to involve interactions between genetic, environmental, and immune factors. Approximately 5%–10% of IBD patients have at least one affected first-degree relative, and twin studies report a 50% concordance rate for Crohn's disease among monozygotic twins (Braus and Elliott 2009). In addition, more than 30 susceptibility genes for IBD have been identified (Noomen et al. 2009). Environmental factors also have been linked to IBD, although it is unclear if they affect only individuals already susceptible to IBD. Smoking increases the risk of developing Crohn's disease and worsens the course but serves a protective function in ulcerative colitis (Lakatos et al. 2007; Sainsbury and Heatley 2005). Appendectomies also appear to protect against development of ulcerative colitis in some studies (Andersson et al. 2001). In contrast, acute infectious gastroenteritis may increase the risk of developing IBD (Porter et al. 2008). Recent years have seen an increase in the focus on immune factors and their influence on IBD, with studies suggesting the presence of disruptions in the innate and adaptive immune system leading to altered responses to intestinal flora and chronic inflammation (Braus and Elliott 2009; Noomen et al. 2009).

Stress and IBD

Clinical observations and anecdotal reports have long suggested a relation between stress and IBD. A prospective longitudinal study of 60 ulcerative colitis patients in remission found that the number of stressful life events in the prior month was an independent determinant of time to relapse (Bitton et al. 2003). Another prospective study of 62 ulcerative colitis patients found that those with more long-term perceived stress had significantly increased risk of disease exacerbation (Levenstein et al. 2000). A smaller prospective study noted a significant relation between daily stress and IBD symptoms occurring the following month (Greene et al. 1994). Although these findings suggest a relation between stress and IBD disease activity, results have not been consistent across studies. In particular, studies involving mixed populations of IBD patients have tended to yield negative results, leading some to suggest that there may be enough differences between ulcerative colitis and Crohn's disease that they should not be studied together. Additional studies have failed to establish a relation between stress and IBD onset (Lerebours et al. 2007). Studies that used experimentally induced psychological stress and animal models of colitis have noted the development of altered intestinal mucosal permeability. This is considered the possible mechanism behind stress and increased risk of inflammation or relapse in IBD (Maunder 2005; Mawdsley and Rampton 2005).

Anxiety and Depression in IBD

Given that IBD is a chronic disorder that often involves significant morbidity, impaired functioning, and reduced QOL, the presence of anxiety and depression in this population is not surprising. Disease activity significantly influences the rates of anxiety and depression, which range from 29% to 35% during remission and rise to 80% for anxiety and 60% for depression during relapse (Mikocka-Walus et al. 2007). In general, Crohn's disease patients are considered to have a higher frequency of psychological disturbances than do ulcerative colitis patients (Caprilli et al. 2006; Sainsbury and Heatley 2005). This is thought to be due to the greater level of impairment and disability associated with Crohn's disease.

Some evidence indicates that depression and anxiety affect Crohn's disease. A small prospective study of Crohn's disease patients found that severity of depression was independently associated with current and future disease activity. Higher levels of anxiety also were associated with disease activity but were not independent of the effects of depression (Mardini et al. 2004). Another prospective study of IBD patients (mostly Crohn's disease) in remission re-

ported that baseline depression scores were associated with the subsequent number of relapses and time to first relapse. Anxiety and low health-related QOL also were related to more frequent relapses (Mittermaier et al. 2004). In a study of 100 Crohn's disease patients who received infliximab, the presence of major depressive disorder was found to reduce the chance of achieving remission (Persoons et al. 2005). However, not all studies have confirmed a relation between psychological problems and number of relapses (Mikocka-Walus et al. 2008b).

IBD and Quality of Life

Compared with the general population, the QOL of IBD patients is significantly reduced, during both remission and active disease. Disease activity or severity is the strongest predictor of QOL among IBD patients (Han et al. 2005; Janke et al. 2005; Lix et al. 2008). Comorbid psychiatric disorders, psychological distress, socioeconomic status, educational level, and perceived quality of care also have been found to influence QOL (Irvine 2008; Sainsbury and Heatley 2005; van der Eijk et al. 2004; A. Vidal et al. 2008). Two disease-specific instruments have been developed to measure QOL in IBD patients: 1) the Inflammatory Bowel Disease Questionnaire, which was designed to measure subjective health status and has been well validated and translated into several languages (Guyatt et al. 1989), and 2) the Rating Form for IBD Patient Concerns (RFIPC), which measures psychosocial concomitants to illness, including effect of disease, sexual intimacy, and body stigma (Drossman et al. 1991).

Coping style also appears to influence QOL, as noted in cross-sectional studies of IBD patients. Concerns about disease reflected by the RFIPC total score were strongly influenced by the presence of depressive coping. Depressive coping, which represented a tendency toward irritability, self-pity, musing, and feelings of resignation, had a greater effect than either demographic or disease-related variables (Mussell et al. 2004). Among another group of IBD patients in remission, greater use of reaction formation and higher rates of somatization most closely and independently influenced health-related QOL (Hyphantis et al. 2010). Many IBD patients also have symptoms of functional GI disorders (Barratt et al. 2005; Minderhoud et al. 2004). Their presence has been noted to increase health care use and adversely affect health-related QOL (Farrokhyar et al. 2006). Some studies have noted that these patients experience reduced psychological well-being, with higher levels of anxiety and depression compared with patients with IBD alone (Mikocka-Walus et al. 2008a; Simren et al. 2002; Tanaka and Kazuma 2005).

Psychological and Pharmacological Interventions in IBD

Partly because of the recognition that stress influences IBD disease activity and partly because of reduced QOL in IBD, attempts have been made to use psychotherapeutic approaches to help this patient population. Clinical trials have used a variety of approaches, including short-term psychodynamic psychotherapy, relaxation training, supportive-expressive group therapy, cognitive-behavioral training, and patient education. Despite these efforts, the results have repeatedly failed to show a positive effect on disease activity, but there have been other benefits (von Wietersheim and Kessler 2006). A prospective randomized multicenter study found a trend for reduced hospital days among Crohn's disease patients who had participated in a course of psychodynamic therapy and relaxation training (Deter et al. 2007). Another large study reported significantly fewer hospital visits in IBD patients who participated in a patient-oriented self-management program (A.P. Kennedy et al. 2004). Other studies have reported improvement in depression scores, mental health scale scores of QOL measures, and patient satisfaction (Elsenbruch et al. 2005; Keller et al. 2004; Mussell et al. 2003; von Wietersheim and Kessler 2006; Waters et al. 2005).

Fewer data are available on the effectiveness of psychopharmacological agents in IBD. Case reports and a small open-label study described use of antidepressants for depression, panic disorder, and smoking cessation. Paroxetine, phenelzine, and bupropion were effective agents that also appeared to reduce IBD disease activity (Mikocka-Walus et al. 2006). Remission of Crohn's disease was described with phenelzine and bupropion, the latter of which may lower tumor necrosis factor- α levels (Brustholm et al. 2006; Kast and Altschuler 2005). This effect is similar to that of infliximab, a chimeric monoclonal antibody against tumor necrosis factor- α , which has proven therapeutic effectiveness in IBD. Nevertheless, depression remains undertreated in patients with Crohn's disease (Fuller-Thomson and Sulman 2006).

Irritable Bowel Syndrome

IBS is characterized by abdominal pain relieved by defecation and accompanied by changes in stool appearance or frequency. Efforts to refine the diagnostic criteria for IBS had led to the current Rome III criteria, which reflect the chronicity of symptoms along with the abdominal pain and change in bowel habits (Drossman 2006). Additional symptoms may include flatulence, bloating, stool urgency or straining, and a persistent sensation of incomplete bowel evacuation. IBS can be subdivided according to predominant bowel pattern: diarrhea, constipation, or alter-

nating. Diagnosis is based on symptomatic history without the presence of accompanying alarm symptoms (e.g., fever, weight loss, rectal bleeding) that might reflect a more serious underlying GI condition. Comorbid medical conditions are common among IBS patients and include GERD, functional dyspepsia, chronic pelvic pain, interstitial cystitis, fibromyalgia, headache, backache, and sleep disturbance (Riedl et al. 2008; Talley 2006).

Epidemiology of IBS

IBS is the most common functional GI disorder and affects approximately 10%–15% of the general population. Western countries have a predominance of females with IBS, but this is not seen in Australia or Asian countries (Gwee 2005; Talley 2006). Despite the frequency of IBS, only 10%–25% of individuals seek medical treatment, yet they make up 25%–50% of all gastroenterology referrals. Currently, IBS care is estimated to account for \$20 billion in direct and indirect costs (Brandt et al. 2009). IBS patients consume 50% more health care costs than do matched control subjects and lose an average of 8.5–22 days from work annually (Brandt et al. 2009; Maxison-Bergemann et al. 2006). QOL among IBS patients is significantly impaired compared with that in the general population.

Pathophysiology of IBS

Despite extensive efforts to study the pathophysiology of IBS, the exact mechanism behind the disorder remains unknown. Current evidence suggests a role for various factors, including abnormal GI motility, visceral hypersensitivity, altered stress responses, changes in serotonin signaling, psychological dysfunction, and inflammatory processes. These factors contribute to altered gut function likely via the brain-gut axis, which connects the central nervous system with the enteric nervous system. Interplay between these systems involves bidirectional communication through sympathetic and parasympathetic pathways, the HPA axis, sensory ganglia, and sites in the brain involved with attention, affect, and pain modulation. At present, no pathophysiological abnormalities are considered specific to all IBS patients.

Altered colonic motility has been observed among IBS patients, but motility changes may be present in other areas along the GI tract. Motility changes are not associated with severity of IBS symptoms, however. Autonomic dysfunction has been detected in some IBS patients, with increased sympathetic activity and decreased parasympathetic activity compared with control subjects, along with altered responses to psychological stress (Grover et al. 2009). Visceral hypersensitivity, the predisposition to having an exaggerated response to visceral stimuli, has been noted among

IBS patients, including lower pain thresholds to gut distention (Longstreth and Drossman 2002). Application of various stimuli, including food, stress, or bowel distention, shows altered sensitivity compared with healthy control subjects (Mertz et al. 1995; Murray et al. 2004; Simren et al. 2007). Differences in cortical processing of pain information have been noted in brain imaging studies (Simren et al. 2007). When rectal distention was used as a pain stimulus, IBS patients appeared to have increased cortical activity in the sensory areas, those involved with attention and affect, and subcortical regions associated with affect, arousal, and autonomic responses (Simren et al. 2007).

Among IBS patients, alterations in stress-mediated pathways have been noted in some studies. Increased corticotropin response to corticotropin-releasing factor and stress has been observed, along with changes in the HPA axis during both rest and stressful circumstances (Grover et al. 2009). Serotonin signaling in the gut is important for motility, secretion, vasodilatation, and visceral sensation. Most serotonin present in the gut is located in enterochromaffin cells, and reuptake of serotonin is achieved by serotonin reuptake transporter proteins (SERT). Among IBS patients, release of serotonin, serotonin signaling, and expression of SERT in the colonic mucosa have been reported to be disturbed in several studies (Mawe et al. 2006).

Psychological factors are known to affect the perception of GI symptoms and pain. Dorn et al. (2007) showed that increased colonic sensitivity was strongly influenced by the tendency to report pain and urgency rather than the actual presence of increased neurosensitivity. In the past, psychological factors have been viewed as influencing symptom distress and health-seeking behavior in IBS patients. Recent studies, however, suggest that psychological factors also may contribute directly to the etiopathogenesis of IBS. A population-based study evaluating the relation between psychological stress, fatigue, health anxiety, and illness and subsequent onset of abdominal pain noted an increased risk caused by psychological distress (Halder et al. 2002). Similarly, a large prospective population-based study reported that after results were adjusted for age, gender, and baseline abdominal pain, high levels of illness behavior, sleep problems, and somatic symptoms were independent predictors of IBS onset (Nicholl et al. 2008). Depression was found to be an independent predictor of developing postinfectious IBS in a study comparing patients with healthy control subjects (Dunlop et al. 2003). More life events and higher hypochondriasis scores were highly predictive of postinfectious IBS in another group of patients (Gwee et al. 1999).

Attention to the role of subclinical inflammatory changes in IBS has increased in recent years partly because of the recognition of the comorbidity between IBS and IBD.

High rates of IBS-like symptoms have been reported among IBD patients in remission. Furthermore, it is not uncommon for IBS patients to have a premorbid history of acute bacterial gastroenteritis. Biopsies of GI tract tissue of IBS patients have identified qualitative and quantitative changes in inflammatory cell populations, including T cells, mast cells, and CD3⁺ lymphocytes (Arebi et al. 2008). In addition, blood samples have shown elevated levels of inflammatory cytokines among patients with postinfectious IBS or diarrhea-predominant IBS (Liebrechts et al. 2007).

IBS and Quality of Life

The QOL of IBS patients has been shown repeatedly to be worse than that in the general population. This decrement in QOL is also found when comparing IBS patients with those who have other chronic disorders such as asthma, migraine headache, and GERD (Frank et al. 2002). Even compared with more serious conditions such as diabetes mellitus and dialysis-dependent end-stage renal failure, IBS patients rate their QOL as worse on several factors such as energy level, pain, and role limitations (Gralnek et al. 2000). Studies also have sought to determine which differences among IBS patients influence QOL. Patients who do not seek medical care or are followed up by only primary care providers report better QOL than do those seen in secondary- and tertiary-care centers (Simren et al. 2004). This is consistent with findings that IBS symptom severity plays a significant role in QOL (Coffin et al. 2004; Sabate et al. 2008). The presence of accompanying extraintestinal symptoms (e.g., fatigue, sleep disturbance, sexual dysfunction) and psychological distress (e.g., hypochondriasis, anxiety) also contributes to reduced QOL (Rey et al. 2008; Sabate et al. 2008).

Psychiatric Comorbidity in IBS

The prevalence of comorbid Axis I disorders is estimated to range from 40% to 94% among IBS patients seen primarily in tertiary-care centers. Depression is the most common disorder, followed by anxiety and somatization disorders (Palsson and Drossman 2005). Bidirectional comorbidity exists between anxiety or depression and IBS because elevated rates of IBS have been detected among patients with anxiety and depressive disorders (Karling et al. 2007). Frequently, however, psychiatric disorders predate the onset of IBS symptoms. The presence of anxiety or depression among IBS patients is associated with more severe GI symptoms, greater functional impairment, and worse prognosis (Karling et al. 2007; S. Lee et al. 2009). Compared with IBS patients seen in secondary- or tertiary-care centers, patients who do not seek medical care do not have increased psychiatric comorbidity. However, some studies do show elevated rates of psychiatric disorders among IBS patients

identified in community samples (Osterberg et al. 2000; Whitehead et al. 2002). Somatization disorder has been reported to be present in 25%–33% of IBS patients, with others showing a tendency to somatize (Choung et al. 2009; Whitehead et al. 2002). Differences in coping mechanisms or personality styles also have been noted, with elevated levels of catastrophizing and neuroticism (Palsson and Drossman 2005). Clinicians have long observed that IBS patients often have a history of physical or sexual abuse. The contribution of this abuse history to IBS remains unclear; it may increase vulnerability to anxiety, depression, somatization, or substance abuse; influence pain perception or coping; or promote seeking health care (Spiller et al. 2007). Limited data suggest that reduced pain coping or somatizing behavior may be present among IBS patients with abuse histories (Creed et al. 2005; Ringel et al. 2004).

Psychological Interventions in IBS

Recognition of the interaction between stress, psychopathology, and IBS has spurred studies examining the effects of various psychological interventions on IBS symptoms and QOL measures. Cognitive-behavioral therapy (CBT), psychodynamic therapy, hypnosis, and stress management or relaxation therapy all have been used in various clinical trials. A recent Cochrane review and meta-analysis concluded that evidence indicates that these interventions are superior to usual care or placement on a waiting list but not better than placebo (Zijdenbos et al. 2009). The meta-analysis was hampered by methodological quality, small sample sizes, group heterogeneity, and differences in outcome measures. Additional reviews and one other recent meta-analysis concluded that psychological therapies, particularly CBT and hypnosis, offer benefits for both IBS symptoms and accompanying psychosocial distress (Ford et al. 2009; Tan et al. 2005; Toner 2005; Wilson et al. 2006).

A considerable number of controlled clinical trials have used CBT, whether alone or as part of a more comprehensive treatment approach including other techniques. Among these, the largest and most methodologically sound study compared CBT with education in female patients with functional bowel disorders, including IBS. Outcome was measured with a composite score that incorporated aspects including bowel symptoms, QOL, and patient satisfaction. CBT produced a significantly greater treatment response than did education (70% vs. 37%) and was comparable to the response to desipramine therapy (Drossman et al. 2003). A recent randomized trial included two different versions of CBT, one self-administered and the other therapist-administered. Both forms of CBT were significantly superior to the control condition in the percentage of patients reporting adequate relief and improvement in IBS symptoms (Lackner et al. 2008). The sustain-

ability of symptom improvements may be questionable, however; another study that followed up patients up to 12 months after CBT was added to standard antispasmodic therapy showed waning of improvements at 6 and 12 months (T. Kennedy et al. 2005). Positron emission tomography (PET) scans were used in another study to determine how CBT benefits IBS patients. Reduced baseline activity in the anterior cingulate gyrus and left medial temporal lobe was interpreted as reflecting reduced attention to visceral stimuli (Lackner et al. 2006).

Psychopharmacological Interventions in IBS

A recent systematic review and meta-analysis of both psychological interventions and antidepressants in IBS concluded that both approaches are effective, but the quality of evidence was greatest for antidepressant therapy. The estimated number needed to treat to prevent persistent IBS symptoms was 4 for both types of treatment (Ford et al. 2009). Antidepressants, specifically TCAs and SSRIs, have been used in several clinical trials involving IBS patients. Harris and Chang (2006) suggested that the rationale for trying antidepressants in IBS was threefold: frequent psychiatric comorbidity, central effects on pain modulation, and central or peripheral effects on visceral sensitivity and motor activity.

Most clinical trials that have used TCAs have used low dosages, although the choice of specific TCA has been quite variable (e.g., imipramine, amitriptyline, desipramine, doxepin, trimipramine). Although pooled results involving more than 500 patients in placebo-controlled trials showed significant benefits for IBS, a recent positive clinical trial involving imipramine was hampered by a considerable dropout rate resulting from side effects (Abdul-Baki et al. 2009; Ford et al. 2009). Another study used functional magnetic resonance imaging (MRI) to compare the effects of amitriptyline with those of placebo. Amitriptyline was associated with reduced pain-related activation of the anterior cingulate gyrus and left posterior parietal cortex during mental stress. These were considered areas involved in cognition and affect rather than sensory functions. This study suggested that TCAs work in the central nervous system to blunt pain and other symptoms exacerbated by stress in IBS patients (Morgan et al. 2005). The effectiveness of low-dose TCAs for functional bowel disorders was supported in a post hoc analysis of a randomized, placebo-controlled trial of desipramine. Clinical response to treatment was associated with detectable desipramine blood levels. However, no relation was established between clinical response and total desipramine dose or plasma drug level (Halpert et al. 2005).

Given that serotonin plays a significant role in control of gut function and pain pathways in the peripheral and

enteric nervous systems, along with the presence of abnormal serotonin signaling and release in IBS, the choice of SSRIs is not surprising. Several randomized clinical trials have used paroxetine, fluoxetine, or citalopram. One double-blind randomized, placebo-controlled trial in IBS patients added paroxetine, 10–40 mg, to a high-fiber diet and noted significant improvement in overall well-being (Tabas et al. 2004). Another randomized controlled trial in constipation-predominant IBS patients found that compared with placebo, 20 mg of fluoxetine significantly reduced abdominal discomfort and bloating and resulted in improvements in stool consistency and bowel movement frequency; these benefits were independent of presence of depression (Vahedi et al. 2005). Several other studies did not show improvements in IBS symptoms with SSRIs (Masand et al. 2009; Talley et al. 2008). Differences in methodology, study population, and outcome measures have complicated attempts to compare these studies (Tack et al. 2006a). The evidence is less positive for SSRIs, but they do offer greater tolerability. Clear benefits from noradrenergic-serotonergic agents remains to be seen because a small open-label pilot study of duloxetine in IBS patients without depression was hampered by significant dropout as a result of adverse side effects (Brennan et al. 2009).

Liver Disorders

Hepatitis C

Epidemiology and Treatment of Hepatitis C Virus

Hepatitis C virus (HCV), the second most common blood-borne disease in the world, affects up to 2% of the world's population (Perry et al. 2008). In the United States, HCV is the leading indication for liver transplantation and is responsible for 8,000–10,000 deaths per year (Dienstag and McHutchinson 2006). Long-term consequences of infection include end-stage liver disease and hepatocellular cancer. Chronic HCV infection impairs QOL and may cause cognitive impairment independent of the presence of cirrhosis (Perry et al. 2008). Acute infection is often asymptomatic; therefore, many patients are unaware of being infected until they develop long-term consequences. The surreptitious nature of the disease makes screening patients at high risk for infection especially important. Intravenous drug use remains the greatest risk factor for HCV. Less commonly, transmission occurs by hemodialysis, blood transfusion, perinatal exposure, intranasal drug use, body piercing, tattooing, sexual contact, and receipt of an organ transplant from an HCV-positive donor (Ghany et al. 2009). Transmission via transfusion declined markedly following routine screening for HCV antibodies beginning in 1992.

Higher-than-average prevalence of HCV infection is found in adults with severe psychiatric disorders (Nelligan et al. 2008), whose prevalence is up to 11 times greater than that of the general population and is linked to comorbid substance abuse (Loftis et al. 2006). More than 90% of injection drug users may be infected with HCV. Incarceration, homelessness, HIV infection, and alcoholism are also associated with increased prevalence of HCV infection (Crone et al. 2006; Nyamathi et al. 2002).

Standard treatment for HCV involves the use of pegylated interferon-alpha and ribavirin (IFN therapy) for 24–48 weeks. Treatment response is measured by sustained virological response, and overall response rates are 54%–56%. Adherence to treatment is an important factor in achieving sustained virological response. Maintaining adherence is a challenge given the length of treatment and multiple side effects, including anemia, leukopenia, fatigue, anorexia, insomnia, cognitive impairment, autoimmune thyroiditis, and psychiatric symptoms. Intolerable side effects are a common reason that patients discontinue treatment prematurely. Efforts to optimize adherence through close monitoring and management of troubling side effects are necessary.

IFN-Induced Depression

IFN-induced depression has been reported to occur in 10%–40% of patients, depending on study design, diagnostic criteria, assessment methods, and study population (Schafer et al. 2007). The incidence of depression is also influenced by the dose and duration of IFN therapy. Depressive symptoms usually develop within the first 12 weeks of treatment and are often accompanied by irritability rather than dysphoria. Symptoms usually resolve within a short time after IFN therapy is ended. Because of its effects on treatment adherence, efforts have been made to identify which patients are at greatest risk for IFN-induced depression. Several studies have found that baseline subclinical or clinical depression increases the risk of developing IFN-induced depression (Capuron and Ravaud 1999; Martin-Santos et al. 2008; Raison et al. 2005a, 2005b; Reichenberg et al. 2005). In contrast, a history of depression or other psychiatric disorder has not proved to be a significant risk factor. The mechanism behind IFN-induced depression is unknown but may be linked to its ability to induce production of proinflammatory cytokines (e.g., interleukin-6), alter the serotonergic system, or activate the HPA axis (Asnis and De La Garza 2006; Malek-Ahmadi and Hilsabeck 2007).

Management of IFN-induced depression requires prompt identification, followed by initiation of antidepressant therapy. Prophylactic antidepressant therapy has been considered; most studies report reduced incidence and severity of depressive symptoms (Gleason et al. 2007; Kraus et

al. 2005a; Morasco et al. 2007; Raison et al. 2007). Nonetheless, this approach lacks support for all patients, partly because of the risks associated with antidepressants (e.g., GI hemorrhage). Support does exist for starting antidepressant therapy in patients with baseline subclinical or clinical depression. SSRIs have been the primary choice and have been effective and well tolerated (Kraus et al. 2008; Schaefer et al. 2005). Mirtazapine is an option for patients with marked insomnia and/or anorexia (Crone et al. 2006). Bupropion and venlafaxine are also reasonable options. Psychostimulants are an alternative, especially for patients with severe fatigue and cognitive slowing, but should be avoided in patients who have HCV with a history of substance abuse. Tryptophan as monotherapy or add-on therapy was recently reported as effective for three patients (Schaefer et al. 2008). It is notable that depressive symptoms may not be equally responsive to pharmacotherapy, with fatigue and anorexia less responsive than mood and cognition (Raison et al. 2005a).

IFN-Induced Hypomania or Mania and Psychosis

Reports of mood lability and irritability are not uncommon with IFN therapy, but frank mania is infrequent and usually requires treatment termination. Most often, hypomania or mania appears to develop after weeks or months of treatment, but cases have been reported of mania appearing after marked dose reduction or abrupt discontinuation of IFN (Constant et al. 2005; Malik and Ravasia 2004; Onyike et al. 2004). The course of IFN-induced hypomania or mania is unclear, but most cases report resolution of symptoms after psychotropic medications are started and IFN therapy stopped. Reports of IFN-induced psychosis are rare (Bozikas et al. 2001; Hoffman et al. 2003; Tamam et al. 2003). Most are accompanied by significant mood disturbance. For hypomania, mania, and psychosis, atypical antipsychotics are likely the best option. Mood stabilizers are a consideration, but the risk of lithium-induced hypothyroidism and carbamazepine-induced hematological disturbances requires caution because they may aggravate similar problems caused by IFN therapy.

IFN-Induced Cognitive Impairment

Patients often report cognitive problems during IFN therapy, including difficulties with memory, concentration, and problem solving. IFN affects the frontal-subcortical system, producing problems with working memory and complex attention (Kraus et al. 2005b; Pawelczk et al. 2008; Perry et al. 2008). The effect depends on the dosage, duration, and route of administration of IFN. The means by which IFN causes cognitive dysfunction are unknown, although PET scans have detected hypometabolism in the prefrontal cor-

tex (Juengling et al. 2000). Functional MRI shows activation of the anterior cingulate cortex, which may produce difficulties in error recognition or processing (Capuron et al. 2005). However, some investigators have been unable to identify objective evidence of cognitive impairment and hypothesize that symptoms are only subjective in nature (Fontana et al. 2007). Regardless, cognitive dysfunction appears to be independent of depressive symptoms and normally resolves after IFN is discontinued (Kraus et al. 2005b; Reichenberg et al. 2005). Frank delirium is rare.

IFN-Induced Fatigue

For many patients, fatigue is the most troubling side effect because of its persistence and overall effect on daily function. IFN-induced fatigue may be associated with alterations in the basal ganglia, including the nucleus accumbens and putamen (Capuron et al. 2007). Some patients may benefit from erythropoietin (if anemic) or thyroid hormone supplementation (if hypothyroid). SSRIs may not significantly lessen IFN-induced fatigue, but stimulants such as modafinil might be effective (Martin et al. 2007); however, data are lacking.

High-Risk Populations for IFN Therapy

Because of the need for treatment adherence and the frequency of psychiatric side effects, concerns have been raised about the ability of patients with preexisting psychiatric and/or substance abuse disorders to undergo successful IFN therapy. Fears about their inability to adhere to treatment and potentially higher risk for psychiatric side effects led many to be excluded from treatment. Subsequent studies involving high-risk populations showed that successful treatment was possible, even though some groups noted higher dropout rates and lower rates of virological response (Robaey and Buntinx 2005; Schaefer et al. 2007; Sylvestre and Clements 2007). At this time, most treatment guidelines recommend that high-risk patients be assessed on a case-by-case basis and that treatment involve careful planning and coordination of care between mental health and hepatology providers (Ghany et al. 2009).

Hepatic Encephalopathy

Hepatic encephalopathy is a clinical condition characterized by disturbances of consciousness, mood, behavior, and cognition, which occur in the presence of acute or chronic liver disease. It is estimated to occur in 50%–70% of patients with cirrhosis and varies from mild cognitive impairment to gross confusion and disorientation to coma. The pathophysiology of hepatic encephalopathy is poorly understood but may involve ammonia, astrocyte swelling, and formation of reactive oxygen and nitric oxide species,

all contributing to alterations in brain function (Haussinger and Schliess 2008; Lemberg and Fernandez 2009; Schliess et al. 2009). Other possible contributors include neurosteroids, endogenous benzodiazepine receptor ligands, inflammatory cytokines, manganese, mercaptans, and octanoic acid (Ahboucha and Butterworth 2008; Butterworth 2008; Rovira et al. 2008). Diagnosis of hepatic encephalopathy is by exclusion of other causes of mental status changes in patients with significant liver disease (e.g., infections, substance abuse, intracranial hemorrhage). Psychometric testing (e.g., Digit Symbol, Line Tracing, Trail-Making Tests/Parts A and B) can be helpful, especially when cognitive impairment is subtle (Crone et al. 2006). Electroencephalogram findings usually show generalized slowing; triphasic waves may be present but are not specific to hepatic encephalopathy (Kaplan 2004). Abnormal P300 event-related potentials reflect underlying impairments in cognitive processing (Saxena et al. 2001). Venous ammonia levels are elevated in many, but not all, patients.

Management of hepatic encephalopathy primarily involves correction of precipitating factors (e.g., infection, hyponatremia, acidosis or alkalosis, constipation, psychoactive medications, GI hemorrhage) (Sundaram and Shaikh 2009). Nonabsorbable disaccharides and nonantibiotics are routinely prescribed, but the evidence for efficacy is lacking (Als-Nielsen et al. 2004b). The benzodiazepine receptor antagonist flumazenil also has been used; two systematic reviews of the literature concluded that treatment of hepatic encephalopathy with flumazenil produced significant symptomatic improvement, but the benefit was short-lived, with no significant benefit on recovery or survival, and flumazenil may provoke withdrawal seizures in patients with benzodiazepine dependence (Als-Nielsen et al. 2004a; Goulenok et al. 2002). Other suggested treatments have included L-acetylcarnitine and ornithine aspartate, but evi-

dence is insufficient to recommend their use (Sundaram and Shaikh 2009). See also Chapter 31, "Organ Transplantation."

Psychopharmacology in Liver Disease

In the face of hepatic dysfunction, added care is required when selecting and prescribing psychotropic drugs. No medications are absolutely contraindicated in patients with liver disease, but some carry a greater risk of significant hepatic toxicity (e.g., nefazodone), and some have a narrower therapeutic window (e.g., lithium, clozapine). Patients with liver disease who have hepatic encephalopathy are particularly sensitive to sedative-hypnotics (e.g., benzodiazepines, barbiturates). Hepatic dysfunction alters the absorption, distribution, metabolism, and excretion of most psychotropic agents. However, no specific biochemical test or marker can provide a direct measure of the degree of altered pharmacokinetics present in a selected patient. Rather, the Child-Pugh Scale (CPS) score can be used to provide a rough guideline for dosing medications (Table 20-1) (Albers et al. 1989; Crone et al. 2006). Among patients with CPS score A, mild hepatic failure or cirrhosis, most can tolerate 75%–100% of the usual starting dose of most psychotropic drugs. For patients with CPS score B, moderate hepatic failure or cirrhosis, a 50%–75% reduction in starting dose is warranted, along with smaller incremental dosing to compensate for a prolonged elimination half-life. Patients with CPS score B often can be successfully treated with 50% of the conventional dose of psychotropic medications. Among patients with CPS score C, severe hepatic failure or cirrhosis, cautious dosing and titration are needed, along with careful monitoring for potential drug-induced worsening of cognitive status (Crone et al. 2006; DiMartini et al. 2010). See also "Hepatic Disease" in Chapter 38, "Psychopharmacology."

TABLE 20-1. Child-Pugh Scale

Factor	1 Point	2 Points	3 Points
Serum bilirubin ($\mu\text{mol/L}$)	≤ 34	35–50	≥ 51
Serum albumin (g/dL)	> 3.5	3.0–3.5	< 3.0
Prothrombin time (s)	< 4	4–6	> 6
International normalized ratio (INR)	< 1.7	1.7–2.3	> 2.3
Ascites	None	Slight, medically controlled	Moderate-severe, poorly controlled
Encephalopathy	None	Stage 1–2	Stage 3–4
Total score ^a	5–6	7–9	10–15
Child-Pugh Scale score	A	B	C

^aCombine scores together from all five factors.

Drug-Induced Liver Disease

Drug-induced liver disease spans from mild asymptomatic transaminase elevations to rare cases of fulminant hepatic failure. Most cases are idiosyncratic and therefore unpredictable, are not dose dependent, and develop after a variable time taking the drug in question. Fortunately, liver injury usually resolves after the drug is discontinued, but this may take up to a year. Risk factors for drug-induced liver disease include obesity, malnutrition, genetic polymorphisms, alcohol abuse, and adulthood (Hussaini and Farrington 2007; Navarro and Senior 2006). Women appear to be more susceptible to severe drug-induced liver disease (Hussaini and Farrington 2007). Patients with preexisting liver disease are not clearly at greater risk for drug-induced liver disease but have less hepatic reserve if injury occurs (Russo and Watkins 2004). There are three types of drug-induced liver disease: hepatocellular, cholestatic, and mixed. Hepatocellular damage causes a significant elevation in alanine aminotransferase relative to alkaline phosphatase, whereas the latter is increased with cholestatic injury. Most psychotropic medications present some risk of hepatotoxicity, but the risks are very low (Lucena et al. 2003; McIntyre et al. 2008; Norris et al. 2008). For most patients, routine monitoring of liver function tests while taking a particular drug is not recommended because of the idiosyncratic nature of drug-induced liver disease (Navarro and Senior 2006). Because it is unclear which patients may progress to severe liver injury, suspected medications should be discontinued in patients who develop alanine aminotransferase elevations three times the upper limit of normal, increases in bilirubin or international normalized ratio (INR), or symptoms of hepatic dysfunction (e.g., right upper quadrant pain, dark urine, pruritus, jaundice, nausea, anorexia) (Navarro and Senior 2006).

Pancreatic Disorders

Drug-Induced Pancreatitis

Drug-induced pancreatitis is a rare cause of acute pancreatitis, accounting for only 0.1%–2% of cases among the general population (Dhir et al. 2007). Timely recognition and diagnosis are needed to avoid serious consequences of acute pancreatitis (e.g., chronic pancreatitis, multiorgan failure, death) (Kaurich 2008). Patients with HIV, cancer, and Crohn's disease and those taking multiple medications are at greatest risk for drug-induced pancreatitis (Dhir et al. 2007). Most cases develop within a few weeks to months of starting a particular drug and are not dose related. The mechanism behind drug-induced pancreatitis is unclear (Kaurich 2008). Valproic acid is the psychotropic

drug most often reported in cases of drug-induced pancreatitis, although the true incidence is 1 in 40,000 (Ben Salem et al. 2007; Gerstner et al. 2007; Zaccara et al. 2007). Transient asymptomatic hyperamylasemia, which occurs in 20% of adults taking valproic acid, does not increase the risk for pancreatitis (Zaccara et al. 2007). Rarely, pancreatitis has occurred with other anticonvulsants, including carbamazepine, gabapentin, lamotrigine, and topiramate (Jadresic 1994; Kaurich 2008; Soman and Swenson 1985; Zaccara et al. 2007). Among antipsychotic agents, clozapine and olanzapine have been associated with the most reported cases, fewer with risperidone and haloperidol, and more rarely with the other atypical antipsychotics (Cerulli 1999; Garlipp et al. 2002; Gropper and Jackson 2004; Hanft and Bourgeois 2004; Kahn and Bourgeois 2007; Koller et al. 2003; Reddymasu et al. 2006; Yang and McNeely 2002). Mirtazapine has been associated with several cases of drug-induced pancreatitis, and bupropion, venlafaxine, and SSRIs are occasionally causative agents (Hussain and Burke 2008; Kaurich 2008; Spigset et al. 2003).

Discontinuation of the offending drug usually results in resolution of pancreatitis within 10 days (Dhir et al. 2007). Following an episode of drug-induced pancreatitis, rechallenge with the same drug is discouraged because of the risk of recurrence. Substitution with another drug in the same class is an acceptable alternative (Dhir et al. 2007).

Pancreatic Cancer

Although pancreatic cancer represents only 2% of all cancer diagnoses in the United States, it is the fourth leading cause of cancer-related deaths (Boyd and Riba 2007; Cardenes et al. 2006). Mean survival is 1 year. Physical symptoms resulting from pancreatic cancer, including fatigue, weight loss, pain, and jaundice, tend to develop late (Hochster et al. 2006). As a result, most patients do not receive a diagnosis until they have advanced disease (Cardenes et al. 2006; Thomson et al. 2006). For decades, investigators have noted a higher-than-expected prevalence of depression among pancreatic cancer patients, even when compared with those who have other types of GI malignancies (Boyd and Riba 2007; Carney et al. 2003; Green and Austin 1993; Passik and Breitbart 1996). Furthermore, one-third to one-half of patients experience anxiety and depressive symptoms before receiving the diagnosis of pancreatic cancer (Passik and Breitbart 1996). The factors contributing to the relation between anxiety, depression, and pancreatic cancer are unknown. Various theories have been proposed, including a paraneoplastic syndrome (Makrilia et al. 2009). Pain is a frequent problem among pancreatic cancer patients and is also likely to contribute to depression (Kelsen et al. 1995). See also Chapter 23, "Oncology."

Conclusion

As noted at the beginning of this chapter, GI disorders span several organ systems responsible for helping to maintain physiological homeostasis through assistance with oral intake, digestion, absorption, and metabolism. Disorders affecting these organ systems produce considerable disruption in daily function, productivity, overall health, long-term survival, and QOL. Psychological distress secondary to GI disorders is perhaps not surprising, but it also may precede the onset of a GI disorder and possibly contribute to its development, clinical course, and subsequent treatment response. The effect of psychological factors or distress is particularly notable for functional GI disorders, which lack clear evidence of physiological or structural abnormalities. Increasing evidence indicates a strong link between the brain and the gut that helps to explain this interaction between psychological factors and GI disorders. Psychotherapeutic and psychopharmacological approaches can be beneficial to GI patients, even in the absence of clear psychopathology resulting from the effect on central brain-gut mechanisms.

Renal Disease

Daniel Cukor, Ph.D.

Deborah Rosenthal-Asher, M.A.

Lewis M. Cohen, M.D.

James L. Levenson, M.D.

Paul L. Kimmel, M.D.

IN THIS CHAPTER we summarize the literature on psychiatric issues in chronic kidney disease (CKD) and end-stage renal disease (ESRD), including psychiatric disorders in renal disease patients, social support, sexual dysfunction, adherence, withdrawal from dialysis, renal psychiatric palliative care, psychotherapy and psychopharmacology, psychiatric adverse effects of renal drugs, and drug interactions. Renal transplantation is also discussed in Chapters 31, "Organ Transplantation," and 34, "Pediatrics," and hemodialysis for toxic ingestions is covered in Chapter 37, "Medical Toxicology." Electrolyte disorders are discussed in Chapter 22, "Endocrine and Metabolic Disorders."

As the techniques of dialysis and transplantation have advanced, ESRD patients are living longer, including those with more severe illnesses and comorbidities. As comorbid psychiatric disorders are widely prevalent among dialysis and renal transplant populations, mental health professionals can play a vital role in management, including intervention for mental health difficulties, promotion of compliance, as well as in palliative care for dying patients and those who wish to decline or discontinue dialysis.

Nephrology has recognized the need for psychiatric consultation since the initial development of kidney dialysis in the late 1960s and early 1970s. Nearly universal access to treatment followed passage of the 1972 End-Stage Renal Disease amendment to the Social Security Act, which provided government subsidy for dialysis. Subsequently, the population has steadily grown, aged, and become more se-

verely ill (McBride 1995). Psychiatry's potential role in the collaborative care of patients with renal disease is increasing. Each year, approximately 80,000 Americans develop ESRD. Over 500,000 individuals are treated for ESRD (United States Renal Data System 2009). About 360,000 people are receiving maintenance dialysis, and 120,000 have a functioning kidney transplant. In 2006, the prevalent dialysis population was 354,754 patients (United States Renal Data System 2009). The number of patients starting renal replacement therapy in the United States continues to increase each year by 5%–7%. An additional 8 million individuals are estimated to have earlier stage CKD in the United States (United States Renal Data System 2009). The current annual cost for treating ESRD in the United States is approximately \$21 billion, and the Medicare expenditure is about \$16 billion for hemodialysis and \$2 billion for transplantation (United States Renal Data System 2009).

The major causes of renal failure include diabetes, hypertension, generalized arteriosclerosis, lupus, AIDS, and primary renal diseases, such as chronic glomerulonephritis, chronic interstitial nephritis, polycystic kidney disease, and other hereditary and congenital disorders. In 1999, only 9% of dialysis patients were free of significant comorbid conditions. Of particular importance, diabetes is now found in almost half of ESRD cases. Diabetic patients are especially likely to have increased morbidity because of its plethora of microvascular and macrovascular complications (Lea and Nicholas 2002).

Renal transplantation is the treatment of choice for many patients, and if a transplant is successful, the patient's survival (United States Renal Data System 2009; Wolfe et al. 1999) and quality of life (Franke et al. 2003; Kimmel and Patel 2006; Laupacis et al. 1996) are improved over what they would have been with maintenance dialysis. A major issue in transplantation is the shortage of donor organs. Transplanted kidneys may come from a living donor or through organ donation following death. During the period from 1992 to 2002, the number of cadaveric transplants increased by only 16%, while living-related transplants increased by 68% (United States Renal Data System 2003). Recent data reveal that this trend has reversed, and the overall number of cadaveric kidney transplants decreased 1% and living donor transplants decreased 6% (United States Renal Data System 2009). Despite this, many more transplants are performed with cadaveric kidneys than with living-donor kidneys. More than 18,000 kidney transplants were performed in 2006 (United States Renal Data System 2009). Long-term kidney survival is greater with living donors (D.D. Koo et al. 1999). The critical shortage of cadaveric organs is leading many transplant programs to liberalize their requirements and to make use of kidneys from living unrelated donors, and from donors with more comorbid conditions.

Peritoneal dialysis and hemodialysis are the two forms of dialysis. In peritoneal dialysis, dialysate fluid is introduced and then removed from the peritoneal space through an indwelling catheter. The peritoneum serves as a semipermeable membrane, and fluid and wastes are removed together with dialysate. Peritoneal dialysis may be performed by a machine in the home at night (continuous cycling peritoneal dialysis [CCPD]), or manually at home four to six times per day (continuous ambulatory peritoneal dialysis [CAPD]). Only 8% of ESRD patients use peritoneal dialysis as the initial mode of renal replacement therapy (United States Renal Data System 2009). Hemodialysis may be conducted at the patient's home, but it usually takes place at outpatient dialysis units for 3- to 4-hour sessions typically held three times per week. Home dialysis requires the participation of another person, who must be available to assist with 12–15 hours of weekly treatment. There has been a great deal of recent interest in quotidian dialysis done nightly at home or frequently in a dialysis facility (Lockridge et al. 2001; Pierratos 2004). Data from uncontrolled studies suggest that this new approach may result in improved quality of life and health. Although patients have not been randomized to dialysis modalities, patients receiving peritoneal dialysis rate their care higher than do those receiving hemodialysis (Rubin et al. 2004).

Psychiatric Disorders in Renal Disease

In a study of psychiatric illness involving 200,000 U.S. dialysis patients, almost 10% had been hospitalized with a psychiatric diagnosis. A psychiatric syndrome was the primary reason for hospitalization of 25% of the subgroup (Kimmel et al. 1998b). Depression and other affective disorders were the most common diagnoses, followed by delirium and dementia. In a smaller scale study in an urban hemodialysis population, roughly 70% of the sample had at least one current Axis I diagnosis, as determined by the Structured Clinical Interview for the DSM (SCID) (Cukor et al. 2007). Depression and anxiety were the two most prevalent psychiatric disorders, followed by substance abuse and psychosis. Compared with other medical illnesses, the primary diagnosis of depression was more frequent in renal failure patients than in those with ischemic heart disease and cerebrovascular disease (Kimmel et al. 1998b).

Depression

Early studies of depression in ESRD reported prevalence rates ranging from 0% to 100%, reflecting widely variable definitions, criteria, and measurement methods (see recent review by Cukor et al. 2006). In the nephrology literature, there is a lack of clarity around the term depression and whether it refers to the affective symptom or the psychiatric disorder (L. Cohen 1996). In addition, the evaluation of depression is complicated by the fact that many of the somatic signs and symptoms of ESRD are very similar to signs of depression. Many uremic patients have diminished appetite, loss of energy, poor sleep, and diminished sexual interest (Kimmel 2002; Kimmel et al. 2007; Meyer and Hostetter 2007).

A variety of techniques have been used to improve the diagnostic accuracy of depression in patients with renal disease. Some ESRD research studies have relied exclusively on self-report instruments that determine the severity of the symptom, but have adjusted the scoring of the measure to account for somatic complaints (Craven et al. 1988; Kimmel et al. 1993; Smith et al. 1985). Other studies (Cukor et al. 2007; Finkelstein and Finkelstein 2000; Hedayati et al. 2006; Watnick et al. 2003) have combined self-report measures with a structured diagnostic interview based on DSM-IV-TR (American Psychiatric Association 2000) criteria or have used multiple measurement points across time (Boulware et al. 2006; Cukor et al. 2008b; Kimmel et al. 2000). There has been much less study of depression in patients with CKD before initiation of dialysis, but screening instruments have recently been validated in this population (Hedayati et al. 2009b).

Studies that have adjusted self-report measures to account for the somatic complaints of renal disease patients have generally produced consistent results across diverse racial samples. In a group of white Canadian hemodialysis patients, Craven et al. (1988) found that a Beck Depression Inventory (BDI) score of 15 or greater, as compared with the standard 10, had better sensitivity and specificity for the diagnosis of major depression in dialysis patients when the Diagnostic Interview Schedule (DIS) was utilized as the criterion for the diagnosis. Kimmel and colleagues (Kimmel 2001; Kimmel et al. 1996, 1998a) studied primarily African American ESRD patients in hemodialysis centers in Washington, DC. They found that about half of the patients scored greater than 10 on the BDI. When the more conservative cutoff of 15 was employed, about 25% of the patients screened positive (Kimmel et al. 2000).

One study (Watnick et al. 2005) validated the BDI and the Patient Health Questionnaire-9 (PHQ-9) against SCID-diagnosed major depressive disorder and found that the optimal cutoff value was 16 for the BDI and 10 for the PHQ-9. Another study (Hedayati et al. 2006) compared the BDI and the Center for Epidemiologic Studies Depression Scale (CES-D) against the SCID in ESRD patients. The prevalence of major depression was 27% in their sample of ethnically diverse patients, including one-quarter of the subjects who were veterans. A BDI cutoff score of 14 and a CES-D score of 18 had the most predictive value. These studies indicate an emerging consensus that there is agreement between the BDI and clinician-administered diagnostic tools and that a BDI score of 14–16 is indicative of major depression in chronic hemodialysis patients. Recent data indicate that the prevalence of major depression is about 20% in CKD patients (Hedayati et al. 2009a).

Depression in patients with ESRD is a strong predictor of worse medical outcomes. Using time to death or hospitalization, Hedayati et al. (2008) found the diagnosis of major depression to be associated with a hazard ratio of 2.07 compared with nondepressed control subjects, after adjustment for other variables. Kimmel et al. (2000) found that tracking multiple measurements of depression produced a more robust association with mortality than any single measurement. Similarly, Boulware et al. (2006) demonstrated that associations with outcomes existed with multiple measurements of depression that did not exist with baseline data. Cukor et al. (2008b) reassessed SCID-diagnosed depressed and anxious ESRD patients after 16 months and noted a variety of clinical trajectories. The persistent course of depression was associated with significantly lower quality of life and more reported health problems compared with intermittent depression. These data suggest that a single measure of depression at a specific point in time might not be as meaningful as assessment of

depression over a longer time span. Despite the high prevalence of depression in dialysis patients, there has been little study of the effectiveness of antidepressants. Selective serotonin reuptake inhibitors (SSRIs) are widely prescribed for depression in ESRD patients, but only two small short-term randomized controlled trials have shown some benefit of paroxetine (J.R. Koo et al. 2005) and fluoxetine (Blumenfeld et al. 1997).

In addition to pharmacotherapy, psychotherapy is an appropriate intervention for depressed ESRD patients, but there are no reported controlled clinical trials of psychotherapy for depression specifically in renal patients (Rabindranath et al. 2005). Despite this lack of evidence, there are indications that psychotherapy, including cognitive-behavioral therapy (CBT), may be an effective intervention strategy (Cukor 2007). Cukor et al. (2007) found higher levels of depressogenic cognitive distortions in SCID-diagnosed depressed hemodialysis patients compared with nondepressed control subjects. One study in which renal transplant recipients were randomly assigned to either individual or group psychotherapy and compared with usual-care patients (Baines et al. 2004) showed that both individual and group psychotherapy were successful in reducing depressive symptoms.

Anxiety

Anxiety is a complicating comorbid diagnosis for many medical illnesses and often co-occurs with depression in ESRD populations (Cukor et al. 2007, 2008a, 2008b). There is relatively little anxiety research specific to ESRD patients, but it appears that an anxiety diagnosis is associated with diminished quality of life (Cukor et al. 2008a; Sareen et al. 2006). One early study (Nichols and Springfield 1984) found that about one-third of patients experienced episodes of moderate anxiety during their first year of dialysis treatment. In a study that assessed psychiatric diagnoses in a sample of 70 predominately African American ESRD patients, about 45% had at least one anxiety disorder. The most common diagnoses identified were phobias and panic disorder (Cukor et al. 2008a). The prevalence of panic disorder was much higher than in community samples and may be related to hypervigilance to bodily sensations associated with hemodialysis or fears about the outcome of ESRD treatment.

Traumatic stress symptoms related to dialysis experiences, serious medical events, or other traumas are also common among hemodialysis patients (Tagay et al. 2007). Phobias to needles or the sight of blood are common in the general population (see Chapter 11, "Anxiety Disorders"), and such phobias are among the most commonly reported reasons that hemodialysis patients do not choose in-center dialysis instead of self-care treatment (McLaughlin et al.

2003). There are no published clinical trials of psychopharmacology or psychotherapy for anxiety in patients with ESRD and very few case reports regarding anxiety in this population.

Substance Abuse

Substance use disorders, such as cocaine or heroin dependence, can lead to CKD (Jaffe and Kimmel 2006; Norris et al. 2001). Substance use may also result in HIV infection, which can secondarily cause renal failure (Kimmel et al. 2003). In a sample of 145 hemodialysis patients, Hegde et al. (2000) found 28% to have difficulty with chronic alcoholism (Hegde et al. 2000). Those who abused alcohol had poorer nutrition than nonabusers, as demonstrated by serum albumin measurements. Another study found cocaine users to be less compliant with their dialysis attendance than nonusers (Obialo et al. 2008). Although additional research is needed regarding substance abuse and dialysis, substance abuse should be taken seriously and addressed with specialist care.

The Disruptive Dialysis Patient

To function well, dialysis units depend on the ability of their staff to provide appropriate patient care. There has been an increase in the number of reported disruptive patients within dialysis units (Hashmi and Moss 2008). Disruption on the unit may impact the individual, as in the case of noncompliance with treatment. A patient's disruptive behavior may also affect other patients receiving dialysis therapy. A disruptive patient may harm others by coming late to appointments, thus disrupting dialysis scheduling for others, or by threatening the staff (Hashmi and Moss 2008).

Withholding dialysis treatment from a disruptive patient must be carefully considered. While all patients should be treated equally and with respect, the balance between the welfare of a disruptive patient and the welfare of health care personnel or other patients should be maintained. If disruptive behavior affects only the patient him- or herself, the individual should not be refused dialysis treatment. For example, treatment cannot be denied to a patient who is noncompliant with his or her medical regimen but continues to want dialysis. For a disruptive patient who continually shows up late to appointments and does not abide by rules of the unit, moving the individual to a different shift or unit could be considered (Hashmi and Moss 2008). Verbal or physical abuse on the unit should not be tolerated, and the welfare of staff and other patients should not be compromised.

Suggested strategies for dealing with disruptive patients include attempting to first create a calm environment, approaching the patient directly about his or her be-

havior, using reflective listening techniques to help the patient feel understood, attempting to understand the reasons for the individual's responses and behavior, outlining specific goals the patient has for treatment, educating the patient about consequences that may result from his or her behavior (ideally through a behavioral contract), and referral to a skilled team member such as a psychologist or social worker (Goldman 2008; Hashmi and Moss 2008; Sukolsky 2004). Two helpful resources addressing dialysis-related disruptive behavior and conflict resolution are the Renal Physicians Association's "Clinical Practice Guideline on Shared Decision-Making in the Appropriate Initiation of and Withdrawal From Dialysis" (Galla 2000) and the Decreasing Dialysis Patient/Provider Conflict (DPC) project (see review by Goldman 2008).

Cognitive Disorders

Cognitive disorders are common in the ESRD patient population (Murray et al. 2006) and may be related to uremia, a variety of medical comorbidities (e.g., electrolyte disturbances, severe malnutrition, impaired metabolism, cerebrovascular disease), or adverse effects of treatment. Uremia is a clinical syndrome resulting from profound loss of renal function and has been associated with cognitive impairment, including difficulty with concentration, memory, and intellectual functioning (Pliskin et al. 1996; Souheaver et al. 1982; Williams et al. 2004). Signs and symptoms of uremia vary considerably, with severity presumably depending on both the magnitude and speed with which renal function is lost. Central nervous system symptoms may begin with mild cognitive dysfunction, fatigue, and headache, progressing to hypoactive delirium and, if untreated, coma. Restless legs syndrome, muscle cramps, and sleep disorders are also common in uremic patients (see Chapter 15, "Sleep Disorders"). Other common symptoms include pruritus, anorexia, nausea, and vomiting (Haddy et al. 2008; Meyer and Hostetter 2007; Weisbord et al. 2003). Anemia is another potential risk factor for compromised cognitive functioning in patients with kidney disease (Pereira et al. 2005). Reduced oxygen availability secondary to anemia may decrease cognitive function, especially in patients with other neurological or cerebrovascular diseases (Johnson et al. 1990).

The rate of cognitive decline and its relationship to CKD have not been well delineated. Kurella et al. (2004) assessed cognitive functioning in a sample of 80 CKD patients not requiring dialysis and 80 ESRD patients receiving hemodialysis. An association between stage of CKD and degree of cognitive impairment was found on measures of mental status, executive functioning, and verbal memory. Another study (Elias et al. 2009) also found an association between CKD severity and cognitive impair-

ment. CKD patients with lower renal function as well as those with higher creatinine demonstrated decreased performance on visuospatial processing, attention, and planning abilities.

Dementia has been identified as a mortality risk factor in ESRD. Hypertension and diabetes, both highly prevalent among ESRD patients, are known risk factors for the development of dementia (Saczynski et al. 2008; Semplini et al. 2006). One large study of hemodialysis patients (Kurella et al. 2006) found a 4% prevalence of dementia in the overall sample. Individuals diagnosed with dementia had a 1.48 times greater risk of death than those not diagnosed with dementia. Furthermore, those who were diagnosed with dementia were twice as likely to withdraw from treatment. Consistent with findings in the general population, age, race, education, diabetes, and cerebrovascular disease were found to be related to dementia.

Dialysis itself has been implicated as a causal factor in the dementia-like memory deficits observed in some patients. Dialysis dementia, or dialysis encephalopathy, is a distinct, progressive neurological disorder whose etiology remains controversial (Fraser and Arieff 1988). Not uncommon 30 years ago, it is now rare. Signs have included memory impairment, dysarthria, stuttering speech, depression, psychosis, asterixis, bizarre limb movements, and generalized tremulousness.

The wide use of recombinant human erythropoietin has improved many of the negative cognitive consequences previously associated with chronic anemia. Maintaining an optimal level of cognitive function is important for quality of life and is a prerequisite for successful adaptation to dialysis.

Social Support

ESRD patients can receive social support from family, friends, and individuals on the dialysis unit (e.g., physicians, social workers, nurses, other patients). Increased levels of social support may positively impact outcomes through various mechanisms, including decreased levels of depressive affect, increased patient perception of quality of life, increased access to health care, increased patient compliance with prescribed therapies, and physiological effects on the immune system (S.D. Cohen et al. 2007b). Higher levels of perceived social support are thought to have a positive influence on health outcomes, utilization of health care services, and compliance. Previous research has demonstrated that social support is related to improved health outcomes and lower mortality for ESRD patients (Christensen et al. 1994; S.D. Cohen et al. 2007b; Kimmel et al. 1998a; McClellan et al. 1991, 1993).

Sexual Dysfunction

The impact of hemodialysis on both male and female sexual functioning is well documented (Levy and Cohen 2001) but often not discussed openly with patients. One recent study reported that 43% of ESRD patients reported having a decreased interest in sex and 47% reported trouble getting aroused (Abdel-Kader et al. 2009). The relative roles of physical dysfunction, medical illness, medication effects, and psychological function in inducing sexual dysfunction in CKD patients have not been determined. A review by Palmer (2003) noted similarly high rates of sexual dysfunction in men and women with ESRD. The first line of treatment for sexual dysfunction is typically sildenafil, which appears to be safe in ESRD patients if they do not have contraindications to treatment (Palmer 2003; Seibel et al. 2002; Zarifian 1999). The subject of sexual performance is often sensitive, and both the patient's and the doctor's perceptions can be influenced by the interplay of cultural, age, gender, racial, religious, and emotional factors (see also Chapter 16, "Sexual Dysfunction").

Treatment Adherence

Clinical and behavioral indices of adherence in dialysis patients include dialysis attendance, interdialytic weight gain, and medication adherence. Lack of adherence to treatment regimens is believed to be a common cause of inadequate dialysis and poor outcome (Kaveh and Kimmel 2001). Many factors may contribute to nonadherence, including depression, anxiety, cognitive dysfunction, personality, the doctor-patient relationship, and financial difficulties. The rate of nonadherence among dialysis patients varies by country as well (Bleyer et al. 1999; Hecking et al. 2004). Common noncompliant behaviors include skipping or missing dialysis sessions and engaging in dietary and medication indiscretions. According to self-reports, 12% of dialysis patients miss one peritoneal dialysis exchange per week, and 5% skip two to three exchanges per week (United States Renal Data System 2009). To maintain optimal health, ESRD patients must adhere to their prescribed treatments. Patients are prescribed regimens for their medications, diet, fluid intake, exercise, medical appointments, and dialysis attendance. Measures of behavioral compliance are clinically meaningful and associated with hard outcomes (Kimmel et al. 1995, 1998a; Leggat 2005). A recent study that examined medication adherence in ESRD found that 37% of hemodialysis patients reported less than perfect adherence to the medication regimen and that increased depressive affect was associated with decreased medication adherence (Cukor et al. 2009). Because

adherence was self-reported, the data may be an underestimation of the actual level of adherence, demonstrating the great need for addressing this issue in this population. Another study found that the median daily pill burden of an ESRD cohort was 19. In one-quarter of the subjects, it exceeded 25 pills per day. Phosphate binders accounted for about one-half of the daily pill burden, and 62% of the participants were noncompliant with the prescribed phosphate binder therapy (Chiu et al. 2009). A recent systematic review of studies of adherence to prescribed oral medications in adult chronic hemodialysis patients found that more than half of the included studies reported nonadherence rates of 50% or more, with a mean of 67% (Schmid et al. 2009).

The development of interventions to target adherence in this population is increasingly gaining attention in the literature. Some of these interventions are educational in nature, attempting to increase knowledge of the importance of adherence and the consequences of noncompliance. However, the efficacy of educational interventions that target adherence is questionable. One study found that the hemodialysis patients who demonstrated better knowledge about the importance of monitoring phosphorus levels in their dietary regimens were *less* compliant, as measured by biomarkers and interdialytic weight gain (Durose et al. 2004). Other interventions introduce psychological techniques such as CBT, social skills training, self-monitoring, and behavioral reinforcement to increase adherence (Nozaki et al. 2005; Sharp et al. 2005b; Tsay and Lee 2005). In a small randomized controlled trial of CBT to increase fluid adherence in hemodialysis patients, results demonstrated an increase in fluid adherence (as measured by interdialytic weight gain) at 10 weeks postbaseline (Sharp et al. 2005a). Another small study (Christensen et al. 2002) compared levels of adherence in hemodialysis patients who participated in a 7-week behavioral self-regulation intervention and matched control hemodialysis patients. The study showed that the intervention patients had higher adherence (as measured by interdialytic weight gain) 8 weeks after completing the intervention compared with the control patients. These studies suggest the potential value of implementing interventions to target adherence, but the studies to date have been small and of short duration and have had bias-prone study designs (Sharp et al. 2005b).

Withdrawal From Dialysis

Withdrawal from dialysis can be viewed as part of the life cycle of the ESRD patient and part of the dying process. In the United States, dialysis withdrawal has been more common among women and older patients and less common

among African American and Asian patients (Kurella Tamura et al. 2010; Leggat et al. 1997; Munshi et al. 2001). Cognitive impairment has also been associated with the decision to withdraw (Chater et al. 2006).

The topic of dialysis withdrawal is commonly approached in the assessment of patient quality of life versus quantity of life (Hackett and Watnick 2007). Reasons for the decisions of individuals who choose not to initiate or continue dialysis have included concerns about being a burden to family members and mistrust of medical treatment (Ashby et al. 2005). However, withdrawal from dialysis is often appropriate for the dying dialysis patient. Many patients and families choose this option because it allows for a quicker death and the end of a patient's suffering (L.M. Cohen and Germain 2005; L.M. Cohen et al. 2003). The median time to death after stopping dialysis is 8 days (Catalano et al. 1996), and dialysis termination usually does not cause pain or discomfort (L.M. Cohen et al. 2000). Withdrawal typically results in lethargy progressing to coma and death. Psychiatrists can assist with determinations of patient capacity and the potential influence of depression or other psychosocial factors. One study that controlled for biomarkers and age found depression to be a unique predictor of withdrawal from dialysis treatment (McDade-Montez et al. 2006). Suicidality is a symptom of depression; thus, for a patient who is experiencing severe depression, the decision to withdraw from treatment should be postponed (Russ et al. 2007).

Renal Palliative Care

In providing better end-of-life care for this very ill population, L.M. Cohen et al. (2005) have advocated that attention be focused on the following issues:

1. *Early frank discussions concerning prognosis and goals of care*—Ideally, these discussions should include the family and should begin when options for care are discussed. The possibility of not starting dialysis, especially if the burdens of dialysis might outweigh the benefits, should be considered. Patients should also know that they have the option of stopping dialysis if their quality of life diminishes. Written advance directives can help focus the discussion, and do-not-resuscitate orders should be strongly considered when cardiopulmonary resuscitation is likely to be futile (Moss 2000).
2. *Attention to symptoms at all stages of the disease process*—Patients with ESRD have a high burden of symptoms, related to dialysis and their comorbid conditions (L.M. Cohen and Germain 2005; Weisbord et al. 2008).

3. *Early hospice referrals*—Such referrals can take place in the hospital, home, nursing home, or inpatient hospice unit. All patients who terminate dialysis should be offered referral to hospice.
4. *Maximal palliative care at the end of life*—This care includes aggressive pain control, spiritual and emotional support, and attention to the patient's terminal treatment preferences and goals. Utmost sensitivity is needed in making decisions about withholding or discontinuing care, and one needs to be alert to cultural biases, countertransference, and other complicating factors (Moss 1998, 2000). In a survey of American nephrologists, nearly 90% reported withholding dialysis at least once in the previous year, and more than 30% reported withholding it at least six times (Moss 2000; Singer 1992).

Psychotherapy in Dialysis Patients

As noted earlier in this chapter, there have been no randomized controlled trials of psychotherapy for depression in ESRD patients. Most trials of psychological intervention have aimed to improve adherence (see "Treatment Adherence" above). There are other recent small randomized controlled trials in dialysis patients showing that group therapy can improve quality of life (Lii et al. 2007) and that CBT can improve sleep disturbance (Chen et al. 2008). Although individual and group psychotherapies have been considered very helpful in ESRD for many years, the evidence base supporting such interventions remains very limited.

Psychopharmacology in Renal Disease

Antidepressants

Among the SSRIs, citalopram and sertraline would be expected to have the fewest potential interactions with other medications taken by patients with renal impairment. Paroxetine clearance is reduced in patients with renal insufficiency (Doyle et al. 1989). Some evidence suggests that dosage adjustments may not be needed for citalopram (Spigset et al. 2000) and fluoxetine (Finkelstein and Finkelstein 2000) in patients with renal insufficiency. While the longest experience has been with the tricyclic antidepressants (TCAs), patients with ESRD, especially those with diabetes, are often more sensitive to the side effects of TCAs. Hydroxylated metabolites of TCAs may be markedly elevated in patients with ESRD and responsible for some TCA side effects. Nortriptyline and desipramine are the preferred TCAs in renal failure because they are less likely to cause anticholinergic effects or orthostatic hypo-

tension than other TCAs (Gillman 2007). Limited data are available on the use of newer antidepressants in patients with renal failure. The half-life of venlafaxine is prolonged in renal insufficiency; its clearance is reduced by over 50% in patients undergoing dialysis (Troy et al. 1994). Desvenlafaxine undergoes significant renal elimination requiring dosage reduction in moderate to severe renal impairment. Because antidepressants are typically metabolized by the liver and those metabolites are excreted by the kidney, it seems prudent to initially reduce the dose for all antidepressants to minimize the potential accumulation of active metabolites (S.D. Cohen et al. 2007a). Ordinary dosages however are frequently required in ESRD patients and are usually well tolerated.

Antipsychotics

Antipsychotics typically do not depend on renal elimination, with the exception of paliperidone, which is largely excreted unchanged in urine and thus requires dose reduction in patients with renal insufficiency (Vermeir et al. 2008). As with TCAs, adverse effects of antipsychotics may be amplified by medical comorbidities in ESRD patients, such as diabetes, hyperlipidemia, and cerebrovascular disease.

Anxiolytics and Sedative-Hypnotics

No clinical trials of pharmacotherapy for anxiety in ESRD patients have been published. The preferred benzodiazepines are those with inactive metabolites (e.g., lorazepam, oxazepam). Even so, the half-lives of lorazepam and oxazepam may rise significantly in patients with ESRD, and dosage reduction is required.

Mood Stabilizers

Lithium is almost entirely excreted by the kidneys. It is contraindicated in patients with acute renal failure. Some clinicians consider lithium relatively contraindicated in patients with stable renal insufficiency. If used, lithium should be conservatively dosed while monitoring renal function frequently. Despite these cautions and lithium's possible nephrotoxicity (discussed under "Renal Effects of Psychotropics" later in this chapter), there are some bipolar patients who do not respond to or tolerate the alternative mood stabilizers; for these patients, lithium is the only effective drug. Lithium is completely dialyzed and may be given as a single oral dose (300–600 mg) following hemodialysis treatment. Lithium levels should not be checked until at least 2–3 hours after dialysis because re-equilibration from tissue stores occurs in the immediate postdialysis period. The dose of gabapentin, pregabalin, lithium, and topiramate should be modified based on creatinine clearance (Ferrando et al. 2010).

Cholinesterase Inhibitors and Memantine

While the data are limited, dosage adjustment of donepezil and rivastigmine is probably unnecessary. Galantamine should be used cautiously in patients with moderate renal insufficiency and is not recommended in patients with severe renal insufficiency. Memantine requires dosage reduction in patients with severe renal insufficiency (Ferrando et al. 2010).

Renal Effects of Psychotropics

The syndrome of inappropriate antidiuretic hormone secretion (SIADH), resulting in hyponatremia, may be caused by many psychotropic drugs, especially carbamazepine and oxcarbazepine, but also SSRIs, TCAs, and antipsychotics. Hyponatremia due to nephrogenic diabetes insipidus (NDI) may be caused by lithium through inhibition of renal tubular water reabsorption. Most patients receiving lithium have polydipsia and polyuria, reflecting NDI. Lithium-induced NDI varies from mild polyuria to hyperosmolar coma, and sometimes has persisted long after lithium discontinuation. Amiloride is considered the treatment of choice for lithium-induced NDI, but it also has been treated with nonsteroidal anti-inflammatory drugs (NSAIDs), thiazides, and sodium restriction (Grunfeld and Rossier 2009). Some studies report that longer duration of lithium therapy is predictive of a decrease in estimated glomerular filtration, while others do not. Although chronic lithium use may result in nephropathic changes in 10%–20% of patients, including interstitial fibrosis, tubular atrophy, urinary casts, and, occasionally, glomerular sclerosis (Bendz et al. 1996), these histological changes are often not associated with impaired renal function. Progression of lithium nephrotoxicity to ESRD is rare (0.2%–0.7%) and requires lithium use for many years (Presne et al. 2003). Other factors besides lithium use that may contribute to such changes include age, episodes of lithium toxicity, other medications (analgesics, substance abuse) and the presence of comorbid disorders (hypertension, diabetes). Lithium nephrotoxicity is not strongly dose related (Freeman and Freeman 2006). One recent meta-analysis concluded that any lithium-induced effect on renal function is quantitatively small and probably clinically insignificant (Paul et al. 2009) and considered acceptable with yearly monitoring of renal function.

Urological Effects of Psychotropics

Drugs with significant anticholinergic activity, such as TCAs and antipsychotics (both low-potency typical agents and atypical agents), frequently cause urinary retention. Less commonly, urinary retention has been reported to occur with SSRIs, serotonin–norepinephrine reuptake inhib-

itors (SNRIs), and bupropion. Urinary incontinence and other lower urinary tract side effects are very common with clozapine (Jeong et al. 2008). Sexual side effects of psychotropic drugs are reviewed in Chapter 16, “Sexual Dysfunction.”

Psychiatric Adverse Effects of Renal and Urological Agents

Anticholinergic agents commonly used to treat overactive bladder are associated with psychiatric adverse effects including cognitive impairment, confusion, fatigue and psychosis. Mild cognitive impairment was found in 80% of elderly patients receiving anticholinergics (Ancelin et al. 2006). Thiazide diuretics are a common cause of hyponatremia, which when severe can cause lethargy, stupor, confusion, psychosis, irritability, and seizures. The risk is increased further if the patient is also taking a psychotropic drug that causes hyponatremia, such as an SSRI (Rosner 2004) or carbamazepine (Ranta and Wooten 2004). Psychiatric adverse effects of other medications frequently used to treat patients with renal disease are covered elsewhere in this book: corticosteroids for autoimmune nephritis (Chapter 25, “Rheumatology”), antihypertensives (Chapter 18, “Heart Disease”), and immunosuppressants after renal transplant (Chapter 31, “Organ Transplantation”).

Drug–Drug Interactions

A number of pharmacodynamic and pharmacokinetic drug interactions frequently occur between drugs prescribed for renal and urological disorders and psychotropic drugs. Anticholinergic side effects will be increased if anticholinergic psychotropic drugs are given to patients taking urinary antispasmodics. Like other anticholinergics, antispasmodics may block the benefits of cholinesterase inhibitors. As noted above, the hyponatremic effects of thiazide diuretics may be enhanced in combination with oxcarbazepine and carbamazepine, and to a lesser degree with SSRIs, TCAs, and antipsychotics (Ranta and Wooten 2004; Rosner 2004).

Diuretics variably affect lithium excretion, depending on the type of diuretic and the volume status of the patient. Thiazide diuretics may reduce lithium excretion, resulting in increased lithium levels. Acute administration of loop diuretics (e.g., furosemide, ethacrynic acid, bumetanide) increases lithium excretion causing a drop in lithium levels, but with chronic use, compensatory changes leave lithium levels somewhat unpredictable but usually not significantly changed. Carbonic anhydrase inhibitors (e.g., acetazolamide) and osmotic diuretics (e.g., mannitol) reduce lithium levels (Ferrando et al. 2010). Potassium-

sparing diuretics (amiloride, triamterene, spironolactone) may increase lithium excretion. Furosemide and amiloride are considered to have the least effects on lithium excretion (Ferrando et al. 2010).

Endocrine and Metabolic Disorders

Ann Goebel-Fabbri, Ph.D.

Gail Musen, Ph.D.

James L. Levenson, M.D.

THE ONSET, COURSE, AND OUTCOMES of endocrine disorders traditionally have been linked to psychological and social factors. A growing body of neuroendocrine research has begun to illuminate important biological mechanisms underlying the interplay of psyche and soma, and there are important clinical ramifications of these connections. In this chapter, we focus primarily on these latter pragmatic issues. Diabetes mellitus is the most common endocrine condition and is now growing in epidemic proportions, so it has been given major emphasis. Other topics covered include disturbances in thyroid, parathyroid, adrenal, growth, prolactin, and gonadal hormones; pheochromocytomas; and metabolic disorders including electrolyte and acid-base disturbances, vitamin deficiencies, osteoporosis, and inherited disorders including the porphyrias.

Diabetes

Type 1 Diabetes

Type 1 diabetes is a chronic autoimmune disease that affects an estimated 500,000 to 1 million people in the United States. It is most commonly diagnosed in children and young adults, with peak onset occurring during puberty (i.e., ages 10–12 in girls and 12–14 in boys). (See also Chapter 34, “Pediatrics,” for discussion of diabetes in pediatric populations.) The exact cause of type 1 diabetes is not known; however, it appears that genetic and environmen-

tal factors trigger an autoimmune response, which attacks the insulin-producing beta cells of the pancreas. Prolonged hyperglycemia can lead to the severe macro- and microvascular complications of diabetes, such as cardiovascular disease, retinopathy, nephropathy, and peripheral and autonomic neuropathy (Kahn et al. 2005).

The Diabetes Control and Complications Trial (DCCT), a 9-year multicenter intervention study in the United States, established that improvement in glycemic control delays the onset and slows the progression of diabetic complications (Diabetes Control and Complications Trial Research Group 1993). The DCCT’s findings have informed and increased the complexity of what is now the standard treatment for type 1 diabetes. As such, treatment is aimed at lowering and stabilizing blood glucose to near normal levels through dietary control, exercise, blood glucose monitoring, and multiple daily insulin injections. Intensive blood glucose management for type 1 diabetes usually entails three or more insulin injections per day (or the use of a continuous insulin infusion pump)—with the goal of mirroring as closely as possible the physiological patterns of insulin release and near-normal blood glucose levels. Hemoglobin A_{1c} is a laboratory value reflective of average blood glucose concentrations over a 2- to 3-month period. It is used as the standard measure of diabetes self-care success and treatment effectiveness, with a typical target of as close to 7% as possible (normal range in people without diabetes is 4%–6%).

Type 2 Diabetes

Approximately 90%–95% (16 million in the United States) of all people with diabetes have type 2 diabetes, which encompasses a variety of abnormalities involving blood glucose metabolism. The hallmark of the disease is insulin resistance, in which the body requires progressively increased pancreatic insulin production to achieve normal glycemia. In patients with type 2 diabetes, the pancreas can no longer meet the need, and chronic hyperglycemia results. Risk factors for type 2 diabetes include obesity and sedentary lifestyle because both lead to insulin resistance. Onset of type 2 diabetes is typically during middle age, but with growing rates of obesity at younger ages, children and adolescents are starting to develop the disease at higher rates. Because they decrease insulin resistance, prescribed weight loss and regular exercise are first-line treatments for type 2 diabetes (Beaser 2001).

The United Kingdom Prospective Diabetes Study (UKPDS), the largest and longest prospective study of type 2 diabetes to date, found that for every 1-point reduction in hemoglobin A_{1c}, there was a corresponding 35% reduction in risk of diabetes complications. Successfully treating hypertension led to similar or greater reduction in cardiovascular complications (Krentz 1999; Matthews 1999). Treatment for type 2 diabetes is aimed at lowering and stabilizing blood glucose levels through weight loss (when applicable), dietary control, exercise, blood glucose monitoring, oral hypoglycemic medication, and treatment with insulin injections if insulin resistance and hyperglycemia persist.

Stress and Diabetes

There is conflicting evidence whether stress directly affects the onset of diabetes or its course (Helz and Templeton 1990; Mooy et al. 2000; Wales 1995). Stress hormones are involved in the body's counterregulatory response to insulin, so it is likely that stress plays a role in increasing blood glucose. Several studies have shown that glycemic control is poorer in people with diabetes who report more stress (Garay-Sevilla et al. 2000; Lloyd et al. 1999). However, it is not clear whether stress directly influences metabolic regulation or whether people under stress change their self-care behaviors. A recent meta-analysis found that psychosocial stressors, especially low social support, were significantly associated with poor metabolic control (Chida and Hamer 2008). In an effort to evaluate the effects of stress under controlled conditions, a few laboratory studies have been undertaken. Although some laboratory studies have suggested that psychological stress can impair glucose control in both type 1 (Moberg et al. 1994) and type 2 diabetes (Goetsch et al. 1993), other studies have not found this effect (Kemmer et al. 1986). Thus, it is not yet clear to

what extent stressful events directly affect the physiology of glucose regulation.

Psychiatric Disorders and Diabetes Management

The publication of the DCCT and UKPDS studies established that intensive management of type 1 and type 2 diabetes improves long-term health outcomes in diabetes (Diabetes Control and Complications Trial Research Group 1993; Krentz 1999; Matthews 1999; UK Prospective Diabetes Study Group 1998a, 1998b). However, the goal of achieving near-normal blood glucose values requires a complex set of daily behaviors and problem solving. Many patients have difficulty sustaining the burden of self-care over time—the stress of coping with a chronic disease is a major risk factor for psychopathology and nonadherence to complex treatment recommendations. There is a growing literature examining the relation of type 1 and type 2 diabetes and psychiatric disorders, especially depression, anxiety, and eating disorders. In both types of diabetes, psychiatric disorders have been linked to treatment nonadherence, worse blood glucose control, and ultimately greater prevalence of micro- and macrovascular complications. Because disease outcomes in diabetes are so dependent on patient behaviors, attitudes, and cognitions, optimal treatment is multidisciplinary, including psychiatrists and other mental health professionals, and takes into account the psychology of individual patients, their support systems, and doctor–patient relationships.

Depression and Diabetes

The prevalence of depression in both type 1 and type 2 diabetes is two to three times higher than that found in the general population (Gendelman et al. 2009; Li et al. 2008). Several studies suggest that patients with depressive disorders appear to develop worse glycemic control and have a heightened risk of diabetes complications such as retinopathy, nephropathy, hypertension, cardiac disease, and sexual dysfunction (Ciechanowski et al. 2000; de Groot et al. 2001). However, it remains unclear if depression is a cause or an effect of poorer outcomes in diabetes. In a meta-analysis of 24 studies of depression, hyperglycemia, and diabetes, Lustman et al. (2000a) reported a consistently strong association between elevated hemoglobin A_{1c} values (indicating chronic hyperglycemia) and depression. They were unable to determine the direction of the association from their analyses, so it remains unclear whether hyperglycemia causes depressed mood or if hyperglycemia is a consequence of depression. Furthermore, Lustman et al. (2000a) noted that the relation may be a reciprocal one, in which hyperglycemia is provoked by depression as well as independently contributes to the exacerbation of depression.

Anxiety symptoms are also frequently reported by patients with diabetes and depression but may independently contribute to diminished quality of life in these patients (Collins et al. 2009). After accounting for depression, one study found that panic symptoms correlated with elevated hemoglobin A_{1c} levels, higher rates of complications, and lower self-rated functional health (Ludman et al. 2006).

Until recently, it was assumed that depression develops as a consequence of diabetes, with both psychosocial and biological mechanisms suggested to account for this excess prevalence. Although depression may be a result of complications and disease duration, it also has been found to occur relatively early in the course of type 1 diabetes before the onset of complications (Jacobson et al. 2002). Therefore, it does not appear that the increased rate of depression in diabetes can be explained solely by emotional reactions to a chronic disease with complications. Another meta-analysis, by de Groot et al. (2001), of studies of depression and diabetes indicated that an increase in depressive symptoms was consistently associated with an increase in severity and number of diabetes complications. Related research showed that the number of diabetes symptoms patients reported was directly related to the number of depressed symptoms patients reported; indeed, this association was stronger than the relation between diabetes symptoms and hemoglobin A_{1c} levels or diabetes complications themselves (Ludman et al. 2004). Depression may cause poorer outcomes in diabetes through biological and behavioral mechanisms because symptoms of depression such as decreased motivation, poor energy, and hopelessness likely interfere with adherence to diabetes treatment and lead to worse glycemic control (de Groot et al. 2001). Depression is associated with increased mortality in diabetes (Black et al. 2003; Katon et al. 2005).

Studies of type 2 diabetes are less clear with regard to the development of depression (Talbot and Nouwen 2000). The increased rates of depression seen in patients with type 2 diabetes appear in some instances to precede the onset of illness, thereby raising an entirely different hypothesis about the etiological relation—that is, that depressive disorders themselves may place patients at risk for developing type 2 diabetes. Katon (2003) proposed a complex model for the relation between depression and chronic medical diseases, which accounts for complex interactions of stress and adverse life events, overall self-care and healthy lifestyle activities, functional impairments, genetic risks, and biobehavioral risks. Support for these concepts derives in part from the fact that patients with depression can have alterations in the hypothalamic-pituitary axis, which lead to increased rates of cortisol production and other counterregulatory hormones, leading to insulin resistance (Musselman et al. 2003). Other biological mechanisms include alterations in

central glucose transporter function and increased inflammatory activation (Cameron et al. 1984; Geringer 1990; Hudson et al. 1984). Depressed patients also decrease physical activity and increase cardiovascular risk factors by smoking and eating high-caloric and fatty foods, which place them at higher risk for developing type 2 diabetes (Marcus et al. 1992). In fact, a meta-analysis found that patients with premorbid major depression had a 37% increased risk of developing type 2 diabetes (Knol et al. 2006). The bidirectional relation between depression and type 2 diabetes was examined recently by Golden and colleagues (2008), who reported a modest association between premorbid symptoms of depression and newly diagnosed type 2 diabetes. They also reported a negative association between untreated diabetes and newly reported depression symptoms, whereas they found a positive association between treated diabetes and symptoms of depression.

Some investigators have suggested that the metabolic problems of diabetes (increased rates of hypoglycemia and hyperglycemia) could themselves play a causal role in the development of depression. There is increasing evidence that diabetes leads to changes in white matter in the brain (Dejgaard et al. 1991) and that these white matter abnormalities, if present in regions of the brain involved in affect regulation (e.g., the limbic system), may play a causal role in the development of depression (Jacobson et al. 2000). At this point, such white matter changes are of unknown etiology; however, they may be associated with accelerated vascular disease in diabetes. Indeed, history of cerebrovascular disease is significantly associated with depression in older adults with diabetes (Bruce et al. 2006).

Screening instruments such as the nine-item depression scale of the Patient Health Questionnaire (PHQ-9) (Kroenke et al. 2001) or the Beck Depression Inventory (BDI; Lustman et al. 2000b; Musselman et al. 2003) are useful in identifying patients with diabetes and depression. The PHQ-9 is currently one of the most widely used screening instruments in medical settings because it is brief and simple to use in routine clinical practice. Diabetes-specific measures of quality of life, such as the Problem Areas in Diabetes (PAID) Scale (Polonsky et al. 1995; Welch et al. 1997, 2003) and the Diabetes Quality of Life (DQOL) Measure (Jacobson 1996), also may be useful in screening patients who are overburdened by diabetes and may be at increased risk for depression.

Evidence is limited and somewhat contradictory about whether specific treatment of depression can lead to improvements in diabetes treatment adherence and improved glycemic control. Two small controlled studies have reported that nortriptyline and fluoxetine are effective treatments for depression in diabetes. However, nortriptyline improved mood but did not improve glucose regulation,

whereas fluoxetine was associated with improvements in mood and a nonsignificant trend for improved hemoglobin A_{1c} levels (Lustman et al. 1997, 2000b). Sertraline maintenance treatment was recently found to lengthen the time to depression recurrence over placebo in patients with diabetes; hemoglobin A_{1c} also was found to improve slightly in relation to symptom improvement and deteriorate with depression recurrence (Lustman et al. 2006). Sertraline maintenance also was shown to decrease the risk of recurrence of depression in younger patients with diabetes (Williams et al. 2007). Compared with patients receiving diabetes education only, patients receiving cognitive-behavioral therapy (CBT) to address their depression symptoms showed significant improvements in hemoglobin A_{1c} levels (Lustman et al. 1998). A similar study showed improved mood in response to CBT but no change in hemoglobin A_{1c} levels during treatment or 1 year later (Georgiades et al. 2007). Rates of depression do not appear to differ among ethnic groups with diabetes, but fewer ethnic minority patients with diabetes report receiving appropriate treatment for depression (de Groot et al. 2006). It appears that standard treatments for depression not only lead to improvement in depressive symptoms but also may in some cases lead to better glycemic control. However, it remains unclear whether psychiatric treatment of depression in diabetes can improve psychological and biomedical outcomes.

The Pathways Study, a large-scale randomized trial, investigated an innovative approach to managing depression and diabetes in primary care clinics that provided enhanced education and support for antidepressant medication taking and behavioral problem solving. Patients receiving this intervention showed improvements in adequacy of medication dosing and improvements in depressive symptoms; however, no hemoglobin A_{1c} differences were observed between intervention patients and control subjects (Katon et al. 2004). Patients with fewer than two diabetes complications experienced the same improvement in depressive symptoms in the intervention and standard care groups; however, patients with multiple complications received more relief from their depression symptoms with the targeted intervention (Kinder et al. 2006). This intervention was shown to add no additional long-term cost to care and possibly to reduce health care costs for patients with multiple diabetes complications (Katon et al. 2008). A similar study, examining a subgroup of patients with diabetes in the Improving Mood—Promoting Access to Collaborative Treatment (IMPACT) trial, found that treating depression in older adults with diabetes contributed to significant clinical benefits to this cohort without adding to health care costs (Katon et al. 2006).

In summary, the high prevalence of depression and its adverse effects in diabetes, combined with clinically proven

treatments, argue for aggressive identification and treatment of depression as early as possible in diabetes. Depression should always be suspected in patients who are having difficulty adapting to diabetes and show poor or worsening glycemic control.

Bipolar Disorder, Schizophrenia, and Diabetes

A number of studies have demonstrated a significantly increased prevalence of diabetes (mainly type 2) in bipolar disorder and schizophrenia. Patients with these disorders have diabetes rates of 10%–15%, which is between two and three times higher than rates in the general population (de Hert et al. 2009). The reasons for this added risk are unclear. Much of the association appears to be related to more obesity in both of these patient populations, which is associated with but not fully accounted for by weight gain associated with psychotropic drugs. It also may reflect the generally poor lifestyle choices of individuals with chronic psychiatric conditions—that is, they are quite sedentary, frequently smoke, and tend to overeat high-carbohydrate and high-fat foods (Newcomer 2006). In fact, both schizophrenia and bipolar patients have an equally high prevalence—about twice that in the general population—of modifiable cardiovascular risk factors, including smoking, obesity, metabolic syndrome, and diabetes (Birkenaes et al. 2007). With several of the atypical antipsychotics, the onset of diabetes may occur suddenly, with emergent ketoacidosis or hyperosmolar coma (Buse 2002; Geller and MacFadden 2003). The diabetes typically recedes once the antipsychotic medication is stopped, but it is likely that the sudden emergence of symptoms occurs in patients who already had glucose intolerance, for the increased risk of diabetes among individuals with schizophrenia precedes the use of the atypical agents (Dixon et al. 2000).

Several proposed mechanisms may help explain the association between antipsychotic treatment and diabetes; these include medication-induced weight gain, serotonin antagonism leading to decreasing insulin levels and corresponding hyperglycemia, and drug-induced leptin resistance (Buchholz et al. 2008). Family history of diabetes should be assessed prior to initiating treatment, and measurements of weight, blood glucose, and lipid levels should be taken at baseline and at periodic intervals throughout treatment. Patients also should be educated about the risks of developing diabetes and encouraged to monitor their weight (Henderson and Doraiswamy 2008). In patients with known diabetes, antipsychotics less likely to cause weight gain and glucose intolerance, such as perphenazine, molindone, aripiprazole, and ziprasidone, should be favored (Guo et al. 2007; Meyer et al. 2008; Van Winkel et al. 2008) (see Chapter 38, “Psychopharmacology,” for a full discussion).

Eating Disorders and Diabetes

Despite its promise of reducing long-term complications of type 1 diabetes, a negative side of intensive diabetes management is weight gain (see also Chapter 14, "Eating Disorders"). During the first 6 years of the DCCT, patients in the intensively treated group gained an average of 10.45 pounds more than the patients in the standard treatment cohort, and 9-year follow-up data showed that this weight was hard to lose (Diabetes Control and Complications Trial Research Group 1988, 2001). A survey of patients' responses to the recommendations of the DCCT study documented that women with type 1 diabetes were especially concerned about tight glucose control causing weight gain (Thompson et al. 1996). It has been argued that the heightened attention to food portions, blood sugars, and risk of weight gain in intensive diabetes management parallels the obsessive thinking about food and body image characteristic of women with eating disorders, and this might place women with diabetes at heightened risk for developing eating disorders.

Disturbed eating behavior, usually mild in severity, is common among adolescent girls and young women in the general population; however, those with type 1 diabetes are more likely to have two or more disturbed eating behaviors than are their peers without diabetes (Colton et al. 2004). Olmsted and colleagues (2008) defined disturbed eating behavior as eating disorder symptoms not yet at the level of frequency or severity to merit a formal diagnosis, including dieting for weight loss, binge eating, or calorie purging through self-induced vomiting, laxative or diuretic use, excessive exercise, or insulin restriction in the case of type 1 diabetes. Studies of the natural history of disturbed eating behaviors in type 1 diabetes indicate that these behaviors persist and increase in severity over time as well as become more common into young adulthood (Colton et al. 2004; Peveler et al. 2005). Evidence suggests that women with type 1 diabetes are 2.4 times more at risk for developing an eating disorder and 1.9 times more at risk for developing subthreshold eating disorders than are women without diabetes (Jones et al. 2000).

Women with type 1 diabetes may use insulin manipulation (e.g., administering reduced insulin doses or omitting necessary doses altogether) as a means of caloric purging. Intentionally induced glycosuria is a powerful weight loss behavior and a symptom of eating disorders unique to type 1 diabetes. Questions such as "Do you ever change your insulin dose or skip insulin doses to influence your weight?" or "How often do you take less insulin than prescribed?" can be helpful in screening for insulin omission, especially when patients present with persistently elevated hemoglobin A_{1c} levels or unexplained diabetic ketoacidosis. Intermittent insulin omission or dose reduction for weight loss

purposes has been found to be a common practice among women with type 1 diabetes. As many as 31% of women with type 1 diabetes report intentional insulin restriction, with rates of this disturbed eating behavior peaking in late adolescence and early adulthood (40% of women between ages 15 and 30 years) (Polonsky et al. 1994). This behavior, even at a subclinical level of severity, places women at heightened risk for medical complications of diabetes. Women reporting intentional insulin misuse had higher hemoglobin A_{1c} values (approximately 2 or more percentage points higher than values in similarly aged women without eating disorders), higher rates of hospital and emergency department visits, and higher rates of neuropathy and retinopathy than women who did not report insulin omission (Bryden et al. 1999; Polonsky et al. 1994; Rydall et al. 1997). The chronic hyperglycemia found in women with diabetes who intentionally omit or reduce their insulin doses places these women at much greater risk for frequent episodes of diabetic ketoacidosis and the long-term onset of macro- and microvascular complications of diabetes. Even subthreshold disturbed eating behaviors are strongly associated with significant medical and psychological consequences in the context of diabetes (Verrotti et al. 1999). In fact, endorsing insulin restriction alone was recently shown to increase mortality risk threefold over an 11-year follow-up period (Goebel-Fabbri et al. 2008).

Because obesity is a significant risk factor in type 2 diabetes, recurrent binge eating may increase the chances of developing it in part because of significantly higher body mass index (BMI) (Striegel-Moore et al. 2000). Initial studies of binge eating in type 2 diabetes relied on small, non-representative samples. Kenardy et al. (1994) found that 14% of the patients with newly diagnosed type 2 diabetes experienced problems with binge eating compared with 4% of the age-, sex-, and weight-matched control group. Night eating symptoms also have been implicated for their association with obesity and poor diabetes control. One study found that patients reporting symptoms of night eating were more likely to be obese, have hemoglobin A_{1c} values higher than recommended targets, and have two or more diabetes complications (Morse et al. 2006). In the largest study of its kind to date, more than 5,000 patients with type 2 diabetes were evaluated to determine whether binge eating was related to weight loss after a 1-year intervention. Larger weight losses were observed in those patients who never endorsed binge eating or who reported that they were no longer binge eating at 1-year follow-up (Gorin et al. 2008). Thus, recurrent binge eating and symptoms of night eating syndrome can be expected to make it increasingly difficult to control diabetes and weight.

A multidisciplinary team approach, including an endocrinologist or a diabetologist, nurse educator, nutritionist

with eating disorder and diabetes training, and mental health practitioner, is ideal for the treatment of comorbid eating disorders and diabetes (Kahn et al. 2005; Mitchell et al. 1997). Depending on the severity of the eating disorder and other comorbid psychopathology, a psychiatrist also may be needed for psychopharmacological evaluation and treatment. At this time, little research has examined treatment efficacy for eating disorders in the context of diabetes; however, a large research literature on treatment outcomes in bulimia nervosa supports the use of CBT in combination with antidepressant medications as the most effective treatment (Peterson and Mitchell 1999; B.T. Walsh and Devlin 1995). These approaches would need to be adapted slightly to address directly the role of insulin omission as the means of caloric purging.

Early in treatment, intensive glycemic management of diabetes is not an appropriate target for a person with diabetes and an eating disorder. As noted earlier, overly intensive diabetes management may actually aggravate obsessive thinking about food and weight in patients with eating disorders. The first goal should focus on medical stabilization. Gradually, the team can build toward increasing doses of insulin, increases in food intake, greater flexibility of meal plan, regularity of eating routine, and more frequent blood glucose monitoring.

Sexual Function and Diabetes

For information on diabetes and sexual function, see Chapter 16, "Sexual Dysfunction."

Cognitive Functioning and Diabetes

Several researchers have studied the effect of diabetes on cognitive functioning. Results from a meta-analysis of 31 studies published between 1980 and 2004 indicated that young and middle-aged diabetic adults, ages 18–50 years, performed significantly more poorly than did their nondiabetic peers on measures of intelligence, attention, psychomotor efficiency, cognitive flexibility, and visual perception (Brands et al. 2005). Effect sizes were largest on tasks that rely on general knowledge and on psychomotor efficiency. In general, performance on virtually all tasks requiring rapid responding or cognitive flexibility was affected to some degree, whereas effects on learning and memory function were modest, with small between-group differences.

The etiology of these neurocognitive differences remains unclear. Early studies emphasized the role of recurrent episodes of severe hypoglycemia (Bjorgaas et al. 1997; Deary et al. 1993; Frazekas 1989; Langan et al. 1991; Perros et al. 1997). Several studies, including the recent 18-year follow-up of more than 1,300 subjects from the DCCT, have found no cognitive effects associated with recurrent

episodes of severe hypoglycemia (Austin and Deary 1999; Diabetes Control and Complications Trial Research Group 1996; Jacobson et al. 2007) but suggested that chronically elevated hemoglobin A_{1c} levels predict cognitive dysfunction and cognitive decline over time (Ferguson et al. 2003; Jacobson et al. 2006, 2007; Ryan 2006; Ryan et al. 2003).

Long-term exposure to hyperglycemia and related micro- and macrovascular damage also has been posited to heighten risk of cognitive decline and dementia in diabetes. In fact, two studies reported a 60%–100% increased risk for cognitive decline among patients with diabetes as compared with those without diabetes (Gregg and Brown 2003). This increased risk appears to be mediated primarily by an increase in vascular dementia rather than a heightened risk for Alzheimer's disease in diabetes (Gregg and Brown 2003).

Hypoglycemia in Diabetic and Nondiabetic Individuals

Hypoglycemia has been a popular explanation for anxiety symptoms, especially panic attacks, with past widespread use of 5-hour glucose tolerance tests for diagnosis and recommendations for dietary management with multiple small meals. This practice is no longer commonly recommended by physicians, but hypoglycemia is still a popular diagnosis among alternative medicine practitioners and many patients. Symptomatic hypoglycemia rarely occurs except in diabetic (mainly insulin-dependent) patients and patients with insulinomas. Although marked hypoglycemia does cause symptoms of adrenergic hyperactivity, they can be reliably distinguished by patients from panic attacks (Schweizer et al. 1986; Uhde et al. 1984).

However, insulin-induced hypoglycemia is an aversive experience, which has been reported to cause phobic anxiety—that is, a fear of hypoglycemia—in diabetic patients, leading to poorer diabetic control (Green et al. 2000).

Thyroid Disorders

Hyperthyroidism and hypothyroidism are accompanied by a variety of physiological, psychiatric, and cognitive symptoms. Patients with psychiatric disorders, especially depression, have elevated rates of thyroid disease (Farmer et al. 2008; Lobo-Escobar et al. 2008). In this section, we focus on cognitive and psychiatric symptoms associated with thyroid problems.

Hyperthyroidism

Hyperthyroidism is accompanied by a host of physiological symptoms, including nervousness, sweating, fatigue, heat intolerance, weight loss, and muscle weakness (Kornstein et al. 2000). The most common cause of hyperthyroidism (or

thyrotoxicosis) is Graves' disease. Graves' disease is an autoimmune disorder that results in hyperthyroidism when thyroid-stimulating immunoglobulins (TSIs) bind to thyrotropin receptors and mimic thyrotropin. TSIs thereby stimulate the synthesis of hormones (thyroxine [T_4] and triiodothyronine [T_3]) while serum thyrotropin levels are very low or undetectable (Porterfield 1997). The factors that trigger this immune response are unknown. Patients with type 1 diabetes are at increased risk for Graves' disease. Some evidence shows that stress can precipitate Graves' disease (Santos et al. 2002; Yoshiuchi et al. 1998) and aggravate treated disease (Fukao et al. 2003).

Patients with Graves' disease often present with anxiety, hypomania, depression, and cognitive difficulties. Both physiological and psychiatric symptoms correlate poorly with thyroid hormone levels (Trzepacz et al. 1989). These symptoms typically resolve with antithyroid therapy (Alvarez et al. 1983; Kathmann et al. 1994) or with use of beta-blockers such as propranolol (Trzepacz et al. 1988b). However, in a study evaluating women with treated hyperthyroidism, mood and anxiety disorders still persisted (Bunevicius et al. 2005). Treatment options for Graves' disease include antithyroid medications, thyroidectomy, and radioactive iodine. Graves' disease patients have been reported to have difficulties with sustained attention and visuomotor speed tasks (Alvarez et al. 1983) and with memory and concentration (MacCrimmon et al. 1979). It is possible that the memory and concentration difficulties appear only after long-term thyroid dysregulation. We do know that without treatment for Graves' disease, psychiatric symptoms such as major depressive disorder, generalized anxiety disorder, and hypomania will persist (Trzepacz et al. 1988a). Affective psychosis (e.g., depression and mania) also can result from thyrotoxicosis (Brownlie et al. 2000).

Although thyroid disorders are known to affect behavior, the relation between thyroid hormones per se and brain function has not been well studied. Kathmann et al. (1994) investigated the effects of T_3 (the biologically active thyroid hormone) on brain performance in healthy subjects. When T_3 levels were experimentally elevated, subjects made subjective overestimates of time intervals and were able to increase their word fluency, in the absence of more global cognitive problems (Kathmann et al. 1994).

Anxiety and irritability are common in Graves' disease prior to treatment. Only a few studies (Bunevicius et al. 2005; Trzepacz et al. 1988b) have investigated the prevalence of psychiatric complaints in hyperthyroid patients and whether these complaints persist after treatment. R.A. Stern et al. (1996) conducted a survey of members of the National Graves' Disease Foundation to investigate patient self-report of psychiatric and cognitive symptoms. The most common symptoms reported were irritability

(78%), shakiness (77%), and anxiety (72%). Slowed thinking was reported by 40%.

In addition to anxiety and cognitive difficulties, some patients with hyperthyroidism experience depression secondary to their medical condition. When patients are given antithyroid therapy, depressive symptoms often disappear. Thus, antithyroid therapy should be the first course of action in treating depression in these patients (Kathol et al. 1986). However, treatment for depression may be indicated if the symptoms are sufficiently problematic or persistent. Hyperthyroidism may present differently depending on the age of the patient. In younger patients, hyperthyroidism typically manifests as hyperactivity or anxious dysphoria (Bhatara and Sankar 1999), whereas in the elderly, it can manifest as apathy or depression, referred to as "apathetic hyperthyroidism" (Mooradian 2008).

Hypothyroidism

Hypothyroid patients often experience weakness, fatigue, somnolence, cold intolerance, weight gain, constipation, hair loss, hoarseness, stiffness, and muscle aches (Kornstein et al. 2000). The most common cause of hypothyroidism is autoimmune thyroiditis (Hashimoto's thyroiditis). Hypothyroidism can also be a side effect of lithium. Radioactive iodine, the most commonly used modality for treating hyperthyroidism (such as in Graves' disease), may cause hypothyroidism, which may go undiagnosed for several years after treatment for hyperthyroidism (New York Thyroid Center 2003).

The symptoms of hypothyroidism overlap with retarded depression, and the diagnosis is easy to miss in patients who already have a depression diagnosis. Physical signs of hypothyroidism include weakness, bradycardia, facial puffiness, weight gain, hair loss, hoarseness, and slowed speech (Kornstein et al. 2000). The best screening test for hypothyroidism is measurement of serum thyrotropin concentration, but an elevated thyrotropin level should be followed by a free T_4 determination to confirm the diagnosis. A serum thyrotropin determination will be misleading in the patient with secondary hypothyroidism caused by pituitary or hypothalamic disease. In such a patient, a free T_4 measurement usually will allow the clinician to make the appropriate diagnosis.

Severe hypothyroidism is relatively rare, although milder hypothyroidism is fairly common (Joffe and Levitt 1992). Hypothyroidism can be divided into three grades (Haggerty and Prange 1995). Grade 1 refers to patients with *overt* hypothyroidism who are usually symptomatic and have elevated serum thyrotropin and low serum free T_4 concentrations. Patients with *subclinical* hypothyroidism are classified as having grade 2 or 3; these patients typically have either mild or no symptoms of thyroid hormone defi-

ciency. The laboratory features of grade 2 hypothyroidism are an elevated serum thyrotropin level and a serum free T_4 level within the normal range. Patients with grade 3 hypothyroidism have normal thyrotropin and free T_4 levels, and the diagnosis can be confirmed only by an exaggerated serum thyrotropin response to thyrotropin-releasing hormone (TRH). Subclinical hypothyroidism is fairly common, affecting 5%–10% of the population, mainly women, and occurs in 15%–20% of women older than 45 years. Subclinical hypothyroidism is particularly common in elderly women.

Cognitive Function

Hypothyroidism can impair memory function. It is not well understood whether this impairment is limited to memory or whether it extends to other cognitive skills such as attention, inhibition of irrelevant information, and task switching. One possibility is that cognitive inefficiency in hypothyroidism is a result of secondary depression. However, in some cases, cognitive problems are independent of depression. For example, Burmeister et al. (2001) found no relation between cognitive ability and level of depression in a group of hypothyroid patients (although patients in this study scored within normal limits on most aspects of cognition). This study suggests that patient perceptions of cognitive difficulty (rather than actual cognitive dysfunction) may be a result of depression, fatigue, or response bias.

Patients with subclinical hypothyroidism often show subtle signs of cognitive dysfunction on tests of memory that may improve after treatment (Baldini et al. 1997; Capet et al. 2000; Jensovsky et al. 2002). Furthermore, Miller et al. (2006, 2007) reported that hypothyroid-related memory dysfunction stems from retrieval deficits rather than any problems in encoding and storing the information. Although most hypothyroid patients who receive treatment are prescribed T_4 , administration of both T_4 and T_3 may improve cognitive performance more than T_4 alone (Bunecivius et al. 1999). Other studies, however, do not support this observation (Sawka et al. 2003; J.P. Walsh et al. 2003). Mennemeier et al. (1993) reported that after thyroid treatment, some forms of cognition returned to normal levels (e.g., performance on the Object Assembly subtest of the Wechsler Adult Intelligence Scale and on the Peterson-Peterson task that assesses short-term memory), whereas other functions remained impaired (e.g., logical memory or paired-associate learning). Whether to treat subclinical hypothyroidism, however, remains controversial.

Depression

Hypothyroidism is a known cause of secondary depression. Almost all patients with hypothyroidism have some concurrent symptoms of depression (Haggerty and Prange

1995). In the early stages of hypothyroidism, circulating T_4 levels decline, whereas T_3 levels often remain in the normal range. The brain preferentially uses T_4 , as compared with other body tissues, and is thus more sensitive than other areas of the body to lower levels of T_4 (Haggerty et al. 1990). This imbalance in thyroid hormones may contribute to mood disorder, and subclinical hypothyroidism is now recognized as a potential risk factor for depression (Haggerty and Prange 1995).

T_3 also has been used to augment the effects of antidepressants, suggesting a link between depression and thyroid function (Cooper-Kazaz et al. 2007). Interestingly, in the elderly, there does not appear to be a link between subclinical hypothyroidism and impaired cognition, depression, or anxiety (Gussekloo et al. 2004; Roberts et al. 2006).

Patients with bipolar disorder with either rapid-cycling or mixed episodes have particularly high rates of subclinical hypothyroidism. In one study, almost 40% of rapid-cycling or mixed-episode bipolar patients were found to have subclinical hypothyroidism (although lithium-induced thyroid dysfunction could have contributed) (Joffe et al. 1988). Every patient with rapid-cycling bipolar disorder should be evaluated for (subclinical) hypothyroidism and receive T_4 if thyrotropin levels are elevated. Some patients may benefit even if they are euthyroid (Haggerty and Prange 1995).

Psychosis

Untreated hypothyroidism can result in psychosis, so-called myxedema madness. This condition was fairly common—reported in up to 5% of all hypothyroid patients (Kudrjavcev 1978)—before the widespread use of modern thyroid function tests, but it is now rare. Psychotic symptoms typically remit when thyrotropin levels return to normal, although cognitive dysfunction may continue (Haggerty et al. 1986). Another rare possibility in hypothyroid patients is Hashimoto's encephalopathy, a delirium with psychosis, seizures, and focal neurological signs, associated with high serum antithyroid antibody concentrations, responsive to corticosteroids, and possibly thought to be an autoimmune disorder (Schiess and Pardo 2008).

Congenital Hypothyroidism

Congenital hypothyroidism usually occurs as a result of thyroid agenesis or dysgenesis, although inherited defects in thyroid hormone synthesis also may play a role. From a global perspective, iodine deficiency is the most common cause of congenital hypothyroidism. Newborns with untreated hypothyroidism develop the syndrome of cretinism, characterized by mental retardation, short stature, poor motor development, and a characteristic puffiness of the face and hands. Because early treatment is essential to prevent permanent mental retardation, all infants born in

the United States are screened for hypothyroidism at birth (American Academy of Pediatrics et al. 2006). Treatment with thyroid hormones before age 3 months can result in normal intellectual development in most infants.

Parathyroid Disorders

Hyperparathyroidism

Hyperparathyroidism can cause bone disease, kidney stones, and hypercalcemia via oversecretion of parathyroid hormone (PTH). Symptoms of hypercalcemia include anorexia, thirst, frequent urination, lethargy, fatigue, muscle weakness, joint pain, constipation, and, when severe, depression and eventually coma.

The prevalence of hyperparathyroidism is 0.1%. It is three times more common in women than in men, and its prevalence increases with age. Hyperparathyroidism may occur as a consequence of radiation therapy to head and neck and is an underrecognized side effect of long-term lithium therapy. Cessation of lithium often does not correct the hyperparathyroidism, necessitating parathyroidectomy. Prior to 1970, more than 90% of patients with hyperparathyroidism presented with renal disease or bone disease. However, after the introduction of routine calcium screening, fewer than 20% of patients present with renal or bone disease, and more than 50% of patients present with no symptoms at all.

With mild hypercalcemia, patients may show personality changes, lack of spontaneity, and lack of initiative. Moderate hypercalcemia (serum calcium concentration = 10–14 mg/dL) may cause dysphoria, anhedonia, apathy, anxiety, irritability, and impairment of concentration and recent memory. In severe hypercalcemia (serum calcium concentration > 14 mg/dL), confusion, disorientation, catatonia, agitation, paranoid ideation, delusions, auditory and visual hallucinations, and lethargy progressing to coma may occur. Verbal memory and logical abilities are also impaired. Psychiatric and/or neurocognitive symptoms were the sole presenting symptoms in 12% (16 of 136) of patients who subsequently underwent parathyroidectomy, and these tended to be the older patients (Casella et al. 2008). Another study found symptoms of depression in 23.4% of patients preparathyroidectomy, and 15.6% had anxiety, both of which declined after surgery (Weber et al. 2007). After treatment of hypercalcemia, psychiatric and cognitive symptoms disappear in most patients (Roman and Sosa 2007).

Hypoparathyroidism

Patients with hypoparathyroidism present with hypocalcemia causing increased neuromuscular irritability. Typi-

cal symptoms include paresthesias, muscle cramps, carpopedal spasm, and (less commonly) facial grimacing and seizures. Complications include calcification of the basal ganglia and pseudotumor cerebri. Psychiatric symptoms may include anxiety and emotional irritability and lability. Severe hypocalcemia causes tetany and seizures. Hypoparathyroidism is caused by inadequate parathyroid hormone secretion, most often as a result of parathyroid or thyroid surgery. Hypoparathyroidism is also common in the 22q11.2 deletion syndrome (velocardiofacial syndrome), in which schizophrenia and bipolar disorder are common in adults and mood, anxiety, attentional, and behavior disorders are common in children (Jolin et al. 2009).

Kowdley et al. (1999) showed that cognitive and neurological deficits are often present in patients with longstanding hypoparathyroidism (≥ 9 years). These deficits are thought to be related to the presence of intracranial calcification and thus irreversible (Kowdley et al. 1999).

Osteoporosis

Osteoporosis is a metabolic disturbance of bone resulting in low bone mass, reduced bone strength, and increased risk of fractures. Osteoporosis occurs most commonly in postmenopausal women. The association between depression and reduction in bone mineral density is well established in premenopausal women (Eskandari et al. 2007; Petronijevic et al. 2008), and some support exists for a similar association in older men (Laudisio et al. 2008; Mezuk et al. 2008). The relation between depression and osteoporosis is complex. Some of the association may be the result of antidepressants, especially selective serotonin reuptake inhibitors (SSRIs), which have been themselves associated with reduced bone mineral density and increased fracture risk (Haney et al. 2007; Mezuk et al. 2008; Ziere et al. 2008). Individuals with depression also tend to have other risk factors for low bone mass, including hypercortisolism (Altindag et al. 2007) and lifestyle factors (smoking, alcohol, physical inactivity). An increased risk of osteoporosis would be expected in patients receiving long-term augmentation of antidepressant therapy with T_3 , but this has not been studied.

Adrenal Gland Disorders

Cushing's Syndrome

Cushing's syndrome results from abnormally high levels of cortisol and other glucocorticoids. The most common cause is the pharmacological use of corticosteroids, followed by excessive corticotropin secretion (most commonly by a pituitary tumor, referred to as Cushing's disease) and

adrenal tumors. Symptoms and signs of Cushing's syndrome include truncal obesity and striae, diabetes, hypertension, hyperglycemia, muscle weakness, osteopenia, skin atrophy and bruising, increased susceptibility to infections, and gonadal dysfunction.

Cushing's syndrome patients commonly experience a range of psychiatric symptoms, including depression, anxiety, hypomania or frank mania, psychosis, and cognitive dysfunction (Arnaldi et al. 2003; Sonino et al. 2006), with rates varying widely across studies. Depression is the most prevalent psychiatric disturbance in Cushing's syndrome. A full depressive syndrome has been reported in 50%–80% of cases, accompanied by irritability, insomnia, crying, decreased energy and libido, poor concentration and memory, and suicidal ideation (Arnaldi et al. 2003). Although antidepressants are less effective than in regular major depressive disorder, they are helpful until definitive treatment of Cushing's syndrome can be provided. Mood symptoms generally improve with resolution of hypercortisolemia (Arnaldi et al. 2003).

Significant anxiety has been reported in up to 79% of cases (Loosen et al. 1992). There are many case reports of Cushing's syndrome patients presenting with a variety of psychotic symptoms, usually as part of a manic or depressive syndrome (Arnaldi et al. 2003), leading to misdiagnosis as bipolar disorder or a schizophrenia spectrum disorder. Mifepristone, a glucocorticoid receptor blocker, may be particularly useful in acute treatment of cortisol-induced psychosis (Johanssen and Allolio 2007).

Cognition may be impaired in patients with Cushing's syndrome. For example, Starkman et al. (2001) found that, compared with a healthy control group, Cushing's disease patients scored poorly on verbal and performance IQ measures and had lower memory quotients, with verbal skills the most affected. The deficits in cognitive function were not explained by depression (Starkman et al. 2001). The neocortex and the hippocampus are rich in glucocorticoid receptors (Sapolsky 2000; Starkman et al. 2001), so it is not surprising that learning and memory are affected in Cushing's syndrome. In fact, Cushing's disease causes reduction in hippocampal volume, reversible after cortisol levels return to normal. This effect is age dependent, such that the older the individual, the less plastic is the hippocampus and the less susceptible the patient is to recovery (Starkman et al. 1999). The data are mixed on whether cognitive deficits improve or persist after treatment of Cushing's syndrome (Arnaldi et al. 2003; Hook et al. 2007).

The primary treatment for corticotropin-dependent Cushing's syndrome is surgery with selective pituitary or ectopic corticotroph tumor resection. Second-line treatments include more radical surgery, radiation therapy (for Cushing's disease), medical therapy, and bilateral adrenalectomy.

Adrenal Insufficiency: Addison's Disease and Corticotropin Deficiency

Insufficient production of adrenal corticosteroids can be caused by several mechanisms. Primary adrenal insufficiency, or Addison's disease, results in deficient secretion of mineralocorticoids and glucocorticoids. The major causes of Addison's disease are autoimmune destruction of the adrenal cortex, tuberculosis, and human immunodeficiency virus. The most common cause of secondary adrenal insufficiency is suppression of corticotropin secretion by chronic glucocorticoid administration. Less common secondary causes include diseases that result in pituitary destruction. In secondary adrenal insufficiency, corticotropin levels are low, whereas in Addison's disease, the deficiency in cortisol results in an increase in corticotropin production. This increase in corticotropin can cause hyperpigmentation, particularly in sun-exposed skin, scars, and mucous membranes. The decrease in mineralocorticoid levels results in contraction of the extracellular volume, leading to postural hypotension. Individuals with adrenal insufficiency are prone to not only hypotension but also hypoglycemia when stressed or fasting. Although electrolytes can be normal in mild Addison's disease, hyponatremia and hyperkalemia are typical. Water intoxication with hyponatremia can occur if a water load is given because cortisol deficiency impairs the ability to increase free water clearance. Other manifestations of adrenal insufficiency include anemia, anorexia, nausea, vomiting, diarrhea, abdominal pain, weight loss, and muscle weakness.

Psychiatric symptoms such as apathy, social withdrawal, fatigue, anhedonia, poverty of thought, and negativism are common in patients with Addison's disease. A large Danish registry study found that patients with adrenal insufficiency had more than twice the number of psychiatric admissions for mood disorders than did patients with osteoarthritis (Thomsen et al. 2006). Nonspecific symptoms such as weakness, fatigue, and anorexia often appear before more specific findings, making it difficult to attribute the cause to adrenal insufficiency. Cognitive impairment, especially memory loss, is often present but ephemeral and varying in severity. During Addisonian crisis, patients may experience delirium, disorientation, confusion, and even psychosis (Anglin et al. 2006). Adrenal insufficiency is particularly likely to be misdiagnosed as primary major depression in patients with chronic medical illness who previously received high doses of corticosteroids, resulting in unrecognized secondary adrenal insufficiency. Another possible psychiatric misdiagnosis is anorexia nervosa.

Although the diagnosis of adrenal insufficiency may be suspected on the basis of a low serum cortisol level in

the morning, definitive diagnosis requires a corticotropin stimulation test. This is typically performed with cosyntropin, a synthetic corticotropin analogue. An increase in the serum cortisol concentration to greater than 20 ng/dL following cosyntropin injection excludes the diagnosis of adrenal insufficiency.

The cause of depression in patients with Addison's disease is not clear. Regardless of the etiology of adrenal insufficiency, urgent treatment is indicated. Both glucocorticoid and mineralocorticoid replacement are usually necessary in the treatment of Addison's disease, whereas glucocorticoid replacement alone is sufficient in secondary adrenal insufficiency.

Adrenal insufficiency is also a feature in adrenoleukodystrophy, a rare, X-linked inherited metabolic disease, which also leads to leukoencephalic myeloneuropathy. Adult onset is rare but commonly presents with psychiatric symptoms, including mania, psychosis, and cognitive dysfunction (Rosebush et al. 1999).

Acromegaly

Acromegaly is a disease of excess growth hormone (GH) secretion. Deficiency of GH in children results in short stature, as discussed in Chapter 34, "Pediatrics." The most common cause of acromegaly is a GH-secreting adenoma of the anterior pituitary. These benign tumors account for 30% of all hormone-secreting pituitary adenomas (DeGroot et al. 2001). Clinical manifestations of acromegaly include headache, cranial nerve palsies, acral enlargement (frontal bossing), increased hand and foot size, prognathism, soft tissue overgrowth (macroglossia), glucose intolerance, and hypertension. Suprasellar extension of the tumor may cause visual field defects.

Psychiatric disturbances associated with acromegaly include mood disorders, anxiety, and personality change (Sievers et al. 2009a, 2009b). Psychiatric symptoms and impairment in quality of life in acromegaly have been attributed to the endocrine disorder itself and the psychosocial stress of disfigurement (T'Sjoen et al. 2007). Personality change described in acromegalic patients includes loss of initiative and spontaneity, with marked lability in mood (Pantanetti et al. 2002).

Treatment of acromegaly may include surgery, medication, and radiation. Surgery is usually the primary treatment for GH-secreting pituitary adenomas and may enhance the effectiveness of subsequent medical therapy. Medical management includes somatostatin analogues (e.g., octreotide), the GH receptor antagonist pegvisomant, dopamine agonists (e.g., bromocriptine), and radiation. In the past, high doses of bromocriptine were some-

times necessary to reduce levels of GH, which increased the risk of psychiatric adverse effects, including psychosis (Boyd 1995).

Pheochromocytoma

Pheochromocytomas are rare catecholamine-secreting tumors derived from the adrenal medulla and sympathetic ganglia. The clinical signs and symptoms result from the release of catecholamines, leading to increased heart rate, blood pressure, myocardial contractility, and vasoconstriction, resulting in paroxysmal hypertension, headache, palpitations, diaphoresis, anxiety, tremulousness, pallor (rarely flushing), chest and abdominal pain, and often nausea and vomiting (Manger 2009). Because these are nonspecific symptoms, pheochromocytomas may mimic anxiety disorders (especially panic disorder), migraine or cluster headaches, amphetamine or cocaine abuse, alcohol withdrawal, brain tumors, subarachnoid hemorrhage, neuroblastoma in children, or temporal lobe seizures (DeGroot et al. 2001). Of the patients tested for pheochromocytoma, fewer than 2% are found to have the tumor (Eisenhofer et al. 2008). Unexplained severe symptomatic paroxysmal hypertension, often referred to as "pseudopheochromocytoma," appears to be triggered by anxiety in many of these patients (Pickering and Clemow 2008).

Cases of classic panic attacks in patients with pheochromocytoma have been reported in both adults and children (Carre 1996; Prokhorova and Fritz 2002). Rarely, the initial psychiatric manifestation has been depression, post-traumatic stress disorder, or psychosis (Benabarre et al. 2005).

Antidepressants have been reported to have unmasked silent pheochromocytomas, presumably by inhibiting neuronal intake of circulating catecholamines.

There is still no consensus as to the "best test" for the diagnosis of pheochromocytoma. Some centers rely on 24-hour urine measurement of increased excretion of catecholamines or catecholamine metabolites, including vanillylmandelic acid (VMA) and metanephrines. Plasma metanephrine determinations have an extremely high sensitivity (approaching 99%) and overall specificity (in the 85%–90% range) (Lenders et al. 2002). The finding of elevated urinary catecholamine levels is not specific to pheochromocytoma and can lead to misdiagnosis. A variety of psychological and physiological stressors can elevate levels of urinary catecholamines. Urinary VMA levels can be elevated with ingestion of foods high in vanillin, including vanilla extract, bananas, coffee, nuts, and citrus fruits (Sheps et al. 1990). Elevated urinary VMA levels are the least specific indicator of pheochromocytoma, whereas elevated

metanephrines are the most sensitive (T.A. Stern and Cremens 1998). Misdiagnosis of pheochromocytoma has been reported in patients with hypertension and raised urinary catecholamines who were taking clozapine (Krentz et al. 2001) or selegiline (Lefebvre et al. 1995).

Multiple cases of factitious pheochromocytoma have been reported and include cases involving intentional vanilla extract ingestion (T.A. Stern and Cremens 1998), phenylpropanolamine abuse (Hyams et al. 1985), surreptitious injection of catecholamines intravaginally (Spitzer et al. 1998), epinephrine injection (Keiser 1991), and conscious altering of autonomic function with Valsalva maneuvers (Kailasam et al. 1995).

The rare possibility of a pheochromocytoma should be considered in patients with panic attacks, headaches, and labile hypertension, particularly those who do not respond to treatment. It is not necessary to screen for pheochromocytoma in patients who have only psychiatric symptoms; elevated catecholamines are common and likely to be false-positive results. Some psychotropic drugs may cause hypertensive reactions that mimic pheochromocytoma, and in rare cases the drugs may be unmasking an unsuspected pheochromocytoma.

Hyperprolactinemia

Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome (Melmed 2001). The differential diagnosis of hyperprolactinemia includes pituitary adenomas, physiological causes (pregnancy and lactation), medication effects, chronic renal failure (via decreased peripheral prolactin clearance), primary hypothyroidism, and lesions of the pituitary stalk and the hypothalamus (e.g., hypothalamic tumors). Clinical signs in women include galactorrhea, menstrual irregularities, infertility, and decreased libido. Men present with diminished libido and rarely with galactorrhea.

Numerous studies and case reports identified an association between hyperprolactinemia and depression and anxiety, as well as resolution of symptoms with treatment of hyperprolactinemia (Kars et al. 2007), but sample sizes have been small. Fava et al. (1982) found that hyperprolactinemic patients reported a significant increase in symptoms of depression, anxiety, and hostility compared with amenorrheic and healthy control subjects. Another study found a surprisingly high prevalence of anxiety and a small increase in hostility yet no significant difference in depression (Reavley et al. 1997).

Medication-induced hyperprolactinemia has been associated with antipsychotics and, to a lesser extent, antidepressants.

Conventional antipsychotic drugs block dopamine D₂ receptors on lactotroph cells and thus remove the main inhibitory influence on prolactin secretion (Wieck and Haddad 2003). Prolactin levels between 10 and 100 ng/L are typical in drug-induced hyperprolactinemia (Melmed 2001). Serum prolactin levels in patients taking therapeutic doses of typical antipsychotics are increased six- to tenfold from mean baseline prolactin levels (Arvanitis and Miller 1997).

Atypical antipsychotics vary with respect to their effects on prolactin. In most reports, clozapine, quetiapine, olanzapine, and ziprasidone either cause no increase in prolactin secretion or increase prolactin transiently, but sustained hyperprolactinemia can occur in patients taking risperidone and paliperidone. Haloperidol raises the serum prolactin concentration by an average of 17 ng/mL, while risperidone may raise it by 45–80 ng/mL, with larger increases in women than in men (David et al. 2000). Women taking prolactin-elevating antipsychotics and not receiving specific interventions to improve bone density showed evidence of ongoing bone demineralization over a year, while women taking prolactin-sparing antipsychotics had a modest overall increase in bone mineral density (Meaney and O'Keane 2007). A study of patients switched from risperidone to aripiprazole reported that previously elevated prolactin levels were reduced to within normal range in 1 week (Byerly et al. 2009), and hyperprolactinemia in patients taking haloperidol was reversed by the addition of adjunctive aripiprazole (Shim et al. 2007).

Antidepressants with serotonergic activity, including SSRIs, monoamine oxidase inhibitors, and some tricyclic antidepressants, can cause modest elevations of prolactin (Papakostas et al. 2006) and may further elevate prolactin levels in patients also taking prolactin-elevating antipsychotics (Wieck and Haddad 2003).

Women taking psychiatric medications that chronically elevate prolactin levels are at risk for premature bone loss secondary to hypoestrogenism. Patients taking prolactin-elevating antipsychotics should be educated about—and regularly monitored for—signs and symptoms of hyperprolactinemia (David et al. 2000; Haddad et al. 2001). No published trials have examined the effects of hormone replacement on bone mineral density in patients taking antipsychotics long term, but preliminary data suggest that active management of bone loss in those with antipsychotic-associated bone disease may halt or even reverse this process (O'Keane 2008).

In patients with mood disorders whose symptoms are unresponsive to treatment and who have galactorrhea and/or amenorrhea, hyperprolactinemia should be considered as a causal factor (Holroyd and Cohen 1990).

Gonadal Disorders

Perimenstrual Disorders and Menopause

For information on perimenstrual disorders and menopause, refer to Chapter 33, "Obstetrics and Gynecology."

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common disorder, affecting 5%–10% of women of childbearing age. Clinical manifestations include amenorrhea or oligomenorrhea, infrequent or absent ovulation, increased levels of testosterone, infertility, truncal obesity or weight gain, alopecia, hirsutism, acanthosis nigricans, hypertension, and insulin resistance. The cause of the disorder is unknown. The risk of developing PCOS is increased during treatment with valproate and seems to be higher in women with epilepsy than in women with bipolar disorders (Bilo and Meo 2008).

There are adverse psychosocial consequences of PCOS. Women with PCOS may complain they feel "abnormal or freakish" (Kitzinger and Willmott 2002), related to hirsutism, obesity, and altered reproductive function (Kitzinger and Willmott 2002). High rates of clinically significant anxiety and depression have been reported in women with PCOS (Benson et al. 2009b; Månsson et al. 2008; Tan et al. 2008). Psychological problems are common in women with hirsutism of any cause. Although these physical abnormalities may affect feelings of self-worth and femininity, some research suggests that psychological morbidity, such as depression, may be caused by neuroendocrine changes in PCOS (Benson et al. 2009a). Of course, both psychosocial and neuroendocrine factors may play a role. A recent self-report study found that three-quarters of women with PCOS worried about being childless; one-quarter had mild to moderate depression and one-quarter had clinical depression, but depression was not associated with infertility concern (Tan et al. 2008). The rate of bipolar disorder may be higher among women with PCOS than in the general population, independent of an association with valproate (Klipstein and Goldberg 2007). Although the causal link between psychological symptoms and PCOS is not resolved, their frequency points to the importance of screening all PCOS patients for psychiatric syndromes, especially depression.

Testosterone Deficiency

Testosterone deficiency in men can result from diseases affecting the testes, pituitary gland, or hypothalamus. Consequences of testosterone deficiency vary depending on the stage of sexual development. Testosterone production declines naturally with age, so that a relative testosterone deficiency occurs in older men. Hypogonadal dis-

orders of the testes (primary hypogonadism) are most commonly caused by Klinefelter's syndrome, mumps orchitis, trauma, tumor, cancer chemotherapy, or immune testicular failure (see Chapter 28, "HIV/AIDS," for a discussion of hypotestosteronism in HIV infection). Pituitary lesions caused by tumors, hemochromatosis, sarcoidosis, or cranial irradiation can lead to secondary hypogonadism. The classic cause of hypothalamic hypogonadism is Kallmann's syndrome (hypogonadotropic hypogonadism with hyposmia, sensorineural hearing loss, oral clefts, micropenis, and cryptorchidism). Hypogonadism in childhood is characterized by failure of normal secondary sexual characteristics to develop and diminished muscle mass. In adult men, typical complaints are sexual dysfunction, diminished energy, decreased beard and body hair, muscle loss, and breast enlargement.

Decreasing testosterone levels as men age may be associated with changes in mood and cognition, but no clear relation between psychiatric syndromes and testosterone level has been established. One study found an adjusted hazard ratio for depression of 4.2 (95% confidence interval [CI]=1.5–12.0; $P=0.008$) in hypogonadal men (Shores et al. 2004). In a community sample of elderly men, free testosterone concentration in the lowest quintile was associated with a higher prevalence of depression (Almeida et al. 2008). The concept of a male climacteric and related mood, anxiety, and cognitive disorders is controversial.

Patients with Klinefelter's syndrome (XYY) are reported to have higher rates of mental retardation and a wide variety of psychiatric and behavioral symptoms, but these are a consequence primarily of the chromosomal abnormality rather than hypogonadism.

The evidence supporting testosterone replacement therapy in hypogonadal men is strong for body composition and sexual function. Questions remain about the value of testosterone replacement in age-related testosterone decline as well as in the treatment of depressive disorder in hypogonadal men. Testosterone does seem to improve mood, as well as sexual dysfunction and muscle strength, in hypogonadal men. However, results from multiple randomized controlled clinical trials are conflicting. Although data derived from androgen treatment trials and androgen replacement do not support testosterone treatment for major depressive disorder, the clinical impression is that, for some subthreshold depressive syndromes, testosterone may lead to antidepressant benefits (Amore et al. 2009). The risks associated with physiological doses of testosterone appear small. The possible increased risk of prostate cancer remains a concern, but little evidence is available to substantiate it.

Some studies have found that testosterone deficiency in women is associated with impaired sexual function, low

energy, and depression, but others have found testosterone levels inversely related to depression (Morsink et al. 2007). What level represents deficiency and the indications, risks, and benefits of replacement are even less well defined than in men (see Chapter 16, "Sexual Dysfunction").

Other Metabolic Disorders

Electrolyte and Acid–Base Disturbances

Hyponatremia and Hypernatremia

Hyponatremia's principal manifestations are neuropsychiatric, and their severity is related to both the degree and the rapidity with which it develops. Patients may have lethargy, stupor, confusion, psychosis, irritability, and seizures. Hyponatremia has many different causes, but those of particular psychiatric relevance include the syndrome of inappropriate antidiuretic hormone secretion (SIADH), which can be caused by many psychotropic drugs (especially carbamazepine and oxcarbazepine but also SSRIs, tricyclic antidepressants, and antipsychotics), and psychogenic polydipsia. Polydipsia leading to hyponatremia in patients with schizophrenia is mediated by a reduced osmotic threshold for the release of vasopressin and by a defect in the osmoregulation of thirst. Acute-onset symptomatic hyponatremia may require emergent treatment with hypertonic (3%) saline. In chronic cases, correction should be gradual to minimize the risk of pontine myelinolysis, relying on fluid restriction and vasopressin receptor antagonists (Siegel 2008).

The signs of hypernatremia are also predominantly neuropsychiatric and include cognitive dysfunction, delirium, seizures, and lethargy progressing to stupor and coma. Similar symptoms are seen with any hyperosmolar state, such as extreme hyperglycemia. Hypernatremia is usually caused by dehydration, with significant total body water deficits. A rare cause is adipsia, the absence of thirst even in the presence of water depletion or sodium excess, usually caused by a hypothalamic lesion (which may result in other psychopathology) (Floris et al. 2008).

Hypokalemia and Hyperkalemia

Hypokalemia produces muscular weakness and fatigue and, if severe, may cause severe paralysis (hypokalemic periodic paralysis), but central nervous system functions typically are not affected. Nevertheless, patients with symptomatic hypokalemia sometimes receive the misdiagnosis of depression. Hypokalemia is very common in eating disorders (see Chapter 14, "Eating Disorders," for full discussion of the metabolic complications of eating disorders), chronic alcoholism, and alcohol withdrawal. The adverse

effects of hyperkalemia are mainly cardiac, but severe muscle weakness also may occur.

Hypocalcemia and Hypercalcemia; Hypomagnesemia and Hypermagnesemia

Hypocalcemia and hypercalcemia were described earlier in this chapter in the "Parathyroid Disorders" section. Magnesium levels usually rise and fall in concert with calcium levels. Hypomagnesemia can cause anxiety, irritability, tetany, and seizures. Low magnesium levels are very common in alcoholic patients and in refeeding starving patients (including those with anorexia nervosa and catatonia). Cyclosporine causes hypomagnesemia, which can contribute to its neuropsychiatric side effects. Hypermagnesemia is much less common, usually resulting from excessive ingestion of magnesium-containing antacids or cathartics, and causes central nervous system depression.

Hypophosphatemia

Hypophosphatemia causes anxiety, hyperventilation, irritability, weakness, delirium, and, if severe, seizures, coma, and death, in addition to symptoms in many other organ systems. Hypophosphatemia occurs in the same settings as hypomagnesemia.

Acidosis and Alkalosis

Metabolic acidosis results in compensatory hyperventilation. When the acidosis is severe and acute, as in diabetic ketoacidosis, fatigue and delirium are present and may progress to stupor and coma. Acute metabolic acidosis is a complication of a wide variety of overdoses and toxic ingestions. Patients with chronic metabolic acidosis appear depressed, with prominent anorexia and fatigue. Patients with severe metabolic alkalosis present with apathy, confusion, and stupor. Respiratory acidosis results from ventilatory insufficiency, and respiratory alkalosis results from hyperventilation (see Chapter 19, "Lung Disease").

Vitamin Deficiencies

Deficiencies of vitamin B₁₂ and folate are discussed in Chapter 24, "Hematology."

Pellagra, originally thought to be a deficiency of niacin, is now recognized to be a complex deficiency of multiple vitamins and amino acids. The classic triad of symptoms is dermatitis, dementia, and diarrhea, but irritability, anxiety, depression, apathy, and psychosis all have been reported (Prakash et al. 2008). Pellagra is now rare in the developed nations, but cases are still reported in anorexia nervosa, inflammatory bowel disease, and alcoholism.

Thiamine deficiency (beriberi) causes cardiac and neuropsychiatric syndromes, including peripheral neuropathy

and Wernicke-Korsakoff encephalopathy. Wernicke's consists of vomiting, nystagmus, ophthalmoplegia, fever, ataxia, and confusion that can progress to coma and death. Korsakoff's is a dementia with amnesia, impaired ability to learn, confabulation, and often psychosis. Improvement usually occurs with thiamine replacement but may be slow. Giving intravenous glucose to a thiamine-deficient patient without coadministering thiamine may precipitate acute beriberi. Thiamine deficiency is well known and most frequent in alcoholic patients, but it also occurs in patients undergoing chronic dialysis, patients refeeding after starvation (including patients with anorexia nervosa), and individuals on fad diets.

Pyridoxine (vitamin B₆) deficiency causes peripheral neuropathy and neuropsychiatric disorders, including reports of seizures, migraine, chronic pain, depression, and psychosis. Homocysteine is elevated in B₆ deficiency and may play a role in accelerating vascular disease and dementia. Pyridoxine deficiency is common because many drugs act as its antagonist. Clinical trials of B₆ supplementation in healthy elderly and in cognitively impaired subjects to date have not shown improvements in mood or cognition.

Vitamin E deficiency can cause areflexia, ataxia, and decreased vibratory and proprioceptive sensation. Although several small studies have reported lower levels of vitamin E in major depression (e.g., Owen et al. 2005), a large epidemiological study in the elderly found no association between low vitamin E levels and depressive symptoms or major depression (Tiemeier et al. 2002). Clinical trials of vitamin E supplementation have not shown any benefit in cognitively impaired individuals.

Porphyrias

The porphyrias are a group of rare disorders of heme biosynthesis that can be inherited or acquired. Neuropsychiatric manifestations occur in the two neuroporphyrias (acute intermittent porphyria and plumboporphyria) and two neurocutaneous porphyrias (hereditary coproporphyria and variegate porphyria). Acute intermittent porphyria is the most common. Recurrent acute attacks are typical in all four, with variable manifestations. In acute porphyria, the cardinal signs are abdominal pain, peripheral neuropathy, and psychiatric symptoms, which can be the sole presenting symptoms, including anxiety, depression, psychosis, and delirium. Seizures, autonomic instability, dehydration, electrolyte imbalance, and dermatological changes also may occur. Symptoms may vary considerably among patients and in the same patient over time, and they can mimic symptoms of other psychiatric and medical disorders, making diagnosis a challenge. Stress has long been considered a precipitant of acute episodes, but data are lacking. The diagnosis is made by measuring porphyrins and their me-

tabolites in stool and urine during an acute episode. Between episodes, porphyrin levels return to normal. Diagnosis is more likely to be made when the clinician has a high index of suspicion. The diagnosis may be especially difficult because neuropsychiatric symptoms may continue well after the end of an acute episode (Millward et al. 2005). Therapy is primarily supportive and includes identification of precipitants. Although barbiturates clearly can trigger attacks, evidence is inadequate regarding the role of other psychotropic drugs. A comprehensive rating of drugs' risk for porphyrinogenicity is available at <http://www.drugs-porphyria.org>.

Other Genetic Metabolic Disorders

Inborn errors of metabolism usually presenting in neonates or young children may in rare cases first present in adolescence or adulthood as a psychiatric disorder. Such a possibility may be suspected because of family history or because psychiatric symptoms present as part of a more complex clinical picture with systemic, cognitive, or motor signs (Sedel et al. 2007). Such a diagnostic possibility also should be considered when a psychiatric disorder presents atypically with subtle "organic" signs and responds poorly to standard treatments. Some of these disorders present with acute and recurrent attacks of confusion, which may be misdiagnosed as acute psychosis. Examples include urea cycle disorders (e.g., ornithine transcarbamylase deficiency) and homocysteine remethylation defects (e.g., hyperhomocysteinemia). Others may produce chronic psychiatric symptoms (e.g., catatonia, hallucinations), including the homocystinurias, Wilson's disease, adrenoleukodystrophy, and some lysosomal disorders (e.g., Gaucher's disease). Mild mental retardation and late-onset behavioral or personality changes may be a manifestation of the homocystinurias, cerebrotendinous xanthomatosis, monoamine oxidase A deficiency, succinic semialdehyde dehydrogenase deficiency, and creatine transporter deficiency. Recognition of such disorders in an adult with only psychiatric symptoms may be very difficult, but earlier recognition and specific intervention can avert irreversible nervous system (and other organ) injury.

Conclusion

Endocrine and metabolic disorders frequently occur in conjunction with common psychiatric conditions. The causal linkages and mechanisms vary widely. In some situations, the endocrine state manifests in part as a psychiatric condition. In other instances, the psychiatric condition may be a complex biopsychosocial and/or biological response to the endocrine disorder. Psychiatric conditions

and their treatment may also increase risk of endocrine disorders. Moreover, treatment with psychotropic drugs can induce endocrinopathies. Consequently, understanding the ways in which these disorders intersect represents an important facet of knowledge for the practitioners treating psychiatric and/or endocrine disorders.

Oncology

Mary Jane Massie, M.D.

Kimberley Miller, M.D., F.R.C.P.C.

CANCER IS A MAJOR PUBLIC health problem in the United States, Canada, and other developed nations. In 2010, more than 1.5 million new cases of invasive cancer are expected to be diagnosed in the United States, and more than half a million people are expected to die of cancer (American Cancer Society 2010). Although one in four deaths is now caused by cancer, death rates from many cancers, including those of the prostate, breast, colon, and rectum, continue to decline because of new adjuvant therapies and the use of targeted therapies that attack cancer cells, leaving healthy cells intact. However, as the death rate decreases and the population ages, more people will be living with cancer, with an anticipated doubling from 1.3 million to 2.6 million between the years 2000 and 2050. Although only modest cancer-specific survival differences are evident for black and white patients receiving comparable treatment for similar-stage cancer, black patients still carry a higher burden because they often receive diagnoses at a later stage and have poorer survival within each stage. Unfortunately, black and Hispanic women and women younger than 60 years and older than 70 years often do not receive irradiation after limited resection for early-stage breast cancer, which leads to a higher local recurrence rate and possibly higher mortality (Friedman et al. 2008). Differences in exposure to risk factors, access to high-quality screening and treatment, stage at presentation, and mortality from other diseases represent the primary targets of research and interventions designed to reduce disparities in cancer outcomes (Bach et al. 2002).

The 2007 Institute of Medicine (IOM) report, *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs*, drew attention to the importance of health care providers discussing psychosocial issues with patients, recognizing psychiatric syndromes, linking patients to psychosocial health care providers, and following up on a plan to address patients' psychosocial needs.

In this chapter, we review psychological factors in cancer risk and progression, the most frequently encountered psychiatric disorders (depression, anxiety, and delirium) in adult cancer patients, psychiatric issues in specific cancers, psychiatric aspects of cancer treatments, psychiatric interventions in cancer patients, survivor issues, and cancer patients' use of complementary and alternative medicine treatments. See Chapter 34, "Pediatrics," for additional coverage of cancer in children.

Psychological Factors Affecting Cancer Risk and Progression

Studies examining the role that stress or psychological factors play in cancer onset, progression, and survival are numerous and have yielded conflicting results in all areas. Methodological differences, including study design and definitions of type of distress, as well as publication bias and the presence of multiple confounding factors are some of the limitations evident and contribute to many reviews recommending use of caution when interpreting

results. It also has been found that in community-based cohorts, study participants with cancer history may overestimate the association between distress and subsequent cancer mortality (Hamer et al. 2009). Although a recent review concluded that psychosocial factors have an adverse effect on cancer incidence and survival, it also noted that approximately 70% of studies reported a null effect (Chida et al. 2008). Another review of 70 studies did not find any psychological factors that convincingly influenced cancer development but “could not totally dismiss” helplessness and repression contributing to an unfavorable prognosis (Garssen 2004). More often than not, associations, rather than clear causality, are identified in studying psychological factors and cancer outcomes.

Although retrospective and case-control studies have suggested an association between severe stressors and cancer risk, larger prospective studies often have not found such an association. In 1,011 of 8,736 randomly selected Danish patients who subsequently developed cancer, the accumulation of stressful life events was associated with an unhealthy lifestyle but not an increase in cancer incidence (Bergelt et al. 2006). Similarly, certain personality traits have not been found to affect cancer risk directly or indirectly (through influence on health behavior) (Bleiker et al. 2008; Hansen et al. 2005). A prospective cohort study of 19,730 adults, with an average follow-up of 9 years, did not detect a significant association between anger control or negative affect and risk of breast cancer, melanoma, or total cancers but did identify weak associations in prostate (hazards ratio [HR] = 1.17), colorectal (HR = 1.14), and lung cancer (HR = 1.24) (White et al. 2007). In evaluating the effect of psychological distress on cancer outcome, some have suggested that associations between patients' self-ratings on distress scales and survival may reflect patients' perception of their disease status rather than a causal effect of distress on the cancer process (Groenvold et al. 2007). Attempts to control for disease status have yielded both positive (Groenvold et al. 2007) and negative (Coates et al. 2000) results in linking distress with cancer outcome.

The evidence associating depression with cancer incidence is weaker than that for cancer progression (Spiegel and Giese-Davis 2003), although the literature has included contradictory and inconclusive results in both. Depressive symptoms were associated with a higher-than-normal frequency of cancer and twice as high a risk for death from cancer in an early large epidemiological study (Persky et al. 1987; Shekelle et al. 1981). Later epidemiological studies and a meta-analysis did not find statistically or clinically significant associations (Archer et al. 2008; Gallo et al. 2000; McGee et al. 1994). A review of depressive symptoms and the prospective incidence of colorectal adenomas and cancer in more than 80,000 women

enrolled in the Nurses' Health Study showed that women with the highest levels of depressive symptoms had elevated risk of colon cancer but not colorectal adenomas (Kroenke et al. 2005). A “small and marginally significant association” (relative risk [RR] = 1.12) between depression and subsequent overall cancer risk was found in a 2007 review, which included 13 studies (Oerlemans et al. 2007).

Mixed results also have been found when examining the possible link between depression and cancer mortality (Coyne et al. 2007; Garssen and Goodkin 1999; Watson et al. 1999). A population-based epidemiological study that included data on 10,025 patients followed up over an 8-year period found that those with cancer and depression had a higher risk of death from all causes than did those with either condition alone (Onitilo et al. 2006). Although depression did not affect survival in pancreatic cancer (Sheibani-Rad and Velanovich 2006), Steel et al.'s (2007) prospective study of 101 patients with hepatobiliary cancer showed that patients with depression, which was present in one-third of patients, had a significantly shorter survival time. Declines in natural killer cell activity were associated with shorter survival (Steel et al. 2007). In a comprehensive review of the effect of the comorbidity of cancer and depression, Archer et al. (2008) concluded that both behavioral (e.g., smoking, alcohol use in head and neck cancer) and biological factors (e.g., cytokines and the stress-hormone axis) contribute to the negative effect. Lutgendorf et al. (2008) reported significant correlation between interleukin-6, cortisol, and vegetative components of depression in women with advanced-stage ovarian cancer. Depression also may affect the course of illness in patients with cancer through its effect on poorer pain control, poorer treatment adherence, and less desire for life-sustaining therapy. Although it remains unclear if alleviating cancer patients' psychological distress will prolong their survival, it is prudent to intervene to improve quality of life and ensure optimal treatment adherence.

Psychiatric Disorders in Cancer Patients

A person's ability to manage a cancer diagnosis and treatment commonly changes over the course of the illness and depends on medical, psychological, and social factors: the disease itself (i.e., site, symptoms, clinical course, prognosis, type of treatments required); the prior level of adjustment; the threat that cancer poses to attaining age-appropriate developmental tasks and goals (i.e., adolescence, career, family, retirement); cultural, spiritual, and religious attitudes; the presence of emotionally supportive persons; the potential for physical and psychological reha-

bilitation; the patient's own personality and coping style; and experience with loss.

Depression

Depressive symptoms in the cancer patient may occur as part of adjustment to different phases of illness (e.g., diagnosis, initiation and completion of treatment, survivorship, recurrence, palliation) or be caused by the cancer itself (e.g., primary or secondary brain tumors) and its related symptoms (e.g., fatigue or pain) and treatments (e.g., exogenous cytokines, corticosteroids). Those with a preexisting history of major depression are at increased risk for a depressive recurrence during their cancer experience. In other words, depressive symptoms may represent a normal reaction, a psychiatric disorder, or a somatic consequence of cancer or its treatment.

Cancer is associated with a rate of depression that is higher than that in the general population and at least as high as the rate associated with other serious medical illnesses (Massie 2004). In patients with cancer, depression has been studied with a range of assessment methods (Härter et al. 2001; Trask 2004), including self-report, brief screening instruments, and structured clinical interviews. Reports of prevalence of depression in cancer are highly variable, given the lack of standardization of methodology and diagnostic criteria used. In more than 150 studies, Massie (2004) found that major depression occurred in 0%–38% of cancer patients and that depression spectrum syndromes occurred in 0%–58%. A clinical rule of thumb is that 25% of cancer patients will likely be depressed enough at some point in the course of disease to warrant evaluation and treatment.

Emotional distress is often not recognized by oncology professionals (Söllner et al. 2001), resulting in distress screening initiatives being developed in many countries. These typically advocate for a two-stage process, involving an initial self-report scale, followed by a diagnostic interview (which remains the gold standard in assessing depression) for those patients reaching a predetermined cutoff score on the screening instrument. The single-item Distress Thermometer compares favorably (Jacobsen et al. 2005) with multiple-item measures, including the 18-item version of the Brief Symptom Inventory (BSI-18; Derogatis 2000) and the 14-item Hospital Anxiety and Depression Scale (Zigmond and Snaith 1983), all of which have been evaluated and identified as useful in screening for distress in cancer patients. Other instruments to screen for distress specific to cancer patients also have been developed (e.g., Herschbach et al. 2004).

Many of the somatic symptoms caused by cancer or its treatment overlap with the diagnostic criteria for major depression, including disturbances in sleep, appetite, en-

ergy, psychomotor activity, and concentration. Emphasis on exploring the psychological symptoms of depression (depressed mood, anhedonia, guilt, worthlessness, hopelessness, helplessness, and suicidal ideation) may be a helpful clinical approach. Hypoactive delirium may resemble depression because the patient may be less engaged, may be less motivated to participate in his or her care, and may even voice suicidal ideation. Differentiating between delirium and depression is extremely important, given the differences in causes, risks, and interventions. See Chapter 5, "Delirium," for a more thorough review. Poorly controlled pain, fatigue, or anorexia-cachexia syndrome also may present with a depressive component.

In cancer patients, risk factors for the development of depression have been found to include younger age, poor social support, and advanced disease. The predominance of women developing major depression seen in the general population does not consistently occur in the oncology setting (Pirl 2004; Rodin et al. 2007a; Strong et al. 2007). The role of specific tumor sites in contributing to emotional distress has conflicting results. Strong et al. (2007) did not find cancer diagnosis to be a predictor for distress, whereas Carlson et al. (2004) found that patients with Hodgkin's disease or lung, pancreatic, head and neck, and brain cancer were most distressed, which is consistent with another large study examining distress by cancer site (Zabora et al. 2001). A strong relation has been found between disease burden (especially pain and fatigue), perceived social support, and insecure attachment style in patients with metastatic cancer (Rodin et al. 2007b). A study in 2,595 early-stage breast cancer patients found that stressful life events, less optimism, ambivalence over expressing negative emotions, sleep disturbance, and poorer social functioning better predicted risk for depression than did cancer-related variables (Bardwell et al. 2006). Biopsychosocial risk factors most commonly associated with depression in cancer are listed in Table 23-1.

Several barriers to the diagnosis of depression in cancer patients exist (Greenberg 2004). At the physician level, difficulty distinguishing somatic symptoms related to cancer and its treatment from depression, as well as uncertainty about the effectiveness of psychosocial interventions, may contribute to fewer referrals for psychosocial services. Lack of access to and poor patient awareness of psychosocial services are additional barriers. At the patient level, reluctance to report depressive symptoms may be related to a fear of psychiatric medication side effects, stigma about psychosocial support, perceived repercussions of expressing "negativity" on the course of the cancer, and social and cultural differences in expression of distress (Söllner et al. 2001). Recognizing and treating depression are essential not only for the patient but also for the patient's

TABLE 23-1. Biopsychosocial risk factors most commonly associated with depression in cancer

Biological	Psychological	Social
Younger age	Relationships	Low supports
Family history of depression	Perceived low supports	Poorer social functioning
Personal history of depression	Anxious or avoidant attachment	Recent loss
Cancer-related factors	Attitudes	Stressful life events
Advanced disease	Less optimism	History of trauma or abuse
Low performance status	Ambivalence in expressing emotions	Substance use disorder
Physical burden (pain, fatigue)	Low self-esteem	
Tumor site (?pancreas, head and neck, lung, brain, Hodgkin's disease)		
Treatment (see Table 23-2)		

loved ones. A recent multinational study of cancer patients and their children showed that depression in a parent (the cancer patient or the patient's partner) is significantly associated with impairment in family functioning (Schmitt et al. 2008).

Suicide and Desire for Hastened Death

Although suicide accounts for a very low number of deaths in cancer patients, an elevated risk has been consistently found. In the United States, a large retrospective cohort study comparing cancer patients with the general population reported that patients with cancer had nearly twice the incidence of suicide (Misono et al. 2008). Higher suicide rates were associated with male gender, white race, and older age at diagnosis. Highest suicide rates were observed in cancers of the respiratory system, stomach, and head and neck. In the United Kingdom, almost 8% of 2,924 outpatient cancer patients had thoughts of being "better off dead" or of hurting themselves in some way in the previous 2 weeks (Walker et al. 2008). Clinically significant emotional distress and substantial pain (and, to a lesser extent, older age) were associated with these thoughts. Desire for hastened death has been positively associated with hopelessness, depression, and higher physical distress and negatively with physical functioning, spiritual well-being, social support, and self-esteem (Chochinov et al. 1998; Rodin et al. 2007c). Those closer to death have been found to express desire for hastened death more commonly (17%) than do those with a prognosis of greater than 6 months (2%) (Chochinov et al. 1998; Rodin et al. 2007c). Understanding the complex contributing factors in a patient with desire for hastened death can aid in differentiating a depressive illness from a desire to have control over intolerable symptoms, or even death acceptance (see also Chapter 9, "Suicidality," and Chapter 41, "Palliative Care").

erable symptoms, or even death acceptance (see also Chapter 9, "Suicidality," and Chapter 41, "Palliative Care").

Anxiety

Anxiety is a normal response to threat, uncertainty, and loss of control. It is common as patients face the existential plight of cancer and the specific threats of deformity, abandonment, pain, or death. The diagnosis and treatment of cancer are stressful and often traumatic. After the initial shock and disbelief of diagnosis, patients typically feel anxious and irritable. They may experience anorexia, insomnia, and difficulty with concentration because they are distracted by intrusive thoughts about their prognosis. Often this acute anxiety dissipates as a treatment plan is established and prognosis clarified. Anxiety is common at crisis points such as the start of a new treatment or the diagnosis of recurrence or illness progression, but it also occurs before routine follow-up visits without evidence of disease.

Specific phobias, panic disorder with or without agoraphobia, generalized anxiety disorder, and posttraumatic stress disorder (PTSD) are the most commonly reported anxiety disorders in cancer patients (Roy-Byrne et al. 2008), and patients frequently present with anxious symptoms in the context of adjustment disorders. In a cross-sectional observational study of 178 patients with cancer, almost half had significant anxiety symptoms, but the rate of anxiety disorders was 18%, comparable to that in the general population. In this study, female gender and poor support systems were correlated with anxiety disorders (Stark et al. 2002). In 1,408 testicular cancer survivors, anxiety disorders correlated with younger age at follow-up, relapse anxiety, psychiatric treatment, peripheral neu-

ropathy, alcohol abuse, economic problems, and sexual dysfunction (Dahl et al. 2005).

Some forms of anxiety can affect a patient's adherence to treatment. Patients with claustrophobia may have difficulty tolerating magnetic resonance imaging (MRI) scans, radiation therapy, or placement in isolation because of neutropenia. Needle phobia and other health-related phobias (see Chapter 11, "Anxiety Disorders") may delay or prevent patient adherence to recommended chemotherapeutic and/or surgical treatments.

PTSD has been reported to occur in 4%–6% of cancer patients (Kangas et al. 2002; Mehnert and Koch 2007), with more patients experiencing subsyndromal episodes of intrusive thoughts, avoidance, or hypervigilance (Jim and Jacobsen 2008). Intrusive thoughts in cancer patients may be focused on past events, including disclosure of diagnosis and traumatic treatment experiences, or on anticipatory fears of cancer recurrence. Reminders of the traumas of cancer can provoke anxiety and physiological arousal. A sample of women 2 years after diagnosis of stages I to III breast cancer had heightened arousal (as measured by skin conductance, heart rate, and facial muscle electrical activity) during mental imagery of the traumatic event as they listened to their own narrative of their two most stressful experiences associated with breast cancer. Breast cancer-specific posttraumatic stress symptoms were noted in 24%, but only 9% reported full PTSD. Those with the strongest responses had current PTSD, and most had comorbid major depressive disorder (Pitman et al. 2001).

Risk factors for posttraumatic stress in cancer patients include perception of cancer as threatening, trauma history, younger age, less social support, and more difficult interactions with medical staff (Jim and Jacobsen 2008). Medical sequelae of cancer treatment (e.g., paresthesias because of nerve injury) may act as a trigger for traumatic memories of treatment (Kornblith et al. 2004). The importance of exploring both patient and caregiver distress was highlighted in a study of 168 non-genetically related patient-caregiver dyads, in which the presence of anxiety disorder in one partner (patient or caregiver) was associated with a greater likelihood of anxiety disorder in the other (Bambauer et al. 2006). In recent years, improved antiemetic treatments have reduced the number of patients who vomit as a result of chemotherapy, but nausea is still common (Hickok et al. 2003). Anxiety related to nausea and vomiting from highly emetogenic chemotherapy may develop into a conditioned response, which may persist after cessation of treatment (Bovbjerg 2006).

Evaluation of acute anxiety in cancer patients includes consideration of conditions that mimic anxiety disorders. Antipsychotics, as well as antiemetic phenothiazines (prochlorperazine, perphenazine, promethazine) or metoclo-

pramide, may cause akathisia. Akathisia's inner feeling of restlessness is frequently misperceived by patients and misdiagnosed by caregivers as anxiety. The abrupt onset of anxiety and dyspnea may signal pulmonary emboli, which are common among cancer patients. Hypoxia related to primary or secondary lung cancer may cause significant anxiety. The experience of severe, intermittent, or uncontrolled pain is associated with acute and chronic anxiety, and the patient's confidence that he or she has the analgesics to control pain alleviates anxiety. Furthermore, anxiety amplifies pain, and the drive behind additional requests for analgesia may be anxiety rather than somatic pain (see also Chapter 11, "Anxiety Disorders," and Chapter 36, "Pain").

Mania

In cancer patients, corticosteroids are the most common reason for hypomania or mania (corticosteroid psychiatric side effects are discussed in detail in Chapter 25, "Rheumatology"). Steroids are commonly given as a component of chemotherapy for lymphoma and multiple myeloma, as an antiemetic or to prevent hypersensitivity reactions with chemotherapy, to reduce cerebral or spinal edema, or to prevent cerebral edema during cranial radiation therapy. Lower doses of corticosteroids also may be used in palliative care to improve appetite, energy, and general well-being. Full-blown manic episodes are rare. In a study of dexamethasone prophylaxis for emesis caused by chemotherapy, the psychological symptoms most commonly reported by patients were insomnia and agitation (Vardy et al. 2006). Although it is more commonly associated with depression, interferon-alpha also has been associated with mania and mixed affective syndromes (Greenberg et al. 2000). Diencephalic tumors are a rare cause of secondary mania (see also Chapter 10, "Psychosis, Mania, and Catatonia").

Delirium

The prevalence of delirium in cancer patients has been reported as 5%–30%, as up to 25%–50% on hospital admission, and as high as 85% in the terminal stages of illness. Advanced age, possible preexisting dementia, and malnutrition are predisposing factors for delirium in cancer, and potential precipitants include intracranial disease, medications, and systemic disease (e.g., organ failure, infection, and hematological or metabolic abnormalities). One study found that a median of three (range = 1–6) precipitants contributed to a delirious episode (Lawlor 2002). In a review of hospitalized cancer patients, daily doses of benzodiazepines greater than 2 mg of lorazepam equivalents, corticosteroids greater than 15 mg of dexamethasone equivalents, or opioids greater than 90 mg of morphine equivalents were associated with an increased risk of delirium (Gaudreau et al. 2005). A follow-up study to evaluate the risk of these medi-

cations found that opioids affected longitudinal risk of delirium but corticosteroids and benzodiazepines did not (Gaudreau et al. 2007). Delirium is associated with greater morbidity and mortality in patients and greater distress in patients, their families, and caregivers.

Early symptoms of delirium are often unrecognized or misdiagnosed by medical or nursing staff because of fluctuation in presentation, presence of a hypoactive subtype of delirium, and lack of mental status examination of the patient. Delirium is frequently misdiagnosed as dementia, depression, anxiety, or other psychiatric disorders. Early recognition of delirium is essential because the etiology may be a treatable complication of cancer or its treatment. In addition to the general causes of delirium (see Chapter 5, "Delirium"), there are particular considerations in cancer patients. Primary brain tumor and brain metastases (especially common with lung and breast cancer) can cause delirium. Immunosuppressed cancer patients, particularly those with hematological malignancies, are at high risk for opportunistic infections. Head and neck cancer patients undergoing surgery are at high risk for delirium because of their older age and high prevalence of alcohol abuse and withdrawal. Several antineoplastic agents (e.g., cytarabine, methotrexate, ifosfamide, asparaginase, procarbazine, and fluorouracil) and immunotherapeutic agents (e.g., interferon and interleukins) can cause delirium and other alterations in mental status (Table 23-2) (Kannarkat et al. 2007; Minisini et al. 2008). Some antibiotics (e.g., quinolones) and antifungals (e.g., amphotericin B), as well as opioids, anticholinergics, and nutritional deficiencies, can cause delirium. Hypercalcemia causes delirium in patients with bone metastases or ectopic parathyroid hormone production. Hyperviscosity syndrome with lymphoma, Waldenström's macroglobulinemia, and myeloma are unusual causes of delirium. Thromboembolic events involving the central nervous system (CNS) also may contribute to acute, subacute, or delayed mental status changes. L-Asparaginase, thalidomide, tamoxifen, and erythropoietin all have been associated with the development of cerebral venous thrombosis (Minisini et al. 2008). Rare autoimmune encephalopathies resulting from paraneoplastic syndromes (Lieberman and Schold 2002) manifest with cognitive impairment and delirium. Limbic encephalopathy (or encephalitis) is a specific type of autoimmune encephalopathy most often reported with small-cell carcinoma of the lung but uncommonly with many other malignancies. Limbic encephalopathy may present with impaired memory, fluctuating mood, and seizures (Kung et al. 2002), as well as a wide variety of psychiatric symptoms including anxiety, depression, schizophreniform or manic psychosis, and personality change (Foster and Caplan 2009) (see also Chapter 32, "Neurology and Neurosurgery").

Chapter 5, "Delirium," and Chapter 41, "Palliative Care," review the general management of delirium. Of special note in the oncology setting is the use of methylene blue (50 mg slow intravenous push or orally every 4-6 hours until recovery) to treat ifosfamide-induced encephalopathy, although controlled trials are lacking (Brunello et al. 2007).

Interplay of Physical and Psychological Symptoms in Cancer Patients

Pain

Pain is a highly prevalent symptom in cancer, and for those not experiencing pain, it is often a commonly feared future symptom. Pain may be a sign of progression of disease, which can contribute to significant distress. Depression and anxiety are very common in cancer patients with severe pain. In a recent systematic review of cancer pain and depression, a statistically significant association between pain and depression was found in 9 of 14 studies, although none of the studies examined a causal relation (Laird et al. 2009). Pain intensity and its effect on enjoyment of life were related to depression.

The psychiatric symptoms of patients who are in significant pain should initially be considered a consequence of uncontrolled pain. Acute anxiety, depression with despair (especially when the patient believes the pain means disease progression), agitation, irritability, lack of cooperation, anger, and insomnia all may accompany pain. Such symptoms usually should not be diagnosed as a psychiatric disorder unless they persist after pain is adequately controlled. Although antidepressants have been studied more often in the nonmalignant pain population, their use as adjuvant analgesics in the management of neuropathic pain in cancer has been recommended, especially for those with comorbid depression. The tricyclic antidepressants (TCAs) and the serotonin-norepinephrine reuptake inhibitors (SNRIs) venlafaxine and duloxetine are most effective, with a possible role for bupropion (McDonald and Portenoy 2006). No evidence indicates increased risk of abuse or addiction in cancer patients receiving opioids. In fact, many patients associate the narcotics with the unpleasant aspects of the illness and avoid them after their recovery (pain management is discussed in full in Chapter 36, "Pain").

Cancer-Related Fatigue

Cancer-related fatigue refers to a pervasive feeling of tiredness, weakness, or lack of energy, related to cancer or its treatment, that is not relieved by rest. Anticancer treatments, including surgery, chemotherapy, radiation, bio-

logical response modifiers, hormones, and hematopoietic stem cell transplants, all may contribute to cancer-related fatigue. Prue et al. (2006) reported that 39%–90% of patients who are undergoing cancer treatment and 19%–38% of patients who have completed active treatment will experience fatigue. Common causes of cancer-related fatigue are listed in Table 23-3. Proposed neurobiological mechanisms have been reviewed by others (Levy 2008; Ryan et al. 2007; Schubert et al. 2007) and include serotonin dysregulation, abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis, circadian rhythm disruption, muscle metabolism or adenosine triphosphate dysregulation, vagal afferent nerve activation, and prolonged inflammatory response involving cytokines (Stone and Minton 2008). Comorbid conditions including anemia, cachexia, pain, depression, and sleep disorders also may contribute to cancer-related fatigue.

Psychiatrists play an important role in the treatment of comorbid psychiatric illnesses while being aware of the potential contribution of sedative-hypnotics and other psychotropic medications to cancer-related fatigue. A recent Cochrane review (Minton et al. 2008) examining drug therapy for cancer-related fatigue found that methylphenidate was superior to placebo, but only two studies, combining 264 patients, met criteria for inclusion, highlighting the relative dearth of evidence in this area. Preliminary results from four studies, including a large randomized, placebo-controlled, double-blind trial of 642 patients, showed the benefit and safety of modafinil in the treatment of cancer-related fatigue (Cooper et al. 2009). Some patients who have persistent fatigue with progressive disease or after cancer treatment respond well to low-dose psychostimulants such as methylphenidate or modafinil and do not need increased doses over time (Carroll et al. 2007). Data are conflicting about the usefulness of exercise programs and psychosocial interventions to decrease cancer-related fatigue. A Cochrane review identified lim-

ited evidence that psychosocial interventions improve cancer-related fatigue during cancer treatment. However, interventions specifically targeting fatigue have yielded more positive results, through assisting patients with their coping and activity management as well as educating them about fatigue (Goedendorp 2009). A meta-analytic review showed that psychosocial interventions may be most useful when applied after the completion of cancer therapy, and exercise interventions may be most useful when applied concurrent with therapy (Kangas et al. 2008). Segal et al. (2009) found in a randomized controlled trial that resistance and aerobic exercise mitigated fatigue in men with prostate cancer who were receiving radiotherapy. Dy et al. (2008) described evidence-based recommendations for screening for, treating, and following up cancer fatigue, anorexia, depression, and dyspnea.

Anorexia-Cachexia Syndrome

Cachexia in cancer patients is debilitating and life-threatening. It is associated with anorexia, fat and muscle wasting, weakness, decreased quality of life, and psychological distress. The causes of cachexia are gastrointestinal (GI) dysfunction, altered metabolism and host response to cancer (cytokine production), hormone production by tumors, and anticancer treatments (Bennani-Baiti and Davis

TABLE 23-4. Causes of cancer anorexia-cachexia syndrome

Gastrointestinal dysfunction

- Mechanical obstruction from tumors of mouth, esophagus, stomach, gastrointestinal tract
- Extrinsic pressure from metastatic disease

Anticancer treatment

- Change in food smell or taste (food aversions): dysosmia, dysgensia
- Nausea, vomiting, mucositis

Altered (hyper) metabolism

- Carbohydrate
- Lipid
- Protein

Host response to cancer

- Cytokine production
 - Tumor necrosis factor, interleukin-1, interleukin-6, interferon

Psychological factors

- Depression
- Anxiety
- Preexisting eating disorder
- Conditioned responses

2008; Inui 2002) (Table 23-4). Anorexia-cachexia drug treatment trials and laboratory-based studies have been summarized by others (Loprinzi et al. 2007).

Anorexia may be the result of depression or anxiety. Preexisting eating disorders complicate nutritional management in cancer patients. Treatments of anorexia and cachexia in cancer patients are shown in Table 23-5.

Psychiatric Issues in Specific Cancers

Prostate Cancer

The prostate is the most common site of cancer in men in the United States. In 2010, an estimated 217,730 new cases will be diagnosed (American Cancer Society 2010). No high-risk prostate cancer-specific genes have been identified; however, *BRCA2* confers a risk of prostate cancer that is 20 times that of the general population (Foulkes 2008). In general, although the reaction of men with prostate cancer depends on age, marital status, recent losses, and social support, older men are less likely to seek or accept intervention for emotional distress.

Routine screening for prostate cancer with the serum prostate-specific antigen (PSA) test has "a modest effect on

prostate cancer mortality” and a substantial risk of over-diagnosis and treatment (Barry 2009). A recent study of anxiety in 1,781 Swedish men who had elevated PSA levels showed that severe anxiety while waiting for PSA results affected only a small group of susceptible men (Carlsson et al. 2007). Anxiety surrounding each PSA test may be greater in spouses than in patients (Kornblith et al. 1994).

It is difficult to distinguish indolent forms of prostate cancer that will not affect the quality or length of patients’ survival from more lethal varieties. It is also difficult to assess the relative risk of treatment complications that may significantly impair quality of life. Controversy among clinicians about primary treatment for early-stage cancer (nerve-sparing radical prostatectomy vs. radiation therapy) or active surveillance creates uncertainty and makes treatment decisions difficult. Counseling assists patients with these choices by considering the extent of disease, age of patient, life expectancy, expense, and geography, and the choices are often based on the potential side effects (e.g., impotence, urinary incontinence, and bowel problems). In general, men undergoing surgery, older men, and men with less serious disease have less mental distress (Litwin et al. 2002).

Men who are reluctant to participate in individual therapy may agree to participate in national psychoeducational or support groups (US Too, Man to Man, MaleCare) and may use other sources of information about the illness, treatment options, and maintenance of good quality of life (Roth et al. 2008). However, many men describe participation in support groups as stigmatizing (B.A. Weber and Sherwill-Navarro 2005). Because many men and their partners develop sexual difficulties in response to erectile dysfunction, which occurs in many men after prostatectomy, radiation treatment, and hormonal therapies, sex therapy for the couple aimed at exploring new sexual possibilities and restoring intimacy can be helpful (Wittmann et al. 2009).

In prostate cancer patients, the most important risk factor for the development of major depressive disorder is a history of depression (Ingram et al. 2003; Pirl et al. 2002). Androgen deprivation therapy by orchiectomy or chronic administration of gonadotropin-releasing hormone agonists may cause hot flashes, reduced libido, erectile dysfunction, fatigue, anemia, decreased muscle mass, and osteoporosis. Men with prostate cancer who received androgen deprivation therapy reported poorer quality of life compared with men who underwent any prostate cancer treatment without hormonal treatment (Wei et al. 2002). A recent prospective cohort study showed that anxiety about cancer “independently and robustly” predicted earlier start of androgen deprivation therapy in older men with biochemical recurrence, although life expectancy may

not change and quality of life may be negatively affected (Dale et al. 2009). Analysis of a sample culled from tumor registries of more than 50,000 men who had survived at least 5 years found that the risk of developing a depressive or cognitive disorder diagnosis after androgen deprivation therapy was no higher than in men who had not received androgen deprivation therapy when tumor characteristics, age, and other factors were controlled (Shahinian et al. 2006). However, the incidence of suicide in older men with prostate cancer has been reported to be 4.24 times that of an age- and gender-specific cohort (Llorente et al. 2005). In this study, depression, recent cancer diagnosis, pain, and foreign birth were risk factors for suicide. Fatigue, a common side effect of irradiation for prostate cancer, may be helped by resistance and aerobic exercise (Segal et al. 2009).

Breast Cancer

Breast cancer is the most common cancer in women, second only to lung cancer in cancer deaths in women. In 2010, an estimated 207,090 new cases of invasive breast cancer and more than 54,000 new cases of in situ breast cancer will be diagnosed in the United States. More than 40,000 men and women are expected to die of breast cancer in 2010 (American Cancer Society 2010). The number of women diagnosed with breast cancer has decreased as a result of the decline in the use of hormone replacement therapy in postmenopausal women, and the modest improvement in the death rate is probably attributable to successful treatment of cancers diagnosed at an early stage (Robbins and Clark 2007). More than 85% of women diagnosed with stage I cancers (small cancers confined to the breast) will be alive 5 years later. Survival drops dramatically when cancers are diagnosed at later stages.

Although only 5% of breast cancer occurs in women younger than 40 years, a disproportionately large number of younger women seek psychiatric consultation regarding treatment options; sexual side effects of treatments; fertility concerns; self- and body-image issues; prophylactic contralateral mastectomy; genetic testing; and the effects of cancer on relationships, children, and career.

Treatment and Side Effects

The treatments of breast cancer include surgery, irradiation, chemotherapy, antiestrogen therapy (tamoxifen; raloxifene; aromatase inhibitors such as anastrozole, letrozole, and exemestane), and zoledronic acid, a bisphosphonate. Local control is still critical; the size, location, and aggressiveness of the tumor usually dictate the initial surgery (mastectomy vs. limited resection). Use of sentinel-node mapping reduces, but does not eliminate, the risk of developing unsightly and, at times, disabling lymphedema. Although many women now have a choice between mastec-

tomy and limited resection, mastectomy is preferred by an increasing number of women because it offers “peace of mind” and avoidance of irradiation (Collins et al. 2009; Throckmorton 2009). Natural tissue or silicone or saline implant breast reconstruction techniques provide satisfactory to excellent results for women eligible for reconstruction (Cordeiro 2008). Involvement of the patient’s husband or partner in preoperative medical appointments, in viewing of the scar, and in discussions about resuming sexual activity is helpful for optimal recovery. Phantom breast syndrome, distinct from postmastectomy pain syndrome, has been described in breast cancer patients who have undergone mastectomies. Spyropoulou et al. (2008) recently found that 22.9% of 105 women after modified radical mastectomy experienced phantom breast syndrome, which was associated with higher Zung Self-Rating Depression Scale scores and younger age.

Chemotherapy with alkylating agents can cause alopecia, ovarian failure, premature menopause (Schover 2008), decline in cognitive function, and weight gain (Hayes 2007). Taxanes can cause painful and disabling peripheral neuropathy, arthralgia or myalgia, and depression (Thornton et al. 2008). Antiestrogen therapy is prescribed over a period of years and may cause insomnia, hot flashes, irritability, and depression in some women (Duffy et al. 1999). Despite early concerns, a large placebo-controlled retrospective cohort study of women with breast cancer concluded that tamoxifen does not increase the risk for developing depression (Lee et al. 2007). An individual patient pooled analysis found that newer antidepressants and gabapentin reduced hot flashes within 4 weeks of initiating treatment by 3%–41% compared with placebo. Venlafaxine (75 mg/day) and paroxetine (10–25 mg/day) are more effective than sertraline (50–100 mg/day) or fluoxetine (20 mg/day) (Henry et al. 2008). However, because tamoxifen requires metabolism by cytochrome P450 (CYP) 2D6 to its active metabolite, paroxetine, fluoxetine, duloxetine, bupropion, and other CYP 2D6 inhibitors should be avoided during tamoxifen therapy (Goetz et al. 2007). Gabapentin (900–2,400 mg/day) reduced hot flashes by 35%–38% compared with placebo. Other options for hot flashes include clonidine, which is less effective, and megestrol acetate, whose safety in this population is unclear. Hot flashes are also an issue for men on androgen deprivation treatment regimens, although much less evidence exists to guide treatment decisions. Zoledronic acid, which is used both to prevent osteoporosis and to treat bone metastases, can cause bone pain, arthralgia, and emotionally devastating osteonecrosis of the jaw. Aromatase inhibitors, which interfere with the body’s ability to produce estrogen, are used to treat breast cancer in postmenopausal women; however, they cause loss of bone density, which is a

significant problem for women who already have osteoporosis or osteopenia,

Many women undergoing chemotherapy report difficulty with concentration and memory, but these reports do not correlate consistently with persistent deficits on neuropsychological testing (see “Survivor Issues” section later in this chapter).

Psychological distress is common at the conclusion of breast cancer treatment. Women who had more physical symptoms or side effects from treatment have great post-treatment distress (Jim et al. 2007). Many feel vulnerable and less protected when not being seen regularly by their oncologist; thus, increased physician visits and emotional support at this time are often beneficial. Ganz et al. (1996) found that survivors appear to attain maximum recovery from the physical and emotional trauma at 1 year after breast surgery. Sexual problems are important to address after acute treatment (see Chapter 16, “Sexual Dysfunction”).

The emotional burden of breast cancer treatment is high, particularly for young women who hope to become pregnant. Although evidence indicates that breast cancer diagnosed during lactation increases the risk of death from breast cancer (Stensheim et al. 2009), no evidence indicates that pregnancy affects the outcome of breast cancer. However, continuation or elective termination of pregnancy is a consideration for some who receive their diagnosis very early in a pregnancy and are unwilling to postpone treatment with teratogenic alkylating agents. Most young women, even women who are considered to have a good prognosis and are likely cured by initial treatments, ponder the ramifications of adoption or future childbearing, taking into account the unpredictability of disease recurrence or progression.

Breast Cancer in Men

Breast cancer in men is rare, and in one cross-sectional survey of 161 men, the prevalence of anxiety and depressive symptoms was low (Brain et al. 2006). However, use of avoidant coping strategies, negative body image, feelings of fear and uncertainty, and unmet informational needs were risk factors for traumatic stress symptoms. Men, like women, may benefit from counseling and support.

Genetics

The two most significant risk factors for breast cancer are increasing age and family history. Fewer than 10% of breast cancers result from hereditary mutations in single dominant genes. However, women with mutations in *BRCA1* and *BRCA2* genes have a 30 times greater risk of developing breast cancer compared with the risk in other women (Antoniou et al. 2003). Of all ovarian cancer, 10% is a result of *BRCA1* and *BRCA2* mutations. The risk of developing con-

tralateral breast cancer in *BRCA1* and *BRCA2* mutation carriers is high at 3% per year, leading to referral of women for MRI and consideration of prophylactic mastectomy (Foulkes 2008). Now that gene testing is available, women who likely have a hereditary predisposition are first referred for consultation with a clinical geneticist, which includes preparing a pedigree, documenting cancer diagnoses, estimating cancer risks, and discussing options for genetic testing and cancer screening and prevention (Robson and Offit 2002). Women who have positive test results for a gene mutation are advised to enroll in a high-risk surveillance clinic where they will receive information about chemoprevention and the potential effectiveness of risk-reducing surgery. Bilateral prophylactic mastectomy is associated with a greater than 90% reduction in the incidence of breast cancer in women with a family history of breast cancer (Hartmann et al. 1999). Risk-reducing salpingo-oophorectomy, usually performed laparoscopically as an ambulatory procedure, reduces breast cancer risk by 50% in *BRCA1* mutation carriers and prevents 80% of ovarian cancer in women with *BRCA1* and *BRCA2* mutations (B.L. Weber et al. 2000).

In some cancer centers, psychiatric consultation is an essential part of the evaluation process. The components of a thorough evaluation of women considering prophylactic surgery have been described (Massie and Greenberg 2005). Some women at high risk choose to have prophylactic mastectomy or risk-reducing salpingo-oophorectomy in the absence of genetic testing. In this case, psychiatric evaluation should be a standard component of the surgical evaluation. The women who later express regret about having had prophylactic mastectomy are those who feel that the decision to have surgery was driven by their surgeon (Payne et al. 2000). A prospective study of women who underwent bilateral mastectomy showed that anxiety decreased after surgery and social activities improved. Sexual pleasure was rated lower 1 year after surgery, and nearly half of the 90 women studied were more self-conscious and felt less sexually attractive (Brandberg et al. 2008). Similarly, mental distress is reduced in women who have risk-reducing salpingo-oophorectomy; however, somatic morbidity (i.e., osteoporosis, palpitations, pain, and stiffness) is increased (Michelsen et al. 2009).

Colorectal Cancer

Although screening can detect precancerous polyps, an estimated 102,900 cases of colon cancer and 39,670 cases of rectal cancer are expected to be diagnosed in the United States in 2010, and more than 51,000 people will die of colorectal cancer (American Cancer Society 2010). Only 39% of colorectal cancers are diagnosed at an early stage, and surgical resection is the only curative therapy. A pa-

tient's adjustment is closely related to the type and extent of surgery, the presence or absence of a stoma and an ostomy, and the partner's adjustment. Psychosocial adjustment to colon cancer can be complicated by anorexia, nausea and vomiting, weight loss, abdominal discomfort, diarrhea, and constipation. Concerns about body image, sexual functioning, fatigue, pain, and odor can lead to social withdrawal (Bernhard et al. 1999; Sahay et al. 2000). In patients with liver metastases, serum interleukin-2R, a cytokine, may be an independent predictor of depression (Allen-Mersh et al. 1998). Confusion occurs in 1% of colon cancer patients in the last 6 months of life but in 28% in the last 3 days. Significant financial burden occurs in the 3–6 months before death (McCarthy et al. 2000).

A recent prospective survey of 1,822 colorectal cancer patients found a low prevalence of global psychological distress at 6 (8.3%) and 12 (6.7%) months postdiagnosis (Lynch et al. 2008). In another survey of colorectal cancer survivors, noncancer comorbid disorders and low-income status had more influence on quality of life than did stage or time since diagnosis. Compared with an age-matched population, long-term survivors reported higher quality-of-life scores, but they had higher rates of depression. Frequent bowel movements and chronic recurrent diarrhea were a problem for many (Ramsey et al. 2002) (see Chapter 30, "Surgery," for a discussion of ostomies). Many self-help groups provide vital education and coping skills for these patients and their families.

Lung Cancer

An estimated 222,520 new cases of lung and bronchus cancer are expected to be diagnosed in the United States in 2010, and 157,300 deaths are expected to occur (American Cancer Society 2010). Lung cancer accounts for 28% of all cancer deaths. Although it is the most preventable of all cancers, with 87% of cases linked to cigarette smoking, lung cancer is difficult to diagnose early. In a study of 4,496 cancer patients, including patients with 14 different primary tumor sites, those with lung cancer had the highest rate of distress on the BSI (Zabora et al. 2001). About one-fifth of patients with non-small-cell lung cancer (NSCLC) have depressed mood at the time of diagnosis, and their depression tends to persist. In one study, depression following the diagnosis or resection of operable NSCLC predicted depression 1 year later (Uchitomi et al. 2003). At the time of diagnosis, many tumors are inoperable. In unresectable NSCLC, self-reported anxiety and depression at baseline were found to predict subsequent psychological distress (Akechi et al. 2001). In one study of 145 survivors of NSCLC who had been disease-free for 5 or more years, most were hopeful. Half viewed their cancer experience as contributing to positive life changes (Sarna et al. 2002).

Depressive symptoms and difficulty concentrating are more common at diagnosis of small-cell lung cancer than with NSCLC. Small-cell lung cancer, more than any other tumor, is associated with paraneoplastic syndromes such as Cushing's syndrome, hyponatremia, and autoimmune encephalopathy. Because pulmonary emboli are common during treatment, dyspnea and anxiety should be evaluated carefully. Hypoxia due to preexisting chronic obstructive pulmonary disease and postradiation hypothyroidism may contribute to cognitive dysfunction. Postthoracotomy neuralgic pain is common.

Patients with small-cell lung cancer may receive prophylactic cranial radiation because the risk of brain metastases is 50% over 2 years. Isolated brain lesions may be removed surgically, but cranial radiation is common once the metastasis is noted. Some cognitive deficits have been noted in long-term survivors of small-cell cancer regardless of whether they received cranial radiation. Leukoencephalopathy has occurred after treatment for small-cell cancer as a result of the combination of chemotherapy and radiation, but changes in chemotherapy have reduced this risk.

Many smokers with cancer and smoking partners of cancer patients experience guilt, but many continue to smoke. Continued smoking is associated with decreased survival, development of a secondary primary cancer, and increased risk of developing or exacerbating other medical conditions. Chemotherapy and radiation are likely to produce more complications and greater morbidity among smokers than among nonsmokers (Sanderson et al. 2002). Although some health care providers are hesitant to raise the issue of smoking cessation during the stress of initial diagnosis, the literature supports early antismoking intervention with patients and their family members (Sanderson et al. 2002). However, in terminal lung cancer, if the patient derives pleasure from smoking, cessation interventions are not indicated. For further review of lung cancer, see Chapter 19, "Lung Disease."

Ovarian Cancer

The second most frequent gynecological cancer among women in the United States, ovarian cancer, is the fifth most frequent cause of cancer death in women and has the highest mortality rate of all gynecological cancers (American Cancer Society 2010). Annually, more than 21,000 new cases of ovarian cancer are diagnosed, and nearly 14,000 deaths result. Ovarian cancer usually has an insidious onset and progression; 70% of cases are stage II to IV at time of diagnosis. The 5-year survival rate is only 46% overall.

Because cancer antigen (CA) 125 levels often rise before symptoms appear, patients' emotions often rise and fall with the report of the CA 125 level. Kornblith et al. (1995) found that more than 60% of ovarian cancer patients de-

scribed being worried, tired, sad, and in pain. In one prospective study, persistent anxiety was present in nearly one-quarter of women who had received an ovarian cancer diagnosis, predictors being neuroticism and marital status (Goncalves et al. 2008). In a prospective study of 63 ovarian cancer patients, a reduction in depression and an increase in anxiety were found 3 months after the completion of chemotherapy (Hipkins et al. 2004). Factors associated with anxiety included poor perceived social support, increased intrusive thoughts, and younger age. Patients report difficulties with sexual desire, response, and communication after gynecological cancer treatment (see Chapter 16, "Sexual Dysfunction"). Infertility concerns are vital for younger women, who require information about fertility and emotional support to make treatment decisions and to cope with those choices.

Melanoma

More than 68,000 Americans are expected to be diagnosed with melanoma in 2010 (American Cancer Society 2010). It is the most aggressive and fatal form of skin cancer, which may result in scarring or lymphedema from lymph node sampling, and affects mobility if lower extremities are involved. Fawzy et al. (2003) reported that a short-term focused psychological treatment could diminish distress and prolong survival. The intervention was associated with survival benefit after 6 years, but the benefit weakened after 10 years. A replication study in 262 Danish melanoma patients showed no prolonged survival after 6 years (Boesen et al. 2007).

Advanced disease may be treated with interferon-alpha, the side effects of which include fatigue, anxiety, insomnia, depression, and rarely mania (Kirkwood et al. 2002). Paroxetine started at the time interferon-alpha is started has been shown to reduce the incidence of depression (Musselman et al. 2001). Because melanoma commonly metastasizes to the brain, changes in personality or other new neurological symptoms should always prompt the clinician to consider CNS imaging.

Head and Neck Cancers

Head and neck cancers are highly distressing (Zabora et al. 2001) and, together with their treatments, often result in facial disfigurement and loss of ability to speak, eat, taste, or swallow. With more than 60% of patients with head and neck cancers surviving longer than 5 years, quality-of-life issues become paramount (American Cancer Society 2010). Disfigurement is associated with reduced quality of life and increased depression but is subjectively experienced and less related to objective ratings of disfigurement (M.R. Katz et al. 2000). Distress may be higher in those patients whose identity is closely tied to body image or ability

to communicate. Treatment is daunting and leads to mucositis, pain, dysphagia, xerostomia, and sticky saliva, all of which make eating difficult and affect social functioning. Feeding tubes and tracheotomies are often necessary. Hypothyroidism is common following radiation treatment to the neck. Cranial radiation for nasopharyngeal cancer has been associated with the development of radionecrosis, resulting in structural and functional brain changes (Cheung et al. 2003), with consequent cognitive dysfunction. Memory, language, motor performance, and executive functions may become impaired.

Head and neck cancer patients often have comorbid substance use disorders, putting them at high risk for alcohol and nicotine withdrawal if admitted to the hospital. Underlying comorbid psychiatric illness and maladaptive coping styles often accompany substance use, which will affect psychosocial intervention. Guilt about the role substance use has in the development of their cancer may contribute to distress. A link between human papillomavirus, a sexually transmitted disease, and tonsillar cancer has been shown, which may add further to feelings of self-blame regarding behavior.

Pancreatic Cancer

Pancreatic cancer is one of the leading causes of cancer deaths, and 80% of cases are unresectable at diagnosis, with a 5-year survival rate of 6% (American Cancer Society 2010). Receiving this information at the time of diagnosis can be a devastating psychological blow and most certainly contributes to high rates of distress and depression seen in these patients. However, several earlier small studies have found that up to 50% of pancreatic cancer patients manifested psychiatric symptoms at least 6 months prior to their cancer diagnosis (Fras et al. 1967; Green and Austin 1993; Joffe et al. 1986), suggesting that there may be a direct tumor-induced effect. One clinical study reported that depressive thoughts were more common in people with pancreatic cancer than in those with gastric cancer (Holland et al. 1986), and a retrospective cohort study found that depression preceded pancreatic cancer more often than other GI malignancies (odds ratio [OR] = 4.6) (Carney et al. 2003). One study of 130 patients with newly diagnosed pancreatic cancer found that 38% had scores higher than 15 on the Beck Depression Inventory. Depression was more common in those who had pain (Kelsen et al. 1995). Larger prospective studies examining distress by cancer site did find pancreatic cancer to be highly distressing but no more so than other tumor sites with high symptom burden and poor prognosis, such as lung and brain cancer (Carlson et al. 2004; Zabora et al. 2001).

The signs and symptoms of pancreatic cancer are typically vague and nonspecific and may include abdominal

pain, anorexia and weight loss, fatigue, and jaundice. Symptoms of upper abdominal disease occur in 25% of patients 6 months before diagnosis. Anorexia, early satiety, and back pain are features of progressive disease, and diabetes also may develop. Management of pain and discomfort includes palliative chemotherapy and/or radiotherapy, opiates, celiac blocks, stenting procedures, pancreatic enzymes to relieve cramping associated with pancreatic insufficiency, and prevention and treatment of constipation and diarrhea. Antidepressants and psychostimulants may be used to treat depression and fatigue.

Psychiatric Aspects of Cancer Treatments

Chemotherapy

The neuropsychiatric side effects of common chemotherapeutic agents are listed in Table 23–2. Most chemotherapy agents are metabolized by CYP 3A4, so careful consideration of drug–drug interactions involving this enzyme is warranted. St. John's wort and modafinil both induce CYP 3A4 and therefore may render chemotherapy less effective, whereas fluoxetine and fluvoxamine both inhibit CYP 3A4 and may increase the level of chemotherapy-related toxicity. Because of its mild inhibition of monoamine oxidase (MAO), procarbazine may contribute to serotonin syndrome if prescribed in combination with a selective serotonin reuptake inhibitors (SSRI) or SNRI antidepressant. See “Survivor Issues” section later in this chapter for discussion of cognitive impairment related to chemotherapy.

Tamoxifen is used in the prevention of breast cancer recurrence, as well as in the metastatic setting, in women with both invasive and noninvasive breast cancers. Inconsistent reports implicate it in the development of depression. In fact, in the noncancer population, the use of tamoxifen recently has been recommended as a third-line augmentation strategy in the treatment of acute mania by the Canadian Network for Mood and Anxiety Treatments (CANMAT), in conjunction with the International Society for Bipolar Disorders (ISBD) (Yatham et al. 2009).

Antidepressants are frequently prescribed to breast cancer patients taking tamoxifen for management of depression and hot flashes. Reports of interactions between tamoxifen and antidepressants have led to concern about antidepressant prescribing (Henry et al. 2008). Tamoxifen is metabolized to its most active metabolite, 4-hydroxy-*N*-desmethyl-tamoxifen (endoxifen), through CYP 2D6. Breast cancer patients with decreased metabolism, through genetic variation (e.g., poor metabolizer genotype) or potent CYP 2D6 inhibition with medications, have been found to have shorter time to recurrence and worse relapse-

free survival. Because of this risk, recommendations have been made by some to avoid the use of potent CYP 2D6 inhibitors, such as fluoxetine or paroxetine, and to use weaker or noninhibitors, such as citalopram. Patients who are unable to tolerate or who are nonresponsive to the weaker CYP 2D6 inhibitors may benefit from a discussion between the oncologist and psychiatrist to establish the best overall treatment for them.

Radiation

Radiation treatment usually requires a patient to remain absolutely still on a flat table for 5–10 minutes daily, 5 days a week, so that a prescribed dose can be applied to a specific site over 2–9 weeks. Patients worry that they cannot remain still either because of claustrophobia or because of inadequate pain control. Fatigue continues to increase during the month following radiation treatment but then begins to diminish. Nausea and vomiting from radiation treatment, more severe when viscera are irradiated, are reduced by serotonin type 3 (5-HT₃) receptor antagonists such as ondansetron. Irradiation for gynecological cancers can cause severe side effects, such as vaginal atrophy, that can interfere with sexual function. Effective use of vaginal dilators, estrogen creams, and vaginal moisturizers for these painful and persistent problems has been described by others (A. Katz 2009). Brain irradiation causes more profound fatigue than does treatment of other sites. Concomitant dexamethasone reduces cerebral edema, but late sequelae of brain radiation, including focal radiation necrosis or leukoencephalopathy, may appear. Newer methods to reduce the volume of brain that requires radiation may decrease these risks.

Hematopoietic Stem Cell Transplant

Hematopoietic stem cell transplant (SCT) broadly includes bone marrow transplants (BMTs) and SCTs from peripheral or umbilical cord blood. Allogeneic transplantation uses donor stem cells, so the patient has a risk of developing graft-versus-host disease (GVHD), whereas autologous transplantation uses the patient's own cells, thereby eliminating this risk.

Although most patients note an improved quality of life physically, psychologically, and socially in the years following their transplant, a review of 22 prospective reports found that a significant minority experience ongoing anxiety and/or depressive symptoms (5%–40%), fatigue, sexual dysfunction, and fertility concerns (Mosher et al. 2009). The psychological stress of hematopoietic SCT begins when transplant is first considered. Although outcomes have improved with the use of autologous hematopoietic SCT, approximately 40% of patients who receive allogeneic hematopoietic SCT die from related complications (Copelan 2006).

An important part of the pretransplant planning is to evaluate and shore up the patient's social support that is of vital importance both while the patient is in isolation and after discharge. During high-dose chemotherapy and irradiation, visitors are limited to avoid infection. Patients often experience nausea, vomiting, mucositis, and fatigue. During this time, psychiatric disorders are extremely common, especially adjustment disorder with anxiety and depression (Khan et al. 2007). GVHD is not generally associated with occurrence of mental disorders (Sasaki et al. 2000), although when severe, it may result in delirium.

The transplant itself is anticlimactic compared with the pretransplant regimen and the anxious period involved in awaiting recovery from pancytopenia. Hypervigilant patients keep charts of their cell counts, anticipating the day of "probable" recovery; others request medications to "sleep through the experience," a passive attitude antithetical to caregivers, who want these patients to participate in self-care.

After a prolonged period of dependence, patients are often very fearful as they anticipate hospital discharge and must assume greater roles in self-care. Persistent fatigue is a major problem when patients resume normal activities at home and work. Chronic anxiety and depression are the most common psychiatric sequelae, and psychological adjustment is particularly difficult for those patients who have delayed or disrupted important developmental life tasks. In the years following hematopoietic SCT, spouses or partners experience similar psychological effects (depressive symptoms, sleep and sexual problems) but less social support, dyadic satisfaction, and spiritual well-being and more loneliness than do their survivor partners, highlighting the attention required for spousal evaluation and psychosocial support (Bishop et al. 2007).

In general, successful adaptation to BMT is associated with the ability to use information about illness and treatment, coupled with the ability to delegate control and authority temporarily and to trust the staff.

Cancer Surgery

See Chapter 30, "Surgery," for a general discussion of the emotional aspects of surgery and Chapter 33, "Obstetrics and Gynecology," for a discussion of gynecological surgery.

Psychiatric Interventions in Cancer

Small sample sizes, high attrition rates contributing to selection bias, and confounding factors are common in both nonpharmacological and pharmacological intervention studies in cancer patients. We acknowledge these limitations and review psychiatric management of the cancer patient.

Psychotherapy

Providing psychotherapeutic support for the cancer patient involves tailoring the intervention to the patient's individual biopsychosocial needs. Exploration of patients' understanding and meaning of their illness and prognosis, concurrent stressors, and current level of supports helps to develop an individualized psychosocial intervention plan. Flexibility in scheduling of patients and in choice of psychotherapeutic model is required. In the clinical setting, an eclectic approach may be undertaken that uses elements of different models of psychotherapy and is related to the chief concerns at the time of treatment. Many cancer patients will confront issues related to loss of control; uncertainty; and fear of future dependency, suffering, and death. Psychotherapy supports patients in navigating these challenges through individual, couples, family, or group interventions by offering a supportive, validating, and nonjudgmental presence; providing realistic reassurance; and emphasizing prior strengths and coping.

Although studies are limited by small sample sizes, confounding factors, and high withdrawal rates with related selection bias, evidence has shown the benefit of psychosocial treatments in reducing emotional distress and improving quality of life (Meyer and Mark 1995; Osborn et al. 2006; Sheard and Maguire 1999).

However, interpretation of the studies may affect conclusions drawn, leading some to suggest that psychosocial interventions do not clearly show a benefit (Coyne et al. 2006). Weaknesses regarding the evidence base include the presence of inconsistent findings in the literature; the quality of the studies; the lack of studies of certain demographic, disease, and treatment factors; and the lack of research on patients with clinically significant levels of distress (Jacobsen and Jim 2008). Alternatively, a meta-analysis of six studies, including incurable cancer patients, found improvement in depression scores in non-clinically depressed samples but no improvement in those with a diagnosis of depression (Akechi et al. 2008). The inherent challenges of implementing a randomized controlled trial in seriously ill cancer patients include high attrition rates, inability to implement standard randomization design, and heterogeneity of patient samples (Moorey et al. 2009).

Educational and behavioral training, through either group or individual psychotherapy, reduces distress in cancer patients (Fawzy et al. 1995; Newell et al. 2002). Cognitive and behavioral models can be tailored to the specific tumor type (Tatrow and Montgomery 2006).

Group therapy and self-help groups facilitate the sharing of information and support coping strategies among cancer patients facing similar situations. In a group setting, patients can glean practical tips and see the range of normal reactions to illness, as well as adaptive coping

styles and strategies that make adjustment to illness easier. Group therapy helps to decrease the sense of isolation and alienation as the patient and family see that they are not alone adjusting to illness. Groups are often disease specific or targeted for patients at the same stage of illness. Spiegel et al. (1989) developed supportive-expressive group therapy led by trained professionals for women with breast cancer. The goals of supportive-expressive psychotherapy are to help patients with existential concerns and disease-related emotions, to deepen social support and physician-patient relationships, and to provide symptom control. The therapist challenges patients' tendency to withdraw from the implications of having metastatic breast cancer. Such groups relieve distress while reducing avoidance of the implications of the diagnosis. This strategy improves mood and pain perception, especially in the most distressed (Goodwin et al. 2001).

In the advanced or terminally ill cancer population, existential, life narrative, dignity-conserving, and meaning-centered interventions may be considered. Driven by previous research indicating the role meaning has in reducing depression and hopelessness, Breitbart et al. (2010) developed a meaning-centered group psychotherapy. When compared with supportive group psychotherapy, meaning-centered group psychotherapy showed significantly greater improvement in spiritual well-being and sense of meaning (Breitbart et al. 2010). Legacy documents created during a 1-hour interview with a terminally ill patient reduce suffering and depressed mood (Chochinov et al. 2005) (see Chapter 41, "Palliative Care").

More recent studies have shown the potential to prevent anxiety or depressive illness in cancer patients. Supportive-expressive group therapy plus relaxation therapy prevented depressive disorders in 227 metastatic breast cancer patients, compared with relaxation therapy alone (Kissane et al. 2007). A study of 465 mixed cancer patients, free of anxiety or depressive disorder, stratified patients by risk of developing either disorder. High-risk patients were less likely to develop an anxiety or a depressive disorder following a brief (three-session) cognitive-behavioral intervention compared with those who received usual care (OR = 0.54); no effect was seen in low-risk patients (Pitceathly et al. 2009).

Earlier studies of the effect of psychosocial interventions suggested that they could prolong survival (Fawzy et al. 1993, 2003; Spiegel et al. 1989). Replication studies, which have been methodologically more rigorous, have failed to find any survival benefit (Boesen et al. 2007; Goodwin et al. 2001; Kissane et al. 2007; Spiegel et al. 2007), suggesting that future trials should focus on improving quality of life, easing suffering, and optimizing coping (Kissane 2009). Three meta-analyses and one systematic review have

not found a survival benefit conferred by psychotherapy (Chow et al. 2004; Edwards et al. 2008; Newell et al. 2002; Smedslund and Ringdal 2004). Some psychological intervention trials in cancer have shown improved survival, but most have not; however, essentially all have reported improvements in psychological well-being.

Psychopharmacology

Choosing a psychotropic medication for a cancer patient requires consideration of a patient's medical comorbidities, potential drug interactions, route of administration, onset of action required with related patient prognostic information, somatic symptom profile (e.g., pain, insomnia, agitation, hot flashes), and adverse-effect profile of the intended psychotropic medication. In cancer patients with thrombocytopenia, intramuscular (IM) injections and restraints should be avoided. Patients who are unable to take medications orally because of mucositis or those with GI obstruction may require alternative routes of administration (see "Alternative Routes" section of Chapter 38, "Psychopharmacology"). Mirtazapine, olanzapine, and risperidone all have orally disintegrating forms. In addition, low albumin levels and ascites may occur in the cancer patient, affecting the volume of distribution of drugs.

Depression

Earlier reports suggested that antidepressants increased one's risk for developing cancer; however, this concern has been dismissed (Theoharides and Konstantinidou 2003). Although antidepressants are commonly used in the clinical setting, the evidence for their use in depressed cancer patients is somewhat limited, with few trials studying patients with major depression (Rodin et al. 2007a; Williams and Dale 2006). Seven placebo-controlled trials have shown benefit in cases of depression or depressive symptoms when fluoxetine, paroxetine, and mianserin were used. However, other placebo-controlled studies have shown no difference in depression when fluoxetine, paroxetine, desipramine, and sertraline were used compared with placebo (Owen and Ferrando 2010).

The SSRIs and SNRIs are often first-line treatments because of clinical experience, safety, and tolerability. Some cancer patients may already be experiencing GI symptoms from their disease or treatment, which may worsen if SSRIs or SNRIs are added. Patients with carcinoid tumors may have elevated levels of serotonin and, therefore, may be less able to tolerate the SSRIs or SNRIs. Because GI bleeding has been reported with SSRIs, caution is advised when prescribing these agents to cancer patients with thrombocytopenia. All of the SSRIs, as well as venlafaxine and mirtazapine, have been associated with hyponatremia. Monitoring of electrolytes is advisable, especially

in cancer patients who have additional risk factors (e.g. those receiving vincristine, those with small-cell lung cancer). Some antidepressants also may alleviate hot flashes, as previously described (see “Breast Cancer” subsection). SNRIs (venlafaxine and duloxetine) may improve neuropathic pain caused by cancer treatments.

Mirtazapine has a high affinity for histaminic H_1 receptors and antagonizes $5-HT_2$ and $5-HT_3$ receptors, possibly contributing to its properties of anxiolysis, sedation, appetite stimulation, and antiemesis. These properties may be advantageous in anorexic-cachectic depressed cancer patients or those experiencing nausea or vomiting from chemotherapy but are less desirable in patients with weight gain from steroids or chemotherapy or those with significant fatigue or sedation. Small studies in which mirtazapine was used have shown improvement in anxiety, depression, and insomnia, with mixed results in nausea (Cankurtaran et al. 2008; Kim et al. 2008). Side effects include constipation, drowsiness, and, rarely, reversible neutropenia, all considerations when treating the depressed cancer patient.

Bupropion may improve sexual function and fatigue in cancer patients. Its stimulating properties make it useful in lethargic patients, but because of its association with increased seizure risk, it should be used with caution in patients who are malnourished or who have a history of seizures or brain tumor. It tends to be weight neutral or to contribute to weight loss, so this agent may not be the preferred choice in depressed cachectic patients. Bupropion may assist in smoking cessation, especially in patients with lung or head and neck cancers.

The TCAs may be used to treat comorbid neuropathic pain caused by chemotherapy and surgery, usually at lower doses than are indicated in depression. Nortriptyline and desipramine have more favorable side-effect profiles compared with amitriptyline, with fewer anticholinergic symptoms.

Psychostimulants can promote a sense of well-being, treat depression, decrease fatigue, stimulate appetite, and improve cognitive function. Psychostimulants are used in cancer pain as an adjuvant to potentiate the analgesic effects of opioids and are commonly used to counteract opioid-induced sedation (Rozans et al. 2002). Because their onset of action occurs within days, rather than weeks as with antidepressants, psychostimulants are often the preferred choice in terminally ill patients. Four out of five non-placebo-controlled studies, together with case series and reports, have shown improved mood in 73%–100% of cancer patients, but well-designed placebo-controlled studies are needed (Orr and Taylor 2007). Side effects may include insomnia, agitation, and, rarely, psychosis. They

may stimulate the cardiovascular system, so caution is advised when treating patients with hypertension or arrhythmias. (See also Chapter 8, “Depression.”)

Mood stabilizers and antipsychotics generally can be continued during cancer treatment. However, complications of chemotherapy, including vomiting, diarrhea, dehydration, and renal insufficiency, may raise lithium levels, and symptoms of toxicity, nausea, diarrhea, and confusion may be misattributed to chemotherapy. Antipsychotics (e.g., haloperidol, olanzapine) may improve nausea and vomiting in cancer patients. Metabolic parameters should be monitored in patients prescribed steroids and atypical antipsychotics, given their risk of causing hyperglycemia, although this is much less of a concern when the cancer is advanced. Patients may be at risk for QT prolongation if prescribed antipsychotics, antibiotics, TCAs, tacrolimus, tamoxifen, octreotide, and ondansetron (Strevel et al. 2007). Cancer patients also may have other risk factors for QT prolongation, including dehydration, hypomagnesemia, hypocalcemia, and hypokalemia. Although close monitoring, collaboration with the treating oncologist, and a thorough risk-benefit analysis must occur, continuation of clozapine during chemotherapy has not resulted in any reports of associated agranulocytosis (Frieri et al. 2008). See also Chapter 10, “Psychosis, Mania, and Catatonia.”

Anxiety

Before initiating treatment with a benzodiazepine, all patients should be screened for depressive symptoms and for specific anxiety disorders such as PTSD and generalized anxiety disorder because of treatment implications. When anxiety is a manifestation of a primary depressive disorder, treatment should be an antidepressant with, or instead of, a benzodiazepine.

Benzodiazepines are frequently given to patients for acute anxiety and/or insomnia and may be prescribed to augment antiemetics during chemotherapy. Dosing depends on the patient's tolerance and the drug's duration of action. Lorazepam and alprazolam are favored in the acute setting because of their rapid onset of action and benefit on an as-needed basis. Buspirone and antidepressants are alternatives for longer treatment of anxiety. Low doses of antipsychotics are useful in patients who are unresponsive to or intolerant of benzodiazepines or in patients who have severe anxiety and agitation. If patients have been taking a benzodiazepine chronically, they may experience withdrawal if the dose is not tapered. Benzodiazepines and opiates may have an additive effect on reducing respiratory drive, contributing to respiratory depression, so caution is advised when using this combination. See also Chapter 11, “Anxiety Disorders.”

Delirium

See Chapter 5, "Delirium," for a discussion of psychopharmacological treatment of delirium and Chapter 41, "Palliative Care," for a discussion of terminal delirium.

Electroconvulsive Therapy

Although the use of electroconvulsive therapy (ECT) in patients with brain tumor was once believed to be contraindicated because of the risk of brain herniation, numerous case reports have described safe and effective use of ECT in such patients (Patkar et al. 2000). (See Chapter 40, "Electroconvulsive Therapy.")

Survivor Issues

Advances in cancer treatment over the past 30 years have led to a rapidly growing population of more than 9 million long-term survivors in the United States, many of them children and young adults. The long-term adjustment of many appears to be largely unimpaired (Kornblith et al. 2004). Some cured cancer patients have delayed medical complications (e.g., organ failure, CNS dysfunction, infertility, secondary malignancies, and decreased physical stamina) and psychological concerns, including fears of termination of treatment; preoccupation with the threat of disease recurrence; pervasive awareness of mortality and a sense of greater vulnerability to illness; difficulty with reentry into normal life; persistent guilt; difficult adjustment to physical losses and handicaps that lead to problems with peer acceptance and social integration; diminished self-esteem or confidence; perceived loss of employment opportunity or mobility; and fear of job and insurance discrimination. Concerns about infertility, often understandably submerged at the time of diagnosis and treatment, reappear when treatment concludes. Several elements are necessary to achieve optimal outcome for cancer survivors: access to state-of-the-art cancer care; active participation or engagement in one's care (active coping); use of social support (or perception that support is available); and a sense of meaning or purpose in life (Rowland and Massie 2010). Cancer survivors with unmet psychosocial needs are more likely to use complementary and alternative medicine (see following section) (Mao et al. 2008).

The survivor's cognitive functioning is also a concern. Some children and adults who have undergone bone marrow transplant or who have been treated for a brain tumor have residual deficits with neuropsychological impairment, including compromised motor and cognitive test performance (Meyers and Brown 2006; Phipps et al. 2008).

Some adult patients who have received chemotherapy and/or hormonal therapy for solid tumors reported cogni-

tive changes. These changes in attention, concentration, memory, and processing speed may affect functioning, are often subtle, and have been challenging to study (Vardy et al. 2008). Possible biological and neural mechanisms that contribute to cognitive changes in patients undergoing chemotherapy include direct neurotoxic effects, changes in neurotransmitter levels, hormonal changes, immune dysregulation, cytokine release, and blood clotting in CNS vessels (Ahles and Saykin 2007). Some treatment-induced changes in neurochemical brain function may be mediated by genetic predisposition (Ahles et al. 2003). Cognitive dysfunction has been found to be independent of depression and fatigue (Correa and Ahles 2008). In one study, breast cancer survivors who participated in a cognitive-behavioral treatment aimed at improving ability to compensate for cognitive dysfunction associated with adjuvant chemotherapy rated the therapy as helpful in improving their ability to compensate for memory problems (Ferguson et al. 2007).

Potential resources include the National Coalition of Cancer Survivorship, the Office of Cancer Survivorship of the National Cancer Institute, and the organizations whose Web sites are shown in Table 23-6.

Complementary and Alternative Medicine

More than 50% of cancer patients use complementary and alternative medicine (CAM) therapies after their diagnosis, during or after standard cancer treatment for symptom management, and for promotion of "general overall health" (Vapiwala et al. 2006). In one study of 2,198 women unaffected by breast cancer, nearly half of the women used CAM with the goal of preventing breast cancer (Myers et al. 2008). A recent survey of more than 4,000 cancer survivors showed that the most commonly used complementary methods were prayer or spiritual practice, relaxation, faith or spiritual healing, and nutritional supplements or vitamins (Gansler et al. 2008). Some complementary therapies (acupuncture; relaxation; yoga; meditation; massage; tai chi; biofeedback; music, art, movement, and aroma therapies) are offered as adjuncts to traditional cancer care aimed at increasing quality of life and decreasing symptoms, with no promise of cure. A course of four sessions of aromatherapy massage has been shown to decrease anxiety and depression in the short term but had no beneficial long-term effects on anxiety, depression, pain, nausea, vomiting, or global quality of life (Wilkinson et al. 2007). Alternative therapies such as shark cartilage, colonics, herbal remedies, and high-dose vitamin therapies do not improve quality of life and may be harmful. Some remedies are highly toxic (Markman 2002). Laetrile, now banned in

the United States, contains cyanide; chaparral tea causes liver damage; and Ma huang, also now banned in the United States, contains ephedrine, a CNS stimulant. Because ginger, garlic, ginseng, and ginkgo have antiplatelet effects, patients are cautioned about their use preoperatively and when thrombocytopenic. Soy and red clover are mildly estrogenic and may stimulate hormonally sensitive cancers (Wesa et al. 2008). Although the number of studies of the use of CAM techniques in people with cancer is increasing, benefits are often inconsistent and may be related to methodological flaws (Jane et al. 2008). No CAM technique or preparation has been shown to cause tumor regression. Several Web sites (e.g., www.mskcc.org/aboutherbs) provide unbiased scientific reviews about complementary therapies and potential drug interactions and adverse effects of herbal and botanical agents relevant to cancer patients (Wesa et al. 2008). See also "Complementary Medicines" section of Chapter 38, "Psychopharmacology."

In the United States, 83 million people use alternative therapies for malignant and nonmalignant disorders, and 70%–90% do not inform their doctors about these treatments (Gertz and Bauer 2001), in part because doctors often do not ask—or make negative remarks—about CAM. A study of women with newly diagnosed early-stage breast cancer found that 28% used alternative medicine (Burstein et al. 1999). Interestingly, the use of alternative medicine was independently associated with depression, fear of recurrence of cancer, lower scores for mental health and sexual satisfaction, and more physical symptoms, suggesting

that those who seek alternative medicine therapies may be experiencing more anxiety, depression, or physical symptoms. Those taking alternative medications may be more in need of but less open to psychiatric consultation. However, a study conducted in Austria in cancer patients at the end of active cancer treatment showed that patients who used CAM were those who had a more active coping style. They were as compliant with standard cancer treatment and more interested in receiving psycho-oncological support than were patients not using CAM (Söllner et al. 2000).

Most patients who elect to use untried or unproven therapies do so in a desperate search for a cure or for a more acceptable quality of life. The clinician must openly communicate about patients' needs and their attitudes toward CAM and find a balance between condoning unproven or harmful treatment and preserving the patients' hope.

THE CONSULTATION psychiatrist is frequently called on to assess patients in medical settings who have primary or secondary hematological disorders. Our review addresses psychiatric issues that are specific to patients who have selected hematological disorders, including iron, B₁₂, or folate deficiency; sickle cell disease; hemophilia; and thalassemia. We discuss the diseases, their unique psychiatric manifestations, and approaches to management. Fear of blood transfusions and psychological factors affecting clotting are described. Finally, hematological side effects of psychotropic medications and their drug interactions are reviewed.

Iron Deficiency Anemia

Iron is a component of hemoglobin and is essential to red blood cell production. Iron deficiency anemia (IDA), an advanced state of iron deficiency, causes a hypochromic microcytic anemia characterized by low or absent iron stores and low iron serum concentration, low transferrin saturation, low serum ferritin, elevated free erythrocyte porphyrin, elevated transferrin, and low hemoglobin concentration (Dorland's Illustrated Medical Dictionary 2003). IDA may manifest with a variety of physical and neuropsychiatric symptoms.

IDA is the most common nutrient deficiency in the world; however, its prevalence and etiology vary by race, sex,

geography, and socioeconomic status. Prevalence is 3% in toddlers ages 1–2 years, 2%–5% in adolescent girls, 2% in adult men, 9%–12% in white women, and about 20% in African American and Mexican American women (Killip et al. 2007; Looker et al. 1997). The World Health Organization (WHO) estimates that 43% of nonpregnant women of reproductive age in developing countries and 12% in industrialized countries are anemic. This number increases to 56% and 18%, respectively, by the third trimester of pregnancy (Milman 2006).

The most common etiology of IDA is blood loss. In men and in postmenopausal women, chronic bleeding from the gastrointestinal tract is the most common cause of IDA. Peptic ulcer, hiatal hernia, gastritis, hemorrhoids, vascular anomalies, and neoplasms are the most common causes of gastrointestinal bleeding in adults. Causes of chronic blood loss also include colon cancer, colonic diverticulae, periampullary tumors, leiomyomas, adenomas, and other malignant or benign neoplasms of the intestine (Coban et al. 2003).

Unsupplemented milk diets do not contain adequate amounts of iron for infants. During the first year of life, iron demands are increased, and milk products are poor sources of iron; prolonged breast feeding or bottle feeding of infants frequently leads to IDA unless there is iron supplementation. Premature infants are at even greater risk of

IDA. Children experience a higher risk during rapid growth periods. The low iron supply in the American diet has put young women and children at higher risk of IDA (Hallberg et al. 1995).

IDA is highly prevalent in pregnant women as the result of iron loss from diversion of iron to the fetus and from blood loss during delivery. Daily iron demand dramatically increases during pregnancy and continues through to term. Breast-feeding leads to additional iron diversion to the baby. For these reasons, IDA continues or worsens for a significant percentage of women during the postpartum period (Milman 2006).

Intestinal malabsorption of iron is an uncommon cause of iron deficiency except after gastrointestinal surgery and in malabsorption syndromes such as celiac disease (Annibale et al. 2003). In malabsorption syndromes, IDA may take years to develop due to the indolent nature of iron loss.

Clinical Manifestations

IDA occasionally results in severe anemia, with some patients having blood hemoglobin levels below 4 g/dL. Severe IDA is associated with all of the various symptoms of anemia (resulting from both hypoxia and the body's response to hypoxia), including tachycardia, palpitations, pounding in the ears, headache, light-headedness, angina, and retinal hemorrhages and exudates. Less severe anemia presents with fatigue, weakness, headache, irritability, and exercise intolerance. Glossal pain, dry mouth, atrophy of tongue papillae, and alopecia may be more specific to IDA (Trost et al. 2006). Physical findings include pallor, glossitis (smooth red tongue), stomatitis, and angular cheilitis.

Neuropsychiatric Manifestations

Neuropsychiatric symptoms of IDA include depression, developmental delay, cognitive deficits, restless legs syndrome, and fatigue. IDA may affect visual and auditory functions. IDA leads to decreased work and exercise performance as well as neurological dysfunction (Cook and Skikne 1989). IDA may result in cognitive and motor developmental delays in infants and young children (Booth and Aukett 1997). The pathophysiology of these behavioral deficits is not well understood (Lozoff 1988). Even school-age children and adolescents with iron deficiency (with or without anemia) have been shown to have lower standardized math scores compared with children with normal iron status (Halterman et al. 2001).

In adults, IDA impairs cognitive function, limits activity, and causes work paucity (Beard et al. 2005). Women who have IDA are more likely to have postpartum fatigue (K.A. Lee and Zaffke 1999). Mild anemia is independently associated with worse selective attention performance and

disease-specific quality-of-life ratings (Lucca et al. 2008). Mildly anemic elderly patients (not limited to those with IDA) score significantly worse than nonanemic control subjects on multiple cognitive, functional, mood, and quality-of-life measures (Lucca et al. 2008).

Patients with IDA may crave both food items and non-food substances. Pica and particularly pagophagia (craving ice) are specific symptoms that reportedly occur in 50% of patients with IDA (Rector 1989; R. D. Reynolds et al. 1968). The mechanism by which IDA produces pica is unknown.

Motor impairment, cognitive dysfunction, and restless legs syndrome probably result from iron deficiency in the central nervous system (CNS) (Krieger and Schroeder 2001). Early studies demonstrated that IDA plays a role in restless legs syndrome and that treatment with iron improves the syndrome (Krieger and Schroeder 2001; O'Keeffe et al. 1994). The severity of restless legs syndrome correlates with serum ferritin levels (Sun et al. 1998). Iron deficiency is also a risk factor for neuroleptic malignant syndrome (Rosebush and Mazurek 1991) and may aggravate akathisia and other extrapyramidal movement disorders.

Diagnosis and Treatment

IDA often is discovered incidentally through screening laboratory tests. IDA is a microcytic, hypochromic anemia. Plasma iron concentration and serum ferritin concentration are low, and iron-binding capacity is increased. Ferritin is the single best test. The classic laboratory findings occur consistently only when IDA is far advanced, is unaccompanied by complicating factors (such as infection or cancer), and is untreated (via transfusions or administration of parenteral iron).

Patients should be educated to maintain a diversified diet with adequate iron. Recovery from IDA almost always requires iron supplementation. Therapy should be initiated immediately. Iron can be replaced orally, parenterally, or (rarely) via blood transfusion. Oral iron is preferred. The adult dosage provides 150–200 mg elemental iron daily, taken in 3–4 doses 1 hour before meals. Poor tolerance to oral iron, poor absorption of iron, iron need in excess of the amount that can be taken orally, or noncompliance may necessitate intravenous therapy. Intravenous iron is effective and safe and is usually indicated in instances when hemoglobin is consistently less than 10 g/dL despite oral therapy (Schaefer et al. 2006). Symptom improvement after iron repletion is often realized quickly. Headache, fatigue, paresthesias, and pica rapidly resolve (Rector 1989). There are conflicting data as to whether oral iron improves cognitive development in infants (Lozoff et al. 1982; Walter et al. 1983). The prognosis of IDA is excellent when the cause of iron deficiency is benign.

Vitamin B₁₂ and Folate Deficiency

Vitamin B₁₂ deficiency and folate deficiency have similar consequences on the nervous system and lead to megaloblastic anemia (E. Reynolds 2006). Both B₁₂ and folate are cofactors for the conversion of homocysteine to methionine. Deficiency of either B₁₂ or folate correlates with high homocysteine levels, which is a risk factor for cardiovascular disease, stroke, dementia, and Alzheimer's disease (Carmel et al. 2003; Ravaglia et al. 2005; E. Reynolds 2006; Se-shadri et al. 2002). Both high homocysteine levels and deficiencies of B₁₂ and folate are also associated with depression (Bottiglieri et al. 2000; Kim et al. 2008b).

Vitamin B₁₂ Deficiency

Vitamin B₁₂ (cobalamin) is found primarily in meat and dairy products. B₁₂ is a necessary coenzyme and cofactor in various reactions, including DNA synthesis and the synthesis of methionine from homocysteine. In the duodenum, vitamin B₁₂ binds to intrinsic factor. Intrinsic factor is released by parietal cells, which are located in the fundus and body of the stomach. The B₁₂ complex is then absorbed in the terminal ileum. There is usually enough B₁₂ stored in the liver to supply daily requirements for up to 2–5 years; therefore, it typically takes years to develop B₁₂ deficiency (Andres et al. 2004). In the elderly, the prevalence of B₁₂ deficiency, including mild and subclinical cases, may exceed 20% (Andres et al. 2004; Loikas et al. 2007).

Pernicious anemia is the most common cause of B₁₂ deficiency (Toh et al. 1997). Pernicious anemia is an autoimmune disorder resulting in the loss of parietal cells in the stomach and subsequent loss of intrinsic factor production, which is necessary for B₁₂ absorption. Pernicious anemia frequently is associated with other autoimmune disorders, including thyroiditis, diabetes mellitus, Addison's disease, Graves' disease, vitiligo, myasthenia gravis, Lambert-Eaton myasthenic syndrome, and hypoparathyroidism (Carmel et al. 2003; Toh et al. 1997).

Dietary B₁₂ deficiency is rare but may occur in strict vegans. B₁₂ deficiency also can occur in children who are exclusively breast-fed and whose mothers are vegetarians (Chalouhi et al. 2008). In the elderly, deficiency usually is secondary to malabsorption due to gastric atrophy or pernicious anemia (Andres et al. 2009). Food or oral cobalamin malabsorption may be caused by *Helicobacter pylori* infection, intestinal overgrowth due to antibiotics, chronic use of metformin (Bauman et al. 2000; K. W. Liu et al. 2006) or antacids, H₂ receptor antagonists, proton pump inhibitors (Valuck and Ruscini 2004), alcoholism, pancreatic failure, and Sjögren's syndrome. Vitamin B₁₂ malabsorption also may result from gastrectomy, gastric bypass surgery (Malinowski 2006; Vargas-Ruiz et al. 2008), ileal diseases

or resection, Crohn's disease, blind loops, and infection with *Diphyllobothrium latum* or HIV (Andres et al. 2004).

Clinical Manifestations

The most common clinical manifestations of B₁₂ deficiency are macrocytic anemia and neuropsychiatric symptoms. Hematological manifestations of B₁₂ deficiency include megaloblastic anemia, macrocytosis with hypersegmented polymorphonuclear leukocytes, thrombocytopenia, leukopenia, pancytopenia or (rarely) hemolytic anemia, and thrombotic microangiopathy. Gastrointestinal manifestations include intestinal metaplasia, diarrhea, jaundice, and increased lactate dehydrogenase and bilirubin levels. Vaginal atrophy may also occur (Andres et al. 2004; Toh et al. 1997).

Neuropsychiatric Manifestations

Neuropsychiatric manifestations are common in vitamin B₁₂ deficiency, especially in the elderly (Andres et al. 2004). The hematological and neuropsychiatric symptoms of B₁₂ deficiency are often disassociated, and neuropsychiatric symptoms may precede hematological signs (E. Reynolds 2006). Symmetrical peripheral neuropathy occurs frequently, with paresthesias and numbness. Subacute combined degeneration of the spinal cord is less common (E. Reynolds 2006). Subacute combined degeneration encompasses both posterior column disruption (resulting in loss of vibration and position sense and ataxia with a positive Romberg's sign) and lateral column disruption (causing weakness, spasticity, and extensor plantar responses) (Toh et al. 1997). Rare manifestations of B₁₂ deficiency include optic neuritis, optic atrophy, and incontinence. Psychiatric symptoms may include mood changes, including depression (Kim et al. 2008b), psychosis, cognitive impairment, and obsessive-compulsive disorder (Bauman et al. 2000; Fava et al. 1997; K. W. Liu et al. 2006; Valuck and Ruscini 2004). B₁₂ deficiency appears to be a risk factor for dementia (Andres et al. 2004). In children, vitamin B₁₂ deficiency may cause irritability, failure to thrive, apathy, anorexia, abnormal movements, and developmental regression, which generally respond to supplementation. Long-term cognitive and developmental retardation are most dependent on the duration of the deficiency and the severity of symptoms (Chalouhi et al. 2008).

Diagnosis and Treatment

A low normal serum vitamin B₁₂ level in the presence of megaloblastic cells (with or without anemia and/or the typical neuropsychiatric findings) should lead to further investigation for B₁₂ deficiency. There is no "gold standard," and there are different normal values for cobalamin levels; however, a deficiency is usually defined as a B₁₂ level

of less than 150 ng/L (Andres et al. 2004). Elevated serum methylmalonic acid and elevated serum total homocysteine can help establish whether deficiency exists (Carmel et al. 2003). Tests for intrinsic factor antibody and serum gastrin and a Schilling test may be helpful in diagnosing pernicious anemia. Differentiating the causes of B₁₂ deficiency yields important clinical information and can guide diagnosis and treatment (Carmel et al. 2003).

Daily injections of 1,000 mcg of hydroxycobalamin or cyanocobalamin are recommended for 1 week, followed by weekly injections of 1 mg for 4 weeks, and then maintenance doses every 1–3 months, depending on the severity of deficiency (Andres et al. 2009). Clinical evidence suggests that oral B₁₂ replacement also is effective as a second-line therapy (Andres et al. 2009). Remission is typically achieved within weeks, but continued maintenance therapy is recommended to fully replete body stores and to maintain longer periods of remission. Significant improvement of neuropsychiatric function has been shown after B₁₂ administration (Andres et al. 2009); the degree of recovery is correlated with symptom severity before treatment (E. Reynolds 2006). Administration of folate, without B₁₂, will reverse the hematological abnormalities, but if there is an unrecognized B₁₂ deficiency, neurological impairment may progress further, sometimes leading to irreversible deficits (E. Reynolds 2006). There is no evidence that B₁₂ injections provide any benefit for symptoms of fatigue or depression in patients who have normal B₁₂ levels.

Folic Acid Deficiency

Folic acid is found in both animal products and leafy green vegetables. Folate is important in mood and cognition, brain growth, and cell differentiation, development, and repair. These mechanisms are likely mediated through nucleotide synthesis and DNA transcription and integrity (Carmel et al. 2003). Adequate folate levels may protect against certain cancers, birth defects (Lucock 2004), and dementia (Wang et al. 2001), presumably by lowering homocysteine (Ravaglia et al. 2005).

Inadequate diet, alcoholism, chronic illness, drugs (e.g., phenytoin, valproic acid, lamotrigine, and barbiturates, trimethoprim/sulfamethoxazole, oral contraceptives, and methotrexate), and malabsorption all can cause folate deficiency (E. H. Reynolds 2002). Deficiency is more common in the elderly (E. Reynolds 2006). Low folate levels are more prevalent in psychiatric inpatients than in patients without psychiatric illness, even after controlling for drug and alcohol abuse (Lerner et al. 2006). Folate deficiency has been reported in up to one-third of psychiatric patients and is especially prevalent in those with depression (Bottiglieri et al. 2000; Carney et al. 1990). It is unclear how much of folate deficiency can be attributed to the use of psychotropic

medications, especially antiepileptic drugs, which are known to decrease folate levels.

Clinical Manifestations

Symptoms of folate deficiency are similar to those of B₁₂ deficiency; however, subacute combined degeneration of the spinal cord is specific to B₁₂ deficiency and depression is more common in folate deficiency (E. Reynolds 2006). The megaloblastic anemia in folate deficiency is identical to that seen in B₁₂ deficiency. Folate deficiency is invariably accompanied by a raised plasma homocysteine level (Bottiglieri et al. 2000; Jacques et al. 1999), which carries an increased risk of cardiovascular disease, dementia (Kim et al. 2008a; Malouf et al. 2003; Ravaglia et al. 2005), and depression (Bottiglieri et al. 2000; Fava et al. 1997; Kim et al. 2008b).

Insufficient folate during conception and early pregnancy may result in neural tube defects. Since 1998, the U.S. Food and Drug Administration has mandated fortification of grains with folate to help lower women's risk of having a pregnancy affected by neural tube defects. This action has led to a reduction in neural tube defects and an improvement of blood folate status and homocysteine levels in adults in the United States (Choumenkovitch et al. 2001, 2002; Dietrich et al. 2005; Jacques et al. 1999).

Diagnosis and Treatment

Low red blood cell folate combined with high plasma homocysteine is a good standard for the diagnosis of folate deficiency and is more accurate than measuring serum folate alone. Full treatment response to folate takes many months (E. Reynolds 2006). Although there are no clear guidelines for the dose or duration of folate therapy, treatment is recommended for at least 6 months; clinical improvement is usually seen within the first few months (E. Reynolds 2006). Dose recommendations vary, but at least 0.4 mg daily is recommended for women of childbearing age (U.S. Preventive Services Task Force 1996), although higher doses are probably more effective. Usually, 1 mg daily is prescribed to pregnant women and women trying to conceive to decrease the risk of neural tube defects (Wald 2004; Wald et al. 2001). To lower the homocysteine level, 0.8 mg daily is typically required (Homocysteine Lowering Trialists' Collaboration 2005). To treat folate deficiency, 1 mg daily until hematological recovery is generally recommended (Kunkel et al. 2000).

The relationship of vitamin deficiency to depression and dementia is complex and probably bidirectional. Depression has been associated with low baseline levels of both folate and B₁₂ (Kim et al. 2008b). In depressed patients, low folate levels were correlated with higher levels of depression, and these patients were less likely to respond to antidepressants (Fava et al. 1997; Papakostas et al. 2004). Supplemen-

tation of fluoxetine with folic acid improved antidepressant response, especially in women, although improvement was attributed to the concurrent decrease in plasma homocysteine levels rather than to increased plasma folate levels (Coppen et al. 2000). A large randomized, placebo-controlled trial in older men, however, showed no difference in depressive symptoms among subjects who received B₁₂, folic acid and B₆ supplementation compared with those who received placebo (Ford et al. 2008).

There is increasing interest in the possibility that elevated homocysteine levels are linked to cognitive impairment and dementia. Researchers have debated whether supplementation of either folate or B₁₂, which can lower homocysteine levels, has any effect on cognition or the development of dementia (Clarke et al. 2008). Findings to date have been inconsistent. Low baseline folate levels and an exaggerated decline in folate levels were predictive of dementia (Kim et al. 2008a). Multiple studies have shown that folic acid supplementation increases blood folate and decreases homocysteine (Durga et al. 2007; Jacques et al. 1999). Most studies found that a higher intake of folate, but not of the other B vitamins, is related to a lower risk of Alzheimer's dementia (Luchsinger et al. 2007; Ravaglia et al. 2005) and to better cognitive functioning (Durga et al. 2007). Other investigators found no association between dietary intake of folate or B₁₂ and the later development of Alzheimer's disease (Morris et al. 2006). Several large reviews show that supplementation of either folic acid or B₁₂ does not have a significant effect on cognition in individuals with either normal or impaired cognitive functioning (Balk et al. 2007; Malouf et al. 2003). Until more definitive information is available regarding the benefits of supplementation, it is prudent to consider checking folic acid and B₁₂ levels in elderly patients and in patients with depression or dementia and supplementing as needed.

Sickle Cell Disease

Sickle cell disease (SCD) is the most common hemoglobinopathy. The disease is a classic example of a balanced polymorphism; the asymptomatic sickle cell trait provides a selective advantage against malaria, while the homozygous disease has devastating consequences. SCD includes the homozygous disease of sickle cell anemia (SCA), sickle cell-beta thalassemia, sickle cell-hemoglobin C, and other SCD variants. Sickle cell trait has insignificant clinical consequences.

SCD occurs primarily in those of African descent, but also afflicts people of Mediterranean, Asian, and Middle Eastern origin. More than 70,000 Americans suffer from SCD. Among African Americans, the prevalence is approximately 1 in 300; 8% carry the trait. Medical advances have

transformed the disease from a pediatric illness into one that chronically extends into adulthood. Life expectancy over the past 35 years has increased, from a mean of age 14 years in the 1970s to close to age 50 years today (Platt et al. 1994).

The vaso-occlusive crisis is the hallmark of SCD. These recurrent crises, or severe pain episodes, are the cause of acute episodes of severe pain and represent the most common reason patients seek medical care. Extremes of temperature, infectious illness, dehydration, and physical exertion may precipitate crises, but the majority of crises occur without an identifiable cause. Vaso-occlusion produces acute pain in the short term and end-organ damage in the long term. Vaso-occlusion potentially affects all organ systems but leads to particular damage in bones, kidneys, lungs, eyes, and brain. Many patients suffer from chronic pain as a result of avascular necrosis, leg ulcers, or poorly understood chronic pain syndromes. The neuropsychiatric manifestations of SCD can be divided into three main categories: 1) depression and anxiety resulting from living with a chronic stigmatizing disease associated with unpredictable, painful crises and high morbidity and mortality; 2) problems related to living with chronic and acute pain (often undertreated), control of which involves long-term use of analgesics, potentially leading to opioid dependency, addiction, and pseudoaddiction; and 3) CNS damage resulting from cerebral vascular accidents, primarily during childhood. These issues are further complicated by poor psychosocial circumstances and the learned helplessness of many patients.

A significant problem with obtaining psychiatric treatment in patients with SCD is that African Americans in general are often reluctant to obtain help for mental health issues and may attempt to overcome mental health problems through self-reliance and determination (Snowden 2001). In addition, lack of psychosocial resources may put SCD patients at higher risk for poor adaptation to SCD (Burlew et al. 2000). There may be additional barriers to accessing care in patients with lower socioeconomic status. In conclusion, psychological and psychiatric complications in patients with SCD are common and contribute to functional impairment and reduced quality of life. Psychological and psychiatric care improves outcomes and should be a routine component of comprehensive SCD care.

Depression and Anxiety

As with many chronic diseases, depression and anxiety are common in adult patients with SCD. The prevalence of depression approaches 30% in SCD (Jenerette et al. 2005; Levenson et al. 2008). Anxiety disorders occur in about 7% of patients (Levenson et al. 2008). Depression and anxiety pre-

dict more daily pain and poorer physical and psychosocial quality of life in adults with SCD and account for more of the variance in all domains of quality of life than does hemoglobin type (Levenson et al. 2008). Studies assessing depression and anxiety in children with SCD have yielded mixed results (Benton et al. 2007). However, children with SCD have a higher prevalence of excessive fatigue, physical complaints, impaired self-esteem, morbid ideation, and feelings of hopelessness (Anie 2005; Yang et al. 1994). These feelings arise in the context of frequent hospitalizations, chronic absences from school, and inability to experience a normal childhood like other children.

The stigma associated with SCD significantly contributes to anxiety and depression (Jenerette et al. 2005). Adults with SCD face physical deformities, the stigma of chronic opioid use and/or mental illness, and biases related to race. The strain of facing these stigmas may have a variety of negative psychological consequences. Physical deformities result from delayed growth and development as a consequence of chronic hemolysis and chronic vaso-occlusion. In comparison with control subjects, pediatric SCD patients weigh less, are shorter, and have delayed puberty (Cepeda et al. 2000). For adolescents, these physical differences may lead to problems with self-esteem, heightened self-consciousness, dissatisfaction with body image, and social isolation (Morgan and Jackson 1986). Participation in athletics is limited due to short stature and fear of initiating a vaso-occlusive crisis. School performance suffers when hospitalizations cause multiple missed school days. Accordingly, adolescents often experience hopelessness and social withdrawal (Hurtig and Park 1989). In the United States, the stigma of SCD is compounded by the disease's predominance in an ethnic minority that already is vulnerable to racial prejudice and stereotyping (Jacob and American Pain Society 2001).

Chronic and Acute Pain and Opioid Use

Patients with SCD most commonly seek medical care for treatment of their pain. In the Pain in Sickle Cell Epidemiologic Study (PiSCES), a prospective cohort study in which adults with SCD completed daily diaries for up to 6 months, patients reported experiencing pain on more than 50% of days, and 29% reported pain on more than 95% of days. Subjects reported having sickle cell crises on 16% of days, but they sought urgent health care for crisis pain on only 3.5% of days (Smith et al. 2008). Previous studies reported a much lower frequency of painful crises; however, those studies used health care utilization as a proxy for crisis (e.g., the classic 1991 study, which reported that the average adult SCD patient experiences 0.8 episodes of vaso-occlusive severe pain episodes per year [Platt et al. 1991]) rather than obtaining patient self-reports. Pa-

tients live with the uncertainty of never knowing when the next severe pain episode will occur. Both the nature of the pain (which has been reported to be as severe as childbirth [Ballas 1998]) and its unpredictable onset can be psychologically debilitating.

Over the last 15 years, opioid treatment has gained mainstream acceptance for the treatment of SCD pain. Opioids help control pain, improve functional capacity, and decrease hospitalizations in patients with SCD (Brookoff and Polomano 1992). Chronic opioid use may result in tolerance, physiological dependence as well as substance dependence, and abuse. There is concern among authors that cognitive deficits may occur with opioid use in patients with chronic pain; however, studies have not revealed consistent evidence to support this claim (Chapman et al. 2002; see also Chapter 36, "Pain").

Substance dependence and addiction behaviors are difficult to define in any chronic pain condition. The few studies that address addiction in SCD report a low prevalence. Despite the lack of evidence in the medical literature for addiction in SCD, medical practitioners often overestimate the prevalence of addiction (Labbe et al. 2005). In surveys of health care practitioners, 63% of nurses believed that addiction was prevalent in SCD (Pack-Mabien et al. 2001), and 53% of emergency department physicians and 23% of hematologists thought that more than 20% of SCD patients were addicted (Shapiro et al. 1997). Some of this misconception results from failure to understand the difference between physiological tolerance and opioid dependence.

Due to skepticism and fear of introducing iatrogenic addiction, medical practitioners may undertreat pain in patients with SCD (Labbe et al. 2005). As a result of undertreatment, patients may develop a pseudoaddiction, where addiction-like behaviors occur as a result of inadequate pain management (Weissman and Haddox 1989). Some SCD patients may seek out illegal narcotics as a way to manage their painful crises. This behavior can lead to long-term problems with true addiction and illicit substance abuse (Alao et al. 2003). Some patients may inappropriately use opioids to help with nonpain symptoms such as insomnia, depression, and anxiety. In the PiSCES study, 31.4% of adult SCD patients were found to abuse alcohol. Although the alcoholic patients did not use more opioids than the nonalcoholic patients, they reported more pain relief from opioids. Alcohol-abusing patients also showed lower use of health care resources and, unexpectedly, reported better overall physical quality of life (Levenson et al. 2007).

Central Nervous System Damage

Brain injury from SCD complications begins early in life and is associated with neurocognitive dysfunction. An estimated 25%–33% of children with SCD have CNS effects

from the disease (Schatz and McClellan 2006). Seizures occur in 12%–14% of pediatric patients with SCD and often herald stroke (Adams 1994; J.E. Liu et al. 1994). Cerebrovascular accidents occur in 10%–15% of children with SCA. These children demonstrate intellectual deficits ranging from borderline to moderate mental retardation, reduced language function, and problems with adjustment (Hariman et al. 1991). Cognitive deficits in children with SCD can result in intellectual impairment and educational problems, as well as problems with attention and concentration, and may lead to dementia later in life (Anie 2005). SCD patients have been found to have lower scores in language skills and auditory discrimination as early as kindergarten; thus, deficits cannot be attributed to school absences (Steen et al. 2002).

Hemophilia

Hemophilia is a bleeding disorder caused by a deficiency of the coagulation factors essential for blood clotting. Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most well-known inherited bleeding disorders. Hemophilia A and B are X-linked diseases and mainly affect males. Female carriers can experience excessive bleeding, as they may have half the normal amount of clotting factors. Hemophilia A and B are clinically indistinguishable from one another.

Disease severity is related to the plasma concentrations of the clotting factors. Classification into severe, moderate, and mild hemophilia is useful for predicting bleeding tendency and prognosis, as well as for guiding treatment (Bolton-Maggs and Pasi 2003; Casey and Brown 2003; Manco-Johnson 2005). Patients with severe hemophilia (<1% clotting factor) typically bleed spontaneously into joints, muscles, soft tissues, and body cavities. During the neonatal period, especially during the first week of life, the risk of intracranial hemorrhage is estimated to be between 1% and 4%. Most children are asymptomatic until they start crawling or walking. Affected children may bruise easily and bleed following minor injuries. Families of these children may inappropriately be suspected of child abuse. By 4 years of age, many children with hemophilia have experienced a bleed into a joint.

Since the 1960s, the availability of purified factor VIII has allowed for home-based infusions, improved quality of life, and increased the life expectancy of patients with severe hemophilia. This has reduced the frequency of recurrent bleeds into large joints and muscles, with resultant fewer complications of joint injury and chronic pain. *Moderate* hemophilia (1%–5% clotting factor) is typically diagnosed by 5 years of age; bleeding episodes in patients with moderate hemophilia occur less frequently. *Mild* hemophilia

(>5% clotting factor) is usually diagnosed later, following trauma, tooth extraction, or surgery. Bleeding episodes in patients with mild hemophilia typically occur secondary to trauma; spontaneous bleeding is rare (Bolton-Maggs and Pasi 2003; Manco-Johnson 2005; White et al. 2001). In the early 1980s, more than 80% of patients with severe hemophilia who were older than 10 years were infected with viral illnesses, including HIV, hepatitis B, and hepatitis C. Beginning in the 1990s, the use of recombinant clotting factors almost eliminated the risk of transmitting viral infections (since there remains a small risk with transfusions). Advances in the treatment of hemophilia have resulted in effective prevention and control of bleeding. Nowadays, patients with severe hemophilia are much less likely to experience bleeding and its associated complications (Bolton-Maggs and Pasi 2003; Manco-Johnson 2005).

The extent of psychiatric disorders in patients with hemophilia is unknown. Higher rates of anxiety disorders have been reported in children and adolescents with hemophilia compared with those with asthma (who also have increased rates of anxiety) (Bussing and Burket 1993). Children with hemophilia must attain developmental milestones while dealing with chronic disease and must confront different disease-related stressors at different ages of development. While facing chronic pain, disability, social ostracism, and job and insurance discrimination, adults living with hemophilia strive for a healthy identity, autonomy, and a good quality of life (Spilsbury 2004).

Physicians who fear inducing drug dependence with opiates are reluctant to prescribe opiates, despite the severe pain associated with joint bleeds. Even adult patients without drug dependence report concern about potential narcotic addiction (Elander and Barry 2003). In actual practice, opiate analgesics may be used safely in patients with hemophilia. It is important to address patient concerns about becoming opiate dependent in order to provide adequate analgesia (Kunkel et al. 2000).

Individual, group, and family psychotherapy are useful psychotherapeutic modalities. Caution is needed in prescribing psychotropic agents to individuals with hemophilia. For older patients with impaired liver function from viral hepatitis, dosages of antidepressants, antipsychotics, or opiate analgesics should be reduced. Several psychotropic agents may increase the risk of bleeding, and caution must be exercised when prescribing those agents to hemophiliacs (Casey and Brown 2003; Gerstner et al. 2006; see “Hematological Side Effects and Drug Interactions of Psychotropic Agents” later in this chapter).

Hemophiliacs who developed AIDS face many additional stressors: opportunistic infections, physical wasting, declining health, chronic pain, CNS complications, frequent monitoring of viral load and CD4+ cell counts,

medication side effects, and disclosure of HIV status, resulting in further social ostracism and insurance discrimination. After a loved one's death from AIDS, bereaved families may need extensive psychological counseling and support. A study in Japan found that 7–9 years after their loved one's death, bereaved family members reported continuing deep sorrow and grief about their loss, as well as resentment, regret, anger, guilt, and anxiety over discrimination. Additionally, up to 70% of bereaved family members reported restricting their daily activities due to stigma of HIV or fear of discrimination, and up to half of bereaved family members continued suffering from mental health problems (Mizota et al. 2006).

When caring for HIV-infected hemophiliacs, health care workers may experience anxiety about exposure to HIV and guilt about having unknowingly administered hepatitis and HIV-infected clotting factors to patients in the 1980s (before safe clotting factors became available). Health care providers are faced with complex ethical and medical dilemmas when caring for HIV-infected hemophiliacs. Examples include whether to disclose HIV status to an HIV-positive child or teenager when the patient's parents oppose the disclosure, and whether to breach the confidentiality of a sexually active hepatitis or HIV-positive hemophiliac in order to inform their sexual partners of the potential risk of contracting hepatitis or HIV (Kulkarni et al. 2001).

Thalassemia

Thalassemia, originally termed *thalassa anemia* ("anemia by the sea") due to its link to the Mediterranean region, is an inherited autosomal recessive blood disease (Lorey et al. 1996; Vichinsky et al. 2005) caused by a mutation in one of the globin chains of hemoglobin. Normal adult hemoglobin is a tetramer composed of two alpha-like and two beta-like globin chains. Adult hemoglobin consists primarily of hemoglobin A ($\alpha_2\beta_2$), with small amounts of hemoglobin A₂ ($\alpha_2\delta_2$) and hemoglobin F ($\alpha_2\gamma_2$). A mutation in either chain results in either decreased (α^+ or β^+) or absent (α^0 or β^0) production of the affected globin chain and a proportional excess of the other chain. These excess globin chains are unstable and precipitate within red blood cells, leading to various clinical manifestations. As of about 1999, 200 beta-globin and 30 alpha-globin mutations have been identified, resulting in considerable clinical variability among the different types of thalassemias (Olivieri 1999). The thalassemias are named according to the globin chain affected by a mutation. Patients with alpha-thalassemia have a mutation in the gene encoding alpha-globin. In beta-thalassemia, there is a mutation in the gene encoding beta-globin (Cunningham 2008).

Demographics

In recent years there has been a dramatic change in the demographics of those affected with thalassemia. Once considered a fatal childhood illness, thalassemia now is considered a chronic adult disease. Due to advances in treatment, the median life span of patients with thalassemia is approaching 40 years of age in North America and other developed countries (Vichinsky et al. 2005). Increased survival as well as changes in immigration have drastically changed the ethnicity and age distribution of patients with thalassemia in North America (Vichinsky et al. 2005). According to the Thalassemia Clinical Research Network (TCRN) of the National Heart, Lung, and Blood Institute, in 1973 only 2% of thalassemics were age 25 years or older. By 2002, 36% of the thalassemic population was older than 25 years. There has been a decline in Mediterranean-origin patients due to declining immigration from these regions as well as the introduction of genetic counseling programs and prenatal screening. Asian patients now account for at least 50% of the thalassemic population in North America due to an increase in Asian immigration to the United States (Vichinsky et al. 2005).

Clinical Manifestations

Because the thalassemias are such a heterogeneous group of disorders, clinical manifestations usually are discussed for the group as a whole. Removal of damaged red blood cells results in splenomegaly, which leads to increased trapping of red blood cells and worsening anemia. Increased but ineffective erythropoiesis can cause bony deformities, resulting in severe disfigurement of the pelvis, spine, and skull (Olivieri 1999); facial deformities, including frontal bossing, overgrowth of the maxillae, and a prominent malar eminence (Raiola et al. 2003); and shortening of the limbs. Iron deposition may cause endocrine (hypogonadism, secondary amenorrhea, short stature) and cardiac (arrhythmias, congestive heart failure) complications (Cunningham 2008). A more comprehensive look at classification of specific clinical manifestations can be found in Cunningham (2008).

Alpha-Thalassemia

Silent carriers (α^+) manifest no clinical symptoms. In alpha-thalassemia *trait*, patients generally do not have symptoms but may have microcytosis, hypochromia and are at risk of later carrying a baby with a more severe alpha-thalassemia *syndrome* (Rappaport et al. 2004). In hemoglobin H disease, patients suffer from symptomatic anemia with microcytosis and hypochromia. It is usually mild, but some patients may develop severe hemolytic anemia with hepatosplenomegaly.

Beta-Thalassemia

Silent carriers (β^+) are clinically asymptomatic. In beta-thalassemia *minor*, patients have mild anemia, microcytosis, and hypochromia. In beta-thalassemia *intermedia*, patients may infrequently require red blood cell transfusions. Patients with beta-thalassemia *major* have severe anemia and hepatosplenomegaly and may require more than eight red blood cell transfusions per year. Without treatment, these patients will die in childhood (Cunningham 2008). Patients with beta-thalassemia *intermedia* and *major* are at risk for transient ischemic attacks and silent brain infarcts (Armstrong 2005).

Treatment

In severe forms of thalassemia, patients require red blood cell transfusions to avoid growth retardation, congestive heart failure, severe bony defects, and endocrinopathies (Schrier and Angelucci 2005). Transfusions are generally based on the severity of the anemia (Olivieri 1999). During pregnancy, rapid growth periods, and infection-associated aplastic crises, more frequent transfusions may be necessary (Borgna-Pignatti 2007; Nassar et al. 2006). Globally and prior to available screening, transfusions carried a risk of red blood cell alloimmunization and transmission of HIV and hepatitis B and C (Schrier and Angelucci 2005).

Regular red blood cell transfusions are associated with iron overload and/or hemosiderosis (Schrier and Angelucci 2005), which may result in cirrhosis, diabetes mellitus, hypothyroidism, hypoparathyroidism, growth failure, sexual immaturity, and cardiac dysfunction (Olivieri 1999). In order to prevent hemosiderosis, patients are treated with iron chelators, usually deferoxamine infusion or oral deferasirox. Currently, the only curative treatment is bone marrow transplant. Gene therapy seems promising but currently is still investigational (Olivieri 1999; Schrier and Angelucci 2005).

Psychosocial Aspects

Prior to the advent of effective therapies and early diagnosis, severely affected individuals rarely survived past early adulthood. Thalassemia may cause psychological problems, as it is an early-onset chronic illness. Frequent hospitalizations, long-term medication use, and a restricted social life are common (Ghanizadeh et al. 2006). Few studies have formally examined the psychosocial issues faced by adults; most of the literature focuses on children and their families. Common issues in children include denial and acting out, body image concerns, depression, anxiety, and impaired self-esteem (Shakin and Thompson 1991). Patients with thalassemia have an increased risk of developing psychosocial disturbances, especially in regard to

physical appearance (bony deformities, delayed or absent sexual development, and/or growth retardation), which may result in poor self-esteem (Vardaki et al. 2004).

The incidence of psychiatric disorders varies widely among patients with thalassemia. Most studies cite depression as the most common psychiatric diagnosis in patients with thalassemia. Fifty percent of patients suffer from a depressed mood, and 60% or more report irritability and anger (Ghanizadeh et al. 2006). Psychological sources of depression include the impact of chronic disease and treatment, poor self-esteem related to physical appearance, impaired fertility, and loss of peers or siblings with the disease (Bush et al. 1998; Telfer et al. 2005).

Depression also may be due to organic causes, such as zinc deficiency (Jeejeebhoy 2007; Maes et al. 1994; Nowak et al. 2005) resulting from regular deferoxamine injections (Lanskowsky et al. 2000; Lukens 1993). Several studies have found that patients with major depression have significantly lower serum zinc levels (Manser et al. 1989; McLoughlin and Hodge 1990; Moafi et al. 2008; Nowak and Szewczyk 2002), although this has not been linked specifically to thalassemia.

Frequent transfusions, hospitalizations, and overnight chelator infusions disrupt daily activities. Schooling can be adversely affected from frequent absences due to illness (Di Palma et al. 1998). Children with thalassemia may have lower mean verbal IQ scores than unaffected children (Sherman et al. 1985). Several studies have found that thalassemic children have impaired abstract reasoning and deficits in attention and memory (Monastero et al. 2000; Zafeiriou et al. 2006). They also suffer from problems with visual-spatial skills and executive functioning (Monastero et al. 2000). Likewise, one study found that adults with beta-thalassemia *major* exhibited impairments on tests of abstract reasoning, attention/processing speed, language abilities, memory, and visual-constructional skills (Armstrong 2005). Cognitive deficits could be a result of chronic anemia. Alternatively, treatment complications such as iron deposits in the brain from multiple transfusions may contribute to cognitive deficits, which are more pronounced in hemosiderotic patients (Armstrong 2005). Patients with beta-thalassemia *intermedia*/*major* also are at risk for transient ischemic attacks and silent brain infarctions, which also may result in neurocognitive deficits (Armstrong 2005).

Most literature supports a multidisciplinary approach to treatment. In places where medical care is combined with psychosocial support, patients show improved social integration and acceptance. They are more likely to finish school and to go on to higher education (McAnarney 1985). Many are able to establish relationships with peers, marry, and start a family (Politis et al. 1990; Psihogios et al. 2002).

Psychiatric illness has been found to have a significant impact on compliance; one study found psychiatric disorders present in 68% of patients who were noncompliant with deferoxamine, but in only 10% of compliant patients (Beratis 1989).

Both psychosocial support and improved doctor-patient communication have been shown to increase compliance with treatment (Bush et al. 1998). It has been recommended that patients receive an annual assessment of their psychological life as part of their routine medical care (Ratip et al. 1995; Tsiantis 1990). Other recommendations include group meetings, support groups for families, patient education, and encouragement of self-management (Masera et al. 1990). It has been found that children with a limited understanding of their disease have poorer psychiatric adjustment (Sherman et al. 1985). It has been recommended that thalassemia clinics be organized so as to minimize disruption to daily activities, such as schooling and employment, by scheduling treatments during evenings or weekends (Telfer et al. 2005).

Fear of Blood Transfusions

In the early 1980s, many patients were infected with transfusion-transmitted HIV and hepatitis viruses. At this time, the risk for transfusion-related hepatitis C infection was as high as 1 in 200 units, and in some cities, the risk for transfusion-related HIV infection was as high as 1 in 100 units. By 1997, the risk for transfusion-related infection had decreased to 1 in 100,000 units for hepatitis C and 1 in 680,000 units for HIV. Due to careful screening and testing of blood donors, improved ability to detect bloodborne pathogens, as well as technology to inactivate viruses in blood products, the blood supply in the United States is now safer than it has ever been, and the risk for transfusion-related viral infection is lower than ever (AuBuchon et al. 1997). Despite improvements in transfusion safety, however, concern persists among the general public. Even though physicians and experts view blood transfusion risks as low, substantial proportions of the population perceive transfusions as risky and are not willing to receive allogeneic blood. Some question the safety of blood transfusions and overestimate the likelihood of contracting transfusion-related HIV infection (Slovic 1987). Even though transfusions of blood are perceived as beneficial, the fear of contracting HIV and the perception that the blood supply is not safe remains the dominant concern for those who decline allogeneic blood transfusions. Instead of

viewing risk as a unidimensional probability-based variable, people's perception of the risk varies with their life experiences, beliefs, values, trust, worldviews, gender, skin color, personal characteristics, and cognitive abilities (Finucane et al. 2000; D. Lee 2006). People differ in their beliefs about what is risky for them, and physicians need to balance the need for blood products with a reasonable discussion of the risks associated with the administration of blood products or with the refusal of such treatment. Some patients' fears of transfusion are unrelated to the fear of infection; fear of blood and fear of needles are some of the most common phobias (Bienvenu and Eaton 1998).

Psychological Factors Affecting Clotting Disorders

In healthy individuals, psychological states such as major depression and anxiety may trigger the formation of blood clots (possibly via release of fibrinogen or von Willebrand's factor) and fibrinolysis (possibly via release of tissue-type plasminogen activator) (von Kanel et al. 2001). In patients with atherosclerosis and impaired endothelial cell function, procoagulant responses to acute psychosocial stressors may be more important than anticoagulant mechanisms and therefore promote a hypercoagulable state (von Kanel et al. 2001). A reduction in fibrinolytic capacity and an increase in procoagulant molecules (i.e., coagulation factor VIII or fibrinogen) have been reported in individuals with persistent psychosocial stressors such as job strain, general life stress, depression or hopelessness, anxiety, neuroticism, negative affect, and low socioeconomic status (Chida and Hamer 2008; Geiser et al. 2008; Thrall et al. 2007; von Kanel et al. 2001, 2004a, 2004b, 2005, 2006). Among patients with anxiety (e.g., panic disorder with agoraphobia or social phobia), fibrinolysis and the coagulation cascade may be activated toward a more hypercoagulable state (Geiser et al. 2008). In individuals without cardiovascular disease, depression may activate the inflammation and coagulation cascade system, which may lead to thrombosis. A positive correlation between markers of thrombosis and depression was demonstrated in patients with major depressive disorder who did not have any cardiovascular disease (Panagiotakos et al. 2004). Patients with major depression and anxiety disorders are at increased risk of thrombosis, which can predispose them to coronary artery disease (Geiser et al. 2008; Kop et al. 1998; Panagiotakos et al. 2004; Thrall et al. 2007).

Hematological Side Effects and Drug Interactions of Psychotropic Agents

Antipsychotics

Various psychotropics and their potential hematological side effects are listed in Table 24-1; potential interactions with anticoagulants are listed in Table 24-2. Antipsychotic agents with no reported hematological side effects include aripiprazole and ziprasidone. Hematological adverse effects of antipsychotics include agranulocytosis, aplastic anemia, neutropenia, eosinophilia, and thrombocytopenia.

Agranulocytosis is rare except with clozapine, but it is the most common and most serious hematological side effect of the antipsychotics (Buckley and Meltzer 1995; Flanagan and Dunk 2008; Gareri et al. 2008; Rajagopal 2005; Sedky et al. 2005). Low-potency antipsychotics have a higher frequency of agranulocytosis than high-potency ones. Clozapine causes agranulocytosis in 0.8% of patients (Flanagan and Dunk 2008; Guzelcan and Scholte 2006; Opgen-Rhein and Dettling 2008). The highest risk of clozapine-induced agranulocytosis is present during the first 6 months of treatment and then decreases significantly. The case fatality rate of clozapine-induced agranulocytosis is estimated as 4.2%–16%, depending on whether a granulocyte colony-stimulating factor (G-CSF) is used (Schulte 2006). A weekly white blood cell (WBC) count is necessary to detect and monitor for clozapine-induced agranulocytosis (Opgen-Rhein and Dettling 2008). A WBC count lower than 2,000/mm³ or an absolute neutrophil count (ANC) lower than 1,000/mm³ is an indication for immediate cessation of clozapine. Stopping clozapine usually leads to recovery in WBC counts within 3 weeks (Berk et al. 2007; Folkenberg 1990; Opgen-Rhein and Dettling 2008). The mortality risk associated with agranulocytosis is significantly increased if infection occurs before the drug is stopped (Gerson and Meltzer 1992; McEvoy et al. 2006). Because clozapine causes bone marrow suppression, G-CSF therapy may help restore normal bone marrow production (Gerson and Meltzer 1992; Lieberman and Alvir 1992; Sedky and Lippmann 2006). Patients with history of clozapine-induced agranulocytosis should be closely monitored in cases of reintroduction. However, the level of risk following reintroduction of clozapine is currently unknown.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) inhibit platelet function and have been associated with bruising and bleeding, especially with concomitant use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) (Andreassen et al. 2006; de Abajo et al. 2006; Goldberg 1998; Mort et al. 2006; Turner et al. 2007; Wessinger et al. 2006).

SSRIs increase CNS 5-hydroxytryptamine (5-HT; serotonin) and reduce 5-HT in platelets (leading to reduced platelet aggregation). Platelets normally release serotonin at the site of a vascular tear, leading to further platelet aggregation and vasodilatation and permitting the sealing of the tear without thrombosis of the vessel (Hourani and Cusack 1991).

Especially in the elderly, bleeding from the upper gastrointestinal tract may occur at a frequency ranging from 1 in 100 to 1 in 1,000 patient-years of exposure to drugs, such as the SSRIs, that have high affinity to 5-HT (de Abajo et al. 2006). The likelihood of gastrointestinal bleeding with SSRIs is similar to low dose NSAIDs (Weinrieb et al. 2005). Caution is advised in patients at high risk of gastrointestinal bleeding, for whom clinicians may consider prescribing an antidepressant with low serotonin reuptake inhibition. Patients who are at risk for gastrointestinal hemorrhage and who are taking antidepressants with high serotonin reuptake inhibition should generally use smaller doses or avoid aspirin and NSAIDs (Loke et al. 2008; Mansour et al. 2006; Serebruany 2006; Weinrieb et al. 2005). Whereas some studies have reported no associated risk of increased gastrointestinal bleeding in patients taking both SSRIs and NSAIDs (Schalekamp et al. 2008; Vidal et al. 2008), others have reported an increased risk of gastrointestinal bleeding among this group of patients (Loke et al. 2008; Weinrieb et al. 2005). Although the evidence to date indicates that SSRIs do not cause intracranial bleeding (Ramasubbu 2004), there is one report that patients taking SSRIs along with statins had a higher risk for subarachnoid hemorrhage-related vasospasm (Singhal et al. 2005). Pharmacovigilance is prudent when SSRIs are used in patients at high risk for hemorrhagic and vasoconstrictive stroke (Ramasubbu 2004).

Although some reviews have concluded there is no increased risk from combining SSRIs with warfarin (Kurdyak et al. 2005), there have been case reports of bleeding with concomitant use of warfarin and the SSRIs. Among the SSRIs, fluoxetine is the most commonly reported offending agent (Skop and Brown 1996). The interactions between warfarin and antidepressants can have potentially serious consequences, resulting from either platelet inhibition or inhibition of the cytochrome P450 (CYP) system. Of the antidepressants, fluoxetine, fluvoxamine, and paroxetine appear to have the highest potential for interactions (Duncan et al. 1998; Halperin and Reber 2007), while citalopram and sertraline may be relatively less likely to interact with warfarin (Duncan et al. 1998) (see also Chapter 38, "Psychopharmacology," Table 38-2 [Drugs with clinically significant pharmacokinetic interactions]).

Agranulocytosis due to tricyclic antidepressants (TCAs) is a rare, idiosyncratic condition caused by direct bone mar-

TABLE 24-1. Psychotropic medications and hematological side effects

Psychotropic agent	Hematological side effects
Antipsychotics	
Conventional agents	Agranulocytosis, anemia (aplastic, hemolytic), eosinophilia, leukopenia, thrombocytopenia
Atypical agents	
Clozapine	Agranulocytosis (1%–2%), eosinophilia, leukocytosis, leukopenia, thrombocytopenia
Other atypicals	Anemia, leukopenia, thrombocytopenia
Antidepressants	
Tricyclic antidepressants	Agranulocytosis, eosinophilia, leukopenia, thrombocytopenia
Serotonin–norepinephrine reuptake inhibitors	Impaired platelet aggregation
Monoamine oxidase inhibitors	
Tranylcypromine	Thrombocytopenia
Selective serotonin reuptake inhibitors	Impaired platelet aggregation
Serotonin ₂ receptor antagonism with serotonin reuptake blockade	
Trazodone	Agranulocytosis
Alpha ₂ antagonism plus serotonin ₂ and serotonin ₃ antagonism	
Mirtazapine	Agranulocytosis, thrombocytopenia
Benzodiazepines	Agranulocytosis (reported but not proven)
Mood stabilizers	
Carbamazepine	Agranulocytosis, anemia, eosinophilia, leukocytosis, leukopenia, pure red cell aplasia, thrombocytopenia
Gabapentin	Leukopenia, neutropenia
Lamotrigine	Agranulocytosis, anemia, neutropenia, pancytopenia, pure red cell aplasia, thrombocytopenia
Lithium	Leukocytosis, thrombocytosis
Phenytoin	Agranulocytosis, granulocytopenia, leukopenia, pancytopenia (with or without bone marrow suppression), thrombocytopenia
Tiagabine	Ecchymosis
Topiramate	Anemia, thrombocytopenia
Valproic acid	Pure red cell aplasia, thrombocytopenia
Zonisamide	Anemia, leukopenia

Note. Some of the reports are based on single cases, and therefore validity is not certain.

TABLE 24–2. Psychotropic medications and their possible interactions with anticoagulants

Psychotropic agent	Interaction with anticoagulant
Antidepressants	
Tricyclic antidepressants	Increased bleeding with warfarin anticoagulants ^a
Selective serotonin reuptake inhibitors	Increased INR with warfarin (fluvoxamine, fluoxetine, paroxetine)
Mood stabilizers	
Carbamazepine (CBZ)	Reduced INR with warfarin; CBZ increases metabolism of warfarin by inducing hepatic metabolism Warfarin decreases effect of CBZ
Anticonvulsants	
Phenobarbital	Reduces INR by inducing hepatic metabolism

Note. Some of the reports are based on single cases, and therefore validity is not certain.

^aAlthough some reports suggest that imipramine may alter the anticoagulant effect of warfarin by unknown mechanism, a more recent study (Yoo et al. 2009) concluded that there is no allosteric effect or competition between both drugs. Until additional information is presented, it may be advisable to monitor the International Normalized Ratio (INR) and clinical response if both drugs are to be administered.

row toxicity, with a lower frequency than is reported for antipsychotics (Oyesanmi et al. 1999). Agranulocytosis has been associated with imipramine (Albertini and Penders 1978; Gravenor 1986), clomipramine (Alderman et al. 1993; Gravenor et al. 1986; Souhami et al. 1976), and desipramine (Crammer and Elkes 1967; Hardin and Conrath 1982). Clomipramine-induced agranulocytosis may be treated with recombinant G-CSF (Hunt and Resnick 1993).

Benzodiazepines

Agranulocytosis has rarely been reported with the benzodiazepines, but no causal relationship has been established. There is no relationship between the daily dose or total cumulative dose and the occurrence of hematological side effects (Moss 1980).

Lithium

Lithium stimulates leukocytosis with a true proliferative response. In patients on lithium therapy for cluster headaches, Medina and colleagues (Albertini and Penders 1978; Medina et al. 1980) documented increases in the number of platelets and in platelet serotonin and histamine levels. In the past, because of its hematological side effects, lithium therapy was considered for persistent leukopenia and thrombocytopenia following chemotherapy or radiotherapy; however, more effective therapies are now available.

Anticonvulsants and Mood Stabilizers

Carbamazepine should be avoided in patients with a history of bone marrow depression. Carbamazepine produces a transient reduction in WBC count in approximately 10% of patients during the first 4 months of treatment (Rall and Schleifer 1980). Very rarely it can cause potentially fatal agranulocytosis and aplastic anemia. Agranulocytosis results from direct toxicity to the bone marrow (Sedky and Lippmann 2006). A baseline complete blood count (CBC) is always advised before starting carbamazepine. Carbamazepine should be discontinued if the WBC count drops below 3,500/mm³. Administration of lithium and carbamazepine concurrently may lower the risk of carbamazepine-induced neutropenia, because lithium stimulates WBC production, predominantly neutrophils (Kramlinger and Post 1990). Carbamazepine induces its own metabolism. Thus, after taking the drug for a period of time, the amount of carbamazepine in the blood will suddenly decrease. Because carbamazepine induces CYP1A2, 2C, and 3A4, it reduces the anticoagulant effect of warfarin, so both the carbamazepine level and the international normalized ratio will need to be monitored frequently when both drugs are used (Herman et al. 2006; Whiskey and Taylor 2007).

Valproate-induced increases in red blood cell mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) have been postulated to result

from alterations in erythrocyte membrane phospholipids (Ozkara et al. 1993). Potentially fatal hematopoietic complications such as neutropenia, thrombocytopenia, and macrocytic anemia have been associated with valproate (Acharya and Bussel 2000; Dulcan et al. 1995; Nasreddine and Beydoun 2008). Lamotrigine also may cause agranulocytosis (de Camargo and Bode 1999; Fadul et al. 2002). All anticonvulsants should be discontinued if the WBC count drops below $3,000/\text{mm}^3$ (Ramsay 1994).

Acetylcholinesterase Inhibitors

Donepezil is associated with anemia, thrombocythemia, thrombocytopenia, ecchymosis, and eosinophilia. The mechanism for the hematological side effects is unknown. Purpura occurs in up to 2% of patients on tacrine. Only one case of agranulocytosis has been reported with tacrine (Micromedex 2007). Rivastigmine has been reported to cause anemia, and galantamine can cause epistaxis, purpura, and thrombocytopenia (Mosby Drug Consult 2007).

Conclusion

Iron deficiency anemia primarily is associated with changes in mood and cognition. Vitamin B₁₂ deficiency is associated with problems in cognition, mood, psychosis, and (less commonly) anxiety. Folate deficiency primarily is associated with problems in mood. Patients who have sickle cell disease, a disease of chronic pain, experience difficulties with depression, anxiety, and stigma and are at risk for substance abuse and dependence. Patients with hemophilia have benefited from advances in treatment; however, their morbidity and mortality were compromised if they received blood products contaminated with HIV, hepatitis B, or hepatitis C. Depression is the most common psychiatric diagnosis associated with thalassemia. Some psychiatric disorders are associated with hypercoagulable states as well.

Most of the commonly used psychotropic medications have uncommon but potentially important hematological side effects or may interact with the anticoagulants used in medically ill patients. In this group of patients, hematological side effects may affect quality of life and contribute to medication noncompliance. When the administration of potentially interacting psychotropic drugs cannot be avoided, these side effects may be reduced by monitoring clinical response and serum drug levels. Psychiatrists who practice psychosomatic medicine should expect to encounter patients with the problems addressed in this chapter, which are frequently seen in medical settings.

Rheumatology

James L. Levenson, M.D.

Chris Dickens, M.B.B.S., Ph.D.

Michael R. Irwin, M.D.

RHEUMATOLOGICAL DISORDERS are an overlapping group of conditions that are characterized by chronic inflammation involving connective tissues and organs. The disorders arise as the result of autoimmune processes, and the various diseases are differentiated on the basis of the clinical presentation and the patterns of immune disturbance.

In this chapter we describe aspects of the rheumatological disorders that are likely to be relevant to a clinician working in the field of psychosomatic medicine. Most of the chapter is devoted to rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE), because these disorders are likely to be encountered most commonly; other disorders, including osteoarthritis, Sjögren's syndrome, systemic sclerosis, temporal arteritis, polymyositis, polyarteritis nodosa, Behçet's syndrome, and Wegener's granulomatosis, are also discussed. Psychiatric side effects of medications used in treating rheumatological disorders are addressed as well. Fibromyalgia is covered in Chapter 26, "Chronic Fatigue and Fibromyalgia Syndromes."

General Principles of Diagnosis and Assessment

Detecting Central Nervous System Involvement in Rheumatological Disorders

Although many clinical signs and symptoms, as well as laboratory test results, are suggestive of neuropsychiatric involvement, none is diagnostic. Psychiatric diagnosis is

primarily based on a constellation of clinical signs and symptoms, and possibly laboratory test results and neuroimaging findings, which should be viewed as corroboratory or exclusionary of comorbid conditions and secondary causes of neuropsychiatric symptoms.

Mental Status Examination and Neuropsychological Testing

The mental status examination is the most sensitive and least expensive tool available for detecting and tracking neuropsychiatric status in patients with rheumatological disorders. Neuropsychological testing provides a more detailed, sensitive assessment of cognitive function, but it is not specific. For example, even in the absence of any rheumatological disorder, neuropsychological testing often detects subtle cognitive abnormalities; consequently, such findings are not necessarily diagnostic of active neuropsychiatric rheumatological disease.

Laboratory Tests

No laboratory test, or set of tests, is considered diagnostic of neuropsychiatric involvement in rheumatological disorders. Nevertheless, laboratory studies serve two purposes. First, they help rule out possible infection, as well as other complications of rheumatological disorders or their treatment that can present with neuropsychiatric symptoms. Second, positive laboratory results can be used to confirm the presence of rheumatological disease activity. Although neuropsychiatric involvement can pursue a clinical course somewhat independent of flares in other

organs, high disease activity increases the likelihood of central nervous system (CNS) involvement because the pathogenesis is shared. However, the absence of systemic disease activity does not preclude primary CNS involvement. Moreover, for certain neuropsychiatric symptoms, particularly fatigue and cognitive dysfunction, systemic disease activity seems to have little, if any, correlation with their severity (Waterloo et al. 2002).

Laboratory tests also can be useful in evaluating the basis for changes in psychiatric symptoms in rheumatology patients with a history of a primary psychiatric illness such as schizophrenia or major depression. Primary psychiatric disorders do not cause elevations in erythrocyte sedimentation rate (ESR), C reactive protein, or other markers of inflammation. Accordingly, if the psychiatric symptoms temporally coincide with a markedly increased ESR, then medical etiologies, particularly infection and CNS involvement, must be strongly considered.

When rheumatology patients present with acute changes in neuropsychiatric symptoms, lumbar puncture is indicated to rule out CNS infection and to assess the degree of disease activity in the CNS. In patients without CNS infection, cerebrospinal fluid (CSF) pleocytosis and increased CSF protein are suggestive of CNS involvement by lupus or other rheumatological disease. In addition, CSF studies should include oligoclonal bands, which are present in only a few disorders, including neurosyphilis, Lyme disease, multiple sclerosis, Sjögren's syndrome, and CNS SLE. Several other CSF tests have been associated with neuropsychiatric SLE but are not widely available or timely (Cohen et al. 2004).

Electroencephalogram

In patients with rheumatological disorders who also have neuropsychiatric symptoms, the electroencephalogram (EEG) often has abnormal findings but seldom is useful as a diagnostic tool (Waterloo et al. 1999), except in identifying subclinical seizure activity or differentiating hypoactive delirium (diffuse slowing on EEG) from depression (normal EEG).

Neuroimaging

Although magnetic resonance imaging (MRI) is the best available imaging technique for identifying focal neurological lesions in patients with rheumatological disorders and neuropsychiatric symptoms, it is inherently limited because it detects only structural lesions, whereas the pathophysiology of the neuropsychiatric problems is often functional. Also, MRI cannot reliably differentiate active from chronic lesions resulting from a previous neuropsychiatric insult (Sabbadini et al. 1999).

Detecting, Diagnosing, and Quantifying Psychiatric Symptoms and Disorders

Despite their high prevalence and significant effect on the patient's illness and overall quality of life, psychiatric disorders are often not fully recognized or treated in patients with rheumatological disorders. Clinicians who focus primarily on the physical aspects of disease may fail to recognize, diagnose, and treat psychiatric disorders. For example, the presence of overlapping symptoms between depression and rheumatological disorders (e.g., fatigue, weight loss, insomnia, and lack of appetite) may lead the clinician to attribute these symptoms to the rheumatological disorder, rather than recognizing the presence of comorbid depression (Copsey Spring et al. 2007). Moreover, treatment of depression may be deferred if clinicians hold the misconception that depression is secondary to the pain and disability, rather than understanding that the presence of comorbid depression can exacerbate such symptoms in rheumatological disorders.

Self-rated questionnaires may be used by rheumatologists or specialist nurses to screen for possible cases of psychiatric disorder, with the recognition that some questionnaires (Beck Depression Inventory [BDI] and the Center for Epidemiologic Studies Depression Scale [CES-D]) tend to overestimate the prevalence of depression in medically ill populations because of their prominent inclusion of somatic symptoms that occur in medical illness including rheumatological disorders (Callahan et al. 1991). Scales that have little somatic content, such as the Geriatric Depression Scale (Sheikh and Yesavage 1989), the Hospital Anxiety and Depression Scale (HADS; Zigmond and Snaith 1983), or disease-specific instruments (Smedstad et al. 1995), may aid accurate diagnosis of depression in such patients (see also Covic et al. 2009 and Chapter 8, "Depression"). With additional training in the clinical assessment of mood-specific symptoms and related somatic symptoms, the diagnosis of depression can be made, with the initiation of antidepressant treatment when indicated; referral to psychiatric specialists can occur for complicated cases.

Complex cases will require more detailed assessment by a psychosomatic medicine specialist. In addition to assessing the patient's current mental state, the psychiatrist should explore the development of psychiatric symptoms and how these relate to the recent disease state and changes in treatment, availability of social support, psychosocial stresses resulting from pain and disability, and stresses independent of the illness. Inquiries about maladaptive coping strategies for physical symptoms (e.g., "I just lie down and wait for my symptoms to ease"; "I simply avoid activities that cause me pain") can identify fruitful targets for

psychological interventions. Assessing psychiatric history and family history will help identify which patients are most vulnerable to developing depression and other psychiatric disorders. Finally, investigating the patient's personal beliefs about the illness, such as the perceived causes, possible outcomes, and likelihood of controlling disease progression through treatment, can identify psychological factors that may facilitate recovery or perpetuate the sick role, thus influencing adherence with and response to treatment and health-related quality of life.

General Principles of Treatment

Primary Neuropsychiatric Involvement

When rheumatological diseases affect the CNS, the primary treatment is *corticosteroids* when the pathophysiology is thought to be neuronal injury or inflammation resulting from autoantibodies and *anticoagulants* when hypercoagulability is involved (e.g., the anticardiolipin antibody syndrome). When corticosteroids are ineffective, other immunosuppressive agents may be helpful.

Primary Psychiatric Disorders

The gold standard of behavioral approaches, cognitive-behavioral therapy (CBT), attempts to change maladaptive ways of thinking and feeling in response to the illness with an extensive range of strategies, including biofeedback and relaxation training, cognitive restructuring and distraction, and activity pacing. Most studies have focused on the management of pain. A recent review of 25 randomized clinical trials that tested psychosocial treatments for RA underscored the effectiveness of CBT in increasing efficacy in coping with pain and in reducing pain, physical disability, and depressive symptoms (Astin et al. 2002). However, findings show substantial variability across outcome measures. For example, among RA patients, Parker et al. (2003) found that CBT added no further benefit to the treatment of depression, as compared with pharmacological treatment alone. In contrast, an intervention (e.g., mindfulness meditation) that specifically targeted affective disturbances by way of attention to regulation of negative affective responses to stress and/or encouragement of positive engagement in daily life was found to produce consistent improvements in depressive symptoms, particularly in those RA patients who were vulnerable to depression and had reported a history of depression (Zautra et al. 2008). Such therapies may reduce pain and improve functioning (Bradley et al. 1987; Sharpe et al. 2001), with some evidence that such behavioral improvements are co-occurring with decreases in cellular markers of inflammation (Zautra et al. 2008).

Whereas pharmacological interventions are more often used to treat depression, the adjunctive use of psychological interventions should be considered in patients with rheumatological disorders who have psychiatric problems, given the positive effects of such interventions on overlapping symptoms of pain and fatigue. Given the salience of these complaints and their effect on disease activity and treatment adherence, rheumatologists, specialist nurses, and physical or occupational therapists might apply cognitive-behavioral principles to optimize patients' care. For example, as a matter of routine, newly diagnosed patients should be educated about the disease and its likely course—an approach that can facilitate adherence. Subjects with severe advanced disease might benefit from psychological adjuncts to physical management. Between these two extremes, maintaining an awareness of the importance of psychological processes in determining illness behavior might help the rheumatologist identify, treat, and make referrals for problems appropriately.

For the treatment of depressive disorders in rheumatological patients, many antidepressants are currently available to clinicians. Although their efficacy in adult populations is widely recognized, few antidepressant studies have specifically targeted rheumatological patients. One study found that sertraline had strong effects on depression outcomes as compared with a group of untreated RA patients who were clinically followed up (Parker et al. 2003). Furthermore, basic studies have suggested that activation of serotonin receptors has potent anti-inflammatory effects (Yu et al. 2008), although the clinical translational implications of these findings for the treatment of depression in RA patients are not known. Current evidence indicates that all antidepressants have approximately equal efficacy in the treatment of depression, but they do differ in their analgesic efficacy, tolerability, and potential drug interactions.

Tricyclic antidepressants (TCAs) have long been recognized to have analgesic benefits, even at low doses (e.g., 25 mg of amitriptyline) and independent of whether depression is present. In higher doses, tolerability and safety are poor, particularly in the elderly. Selective serotonin reuptake inhibitors (SSRIs) have comparable antidepressant efficacy but less analgesic efficacy. Serotonin-norepinephrine reuptake inhibitors (SNRIs) possess more analgesic potential than do SSRIs. The only randomized, placebo-controlled trials reporting analgesic efficacy of antidepressants in rheumatological disorders have been of TCAs (e.g., Ash et al. 1999; Grace et al. 1985). (See Chapter 36, "Pain.") Drug interactions may occur, although this is generally not a problem with first- and second-line treatments for RA.

Treatment of anxiety, mania, psychosis, delirium, and pain in rheumatological disorders is similar to their treatment in other medical diseases, following the principles

reviewed in other chapters in this book (Chapter 5, “Delirium”; Chapter 10, “Psychosis, Mania, and Catatonia”; Chapter 11, “Anxiety Disorders”; Chapter 36, “Pain”).

Rheumatoid Arthritis

RA affects approximately 0.8% of the population (range= 0.3%–2.1%), with women being affected approximately three times more frequently than men. It is a chronic disorder characterized by persistent inflammatory synovitis. Although any synovial joint can be affected, the disease typically involves peripheral small joints in a symmetrical pattern. Inflammation of the synovium can result in destruction of joint cartilage and bony erosions, which can eventually result in destruction of the joint. Extra-articular manifestations are common, with some degree of extra-articular involvement being found in most patients. These extra-articular manifestations vary widely among patients but may include systemic symptoms (e.g., anorexia, weight loss, myalgia); more localized abnormalities such as rheumatoid nodules; or involvement of the cardiovascular system (e.g., vasculitis, pericarditis), respiratory system (e.g., pleural effusions, pulmonary fibrosis), or CNS (e.g., spinal cord compression, peripheral neuropathy). The typical course of RA is prolonged, characterized by relapses and remissions. As the disease advances, progressive joint destruction results in limitations to joint movements, joint instability and deformities that increase pain, and functional disability.

The main aims of treatment of RA are 1) analgesia, 2) reduction of inflammation, 3) joint protection, 4) maintenance of functional ability, and 5) reduction of systemic manifestations. Pharmacological management of RA involves several different types of drug treatment:

- ♦ Nonsteroidal anti-inflammatory drugs (NSAIDs) control symptoms and signs of local inflammation, although they do not appear to alter the eventual course of the disease.
- ♦ Several drugs alter the course of the disease by reducing the inflammatory component of RA (e.g., methotrexate, antimalarials, minocycline, and sulfasalazine); gold and penicillamine are almost never used anymore.
- ♦ Corticosteroids can be used to reduce signs of inflammation by systemic administration (oral or parenteral) or by local injection.
- ♦ Currently available biological response modifiers include the anti-tumor necrosis factor (TNF)-alpha therapies—namely, etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), and an interleukin-1 (IL-1) receptor antagonist, anakinra (Kineret) (Olsen and Stein 2004).

- ♦ Immunosuppressive agents (azathioprine, leflunomide, cyclosporine, and cyclophosphamide) also reduce inflammation in RA, but because of toxicity, their use is limited to patients who do not respond to other treatments.

Neuropsychiatric Disorders in Rheumatological Disease

Epidemiology of Neuropsychiatric Disorders in RA

Neuropsychiatric disorders are common in patients with rheumatological diseases, as they are in most chronic illness populations. In a recent cross-sectional population survey in 17 countries with more than 85,000 participating adults, the presence of a mental disorder was assessed by a structured diagnostic interview in persons with and without arthritis (He et al. 2008). Findings from this large and diverse population sample indicated that depression was about twice as likely to occur in persons with arthritis compared with those without (odds ratio [OR]=1.9; 95% confidence interval [CI]=1.7 to 2.1) with similar increased risk for dysthymia (OR=2.4; 95% CI=2.0 to 2.7), anxiety disorders (OR=1.9; 95% CI=1.8 to 2.3), and possibly alcohol dependence, although the prevalence of alcohol abuse or dependence was fairly low (He et al. 2008). In a nationwide cohort study from Sweden with follow-up over three decades, individuals with rheumatological diseases had a higher risk of psychiatric disorders than did the general population, with a standardized incidence ratio of 1.45 for RA (Sundquist et al. 2008). Finally, according to standardized research interviews, it is estimated that nearly one-fifth of patients with RA have a psychiatric disorder, most often a depressive disorder.

Etiology of Neuropsychiatric Manifestations in RA

Neuropsychiatric manifestations in RA can arise through several processes, including direct CNS involvement, emotional reactions to chronic illness, and possibly secondary effects of the illness (e.g., the CNS effects of inflammatory cytokines).

Involvement of the central nervous system in RA. Despite its multisystem manifestations, neurological complications in RA are not common. When CNS involvement is present, the most common form is peripheral neuropathy. Direct involvement of the CNS is rare. Atlanto-axial subluxation may occur, resulting in transverse myelitis, and is the most widely recognized CNS complication of RA.

Vasculitis in RA can involve cerebral vessels, resulting in cerebral ischemia or infarction, and has been associated with acute and chronic brain syndromes (Ando et al. 1995; Kurne et al. 2009; Zolcinski et al. 2008). Treatment with

corticosteroids usually can alleviate vasculitis and edema, with resultant improvement in symptoms, but impairment from the infarction is permanent.

Psychiatric disorders as an emotional reaction to chronic illness. Given the well-recognized association between chronic psychosocial stress and depression (G.W. Brown and Harris 1989), it is thought that the burden of chronic physical symptoms along with personal losses resulting from RA and its associated disability contribute to the increased risk of depression in RA patients. Albers et al. (1999) found that in 89% of RA patients, the disease adversely affected at least one domain of socioeconomic functioning (e.g., work, income, required rest time during day, leisure activity, transport mobility, housing, social dependency), with 58% experiencing adverse effects in at least three domains. Other social effects to consider are loss of personal ambitions, loss of social role, loss of future financial security, relationship disturbances, and body image concerns. Social support that might help to offset the stress of RA may be less available because of limited mobility. Furthermore, RA patients may have fewer coping resources available to deal with comorbid illnesses and stresses unrelated to RA. Finally, such chronic psychosocial and interpersonal stressors are known to increase cellular and molecular markers of inflammation (Davis et al. 2008; Pace et al. 2006), which might contribute to a worsening of disease activity and a further exacerbation of disease-related stress. Indeed, chronic negative events are associated with increases in the cellular production of the inflammatory cytokine interleukin-6 (IL-6) in RA patients, which leads to increases in symptoms of fatigue independent of pain severity (Davis et al. 2008). However, such stress-induced activation of inflammatory signaling appears to be blocked by treatments that antagonize production of inflammatory cytokines (e.g., use of TNF- α antagonists such as infliximab, etanercept, or adalimumab) (Motivala et al. 2008).

Psychiatric symptoms as consequences of RA and associated inflammation. Animal models, cell culture data, and anti-inflammatory cytokine antagonist treatments provide converging evidence that dysregulation of the proinflammatory cytokine network underlies synovial inflammation in patients with RA. Indeed, proinflammatory cytokines show potent additive effects; TNF- α strongly induces production of IL-1 and IL-6, which promotes a cascade of processes, such as leukocyte infiltration of synovial tissue, collagenase and prostaglandin E production, and bone resorption.

Basic research on neural immune signaling has shown that peripheral proinflammatory cytokines exert potent effects on neural processes that lead to a constellation of

behavior changes, including abnormal sleep, depressed mood, and social withdrawal (Miller et al. 2009). Experimentally induced immune activation is associated with depressed mood, fatigue, and increases in pain sensitivity (Eisenberger et al. 2009; Reichenberg et al. 2001). These findings may be particularly relevant for RA patients because the use of medications that block peripheral proinflammatory cytokine activity (e.g., TNF antagonists) is associated with a lower prevalence of major depressive and anxiety disorders independent of clinical status (Uguz et al. 2009). Likewise, in an open study, infliximab induced acute (within hours) improvement in sleep as measured by polysomnography (Zamarron et al. 2004). Together, these data raise the possibility that inflammatory responses may initiate and perpetuate behavioral complications in RA. Alternatively, targeting inflammatory mechanisms may represent a novel strategy to ameliorate depressive symptoms in RA; for example, etanercept has been found to reduce depressive symptoms in patients with psoriasis (Tyring et al. 2006). Finally, in animal studies of "sickness behaviors," novel antidepressant drugs that target the inflammatory signaling pathways that are activated in RA (e.g., stress-activated/mitogen-activated protein kinases [SAPK/MAPK]) may work jointly to reverse the behavioral symptoms and to reduce the inflammation found in RA (Malemud and Miller 2008).

Reciprocal Associations Between Psychiatric Symptoms and Clinical Disease

Depression and Clinical State

Numerous studies have examined the associations of depression with the physical symptoms of RA. Older cross-sectional studies that used self-report measures showed that levels of depressive symptoms are associated with the severity of the pain experienced (Frank et al. 1988; Hurwicz and Berkanovic 1993; Peck et al. 1989; Smedstad et al. 1995; Wolfe 1999) and the degree of functional disability (G.K. Brown et al. 1989; Hurwicz and Berkanovic 1993; Pow 1987; Smedstad et al. 1996; Wolfe 1999). Some of the associations observed might be attributable to the use of depression measures such as the BDI, in which physical symptoms associated with the RA itself—for example, disturbed sleep, fatigue, and loss of appetite—are rated as indicators of depression. Exclusion of these somatic items leaves smaller but still significant associations between depression and the physical symptoms of RA (Peck et al. 1989).

Few longitudinal studies have examined the reciprocal associations between depression and changes in the severity of RA symptoms. Wolfe and Hawley (1993) found that changes in depression were associated with changes in pain and disability, although only 17% of the variance in

depression was accounted for by these two variables, indicating that the degree of association was weak. However, in a recent study involving more than 22,000 patients with RA followed up for nearly 10 years, self-reported increases in depression were primarily predicted by symptoms of pain and fatigue (Wolfe and Michaud 2009).

The literature just cited indicates that psychological symptoms, particularly depression, are most marked in patients with worse pain and disability, although the strength of this association is modest at best. However, it is possible that these studies underestimate the strength of the association of physical symptoms and psychological problems. The measures used to assess physical state are generic assessments of functional ability. If depression is related to loss of function, the value or meaning of the lost activity to the individual could be important. In other words, generic measures provide a broad overview of function but may not be sensitive to what is important to the individual. Katz and Yelin (1995) performed an extremely detailed prospective longitudinal study of women with RA. Subjects were followed up for 4 years to identify aspects of functioning that predicted the development of depression in the final year of the study. Although generic measures of function predicted a fourfold increase in depression, a 10% loss in activities that the individuals had identified as being important to them resulted in a sevenfold increase in depression in the subsequent year.

Furthermore, the vast majority of the research performed in this area has focused on ambulatory outpatients, probably for a combination of ethical and convenience reasons. The association between physical and psychiatric symptoms may be weak because of the mild to moderate nature of the symptoms in many of the patients studied. Mindham et al. (1981) conducted a prospective study involving a small number of patients with RA. They confirmed the positive association between symptoms of RA and the development of psychiatric symptoms considered to be of "pathological severity," but this association was weak and nonspecific in most of their patients. Only in subjects with the most severe and disabling RA did they find an association between symptoms of RA and the development of several psychiatric symptoms together, indicating the development of a psychiatric disorder. Thus, the association between symptoms of RA and psychological symptoms may become more pronounced in subjects with the most severe disease.

Role of Cognitive Appraisal Mechanisms

The way RA patients think about their illness is crucial to understanding the association of depression with pain and disability. Depression is associated with increased worry about illness and conviction of severe disease. Depressed

RA patients perceive their illness as being more serious and feel hopeless about a cure compared with nondepressed RA patients (H. Murphy et al. 1999). Furthermore, depressed patients are more likely to have cognitive distortions relating to the RA (Smith et al. 1988). These associations remain significant in RA patients even after the extent of disease and pain levels are controlled, indicating that the association between depression and negative appraisals of health status is not simply the result of depressed people having more severe illness.

The way people think about or understand their illness is also important because it influences the way RA patients cope with the illness. According to Leventhal's model, individuals hold personal representations and beliefs about their health and any threat posed to it (Leventhal et al. 1997). These personal representations have both cognitive and emotional components, are based on a lay knowledge or understanding of health and illness, and thus may significantly differ from those of the consulting clinician. Patients' perceptions of a health threat initiate the use of coping strategies, the results of which are then appraised and may result in a change in the representations or a revision of the strategy. Coping strategies may be broadly described as adaptive if they result in normalization of a patient's life—that is, minimizing symptom effect—or maladaptive if they result in increased dependency. Depression is associated with impairment of general coping, especially at high levels of pain (G.K. Brown et al. 1989; Hurwicz and Berkanovic 1993).

Thus, psychiatric disorders, particularly depression, appear to be associated with a more negative appraisal of the illness and impairment in ability to cope with the illness. As such, these cognitive appraisal mechanisms may act as mediators in the association between the physical symptoms of RA and psychiatric disorders. It should be recognized, however, that the amount of variance in depression accounted for by perceived control, coping ability, and cognitive distortions is small, with the majority being unexplained (Persson et al. 1999).

Other Psychosocial Factors Contributing to Psychiatric Symptoms

Several other psychosocial and behavioral factors that may predispose any RA patient toward psychiatric problems have been suggested.

Neuroticism. Some individuals are predisposed to experience and react to stress, including health stress, in a negative way. People with such negative affectivity, or *neuroticism*, have been shown to be more sensitive to physical sensations (Larsen 1992), interpret physical sensations as threatening (Larsen 1992), experience more emotional dis-

stress regardless of the environment (Ormel and Wohlfart 1991), and choose less effective coping strategies (Bolger and Zuckerman 1995). The importance of neuroticism has been confirmed in patients with RA. In a prospective study, RA patients completed daily reports on joint pain and mood for a period of 75 days. Those scoring higher on neuroticism experienced more chronic distress, regardless of their pain intensity (Affleck et al. 1992). Another prospective study found neuroticism to be the most effective predictor of anxiety and depressed mood in RA patients after 3 and 5 years, irrespective of other psychosocial and medical factors assessed (Evers et al. 2002).

Social support. It is recognized that social support is associated with health and good quality of life in the general population. Some studies have found that social support benefits patients with RA. In patients with RA, social support and its actual or perceived availability have been shown to be associated with use of more adaptive coping strategies (Holtzman et al. 2004), greater perception of ability to control the disease (Spitzer et al. 1995), and less psychological distress (Zyrianova et al. 2006). Not all social contacts are supportive, however, and critical or punishing comments are associated with increased psychological distress (Griffin et al. 2001).

RA has an adverse effect on the availability of social support to its patients, however. Patients with RA have been shown to have reduced social networks and social support (Fyrand et al. 2001). This disruption of social support appears to be greatest in those with disease of longest duration with the most severe functional disability, possibly caused by a significant reduction in the availability of important others to patients with RA (S. Murphy et al. 1988). That may be why longitudinal studies have found that social support's benefits are short term in RA (Demange et al. 2004; Strating et al. 2006). Importantly, such subjective social isolation may drive increases in inflammation and contribute to disease activity. Among socially isolated older adults who report high levels of loneliness, the expression of inflammatory response genes increases, which is driven in part by a reduced glucocorticoid receptor sensitivity and a failure of endogenous glucocorticoids to downregulate the inflammatory response (Cole et al. 2007).

Social stresses. Social stresses are recognized as being potent causes of depression in the general population. Particularly important in causing depression are those stresses in which the degree of threat to the individual is great—so-called severe events and marked difficulties (G.W. Brown and Harris 1979). As indicated previously, in addition to the burden of the symptoms, RA patients experience considerable hardship in association with their chronic illness.

Social stresses independent of those of RA are also likely to contribute to the development of depression in RA patients, however. In fact, among ambulatory outpatients, the stresses independent of RA may well have a greater importance in predicting depression than do the RA-related stresses (Dickens et al. 2003). The findings of this study indicate that in patients with mild to moderate arthritis, RA-related life difficulties cause psychological distress that does not amount to a full-blown psychiatric disorder, perhaps because the degree of threat is not marked. The combination of RA-related and RA-independent stresses, however, is sufficient to cause a depressive disorder. Clearly, in subjects with the most severe, disabling arthritis, the situation is likely to be different, with RA-related difficulties alone being a sufficiently potent stress to result in depressive disorder (Mindham et al. 1981).

In 27 independent studies involving more than 3,000 RA patients, stress, defined as minor hassles and life events lasting hours or days, was associated with subsequent increases in disease activity (Straub et al. 2005). In addition, some studies have suggested that social stresses might play an important part in triggering the onset of RA in adults (e.g., Baker and Brewerton 1981). Whereas some studies used unreliable retrospective measures that could be contaminated by the RA patients' effort to explain the onset of their disease, Conway et al. (1994) used a structured life event interview (e.g., Life Events and Difficulties Schedule; G.W. Brown and Harris 1989) to evaluate the associations between negative life event and RA disease onset. However, among 60 consecutive outpatients with RA, no evidence showed an increase in stressful events in the 12 months preceding the onset of RA, although conclusions from this study were constrained by the use of normative data rather than an experimental control group.

Sleep disturbance. Sleep disturbance is thought to contribute to pain, fatigue, and depressed mood in patients with RA, and several studies showed that subjective sleep complaints correlate with fatigue, functional disability, greater joint pain, and more depressive symptoms in these patients (Moldofsky 2001). Indeed, sleep difficulties, pain, depressed mood, and fatigue appear to cluster in RA; depression is associated with greater pain, whereas sleep difficulties are associated with fatigue, depression, and pain (Drewes et al. 1998; Frank et al. 1988; Nicassio et al. 2002). However, the relation between sleep disturbance and other symptoms is complex. For example, sleep disturbance may be a symptom of depression, or it may precipitate feelings of depression because it interferes with normal activities. Alternatively, both sleep disturbance and depression may be manifestations of an underlying biological disturbance such as an increase in inflammatory activity, which may al-

ter CNS function, as noted previously. For example, sleep loss induces increases in the production of inflammatory markers (Irwin et al. 2006, 2008), which then promote symptoms such as pain, fatigue, and affective disturbance. In turn, nocturnal elevations of proinflammatory cytokines and pain might recursively initiate further difficulties with sleep (Irwin et al. 2008), leading to a feed-forward vicious circle with progressive deterioration in clinical outcomes.

Effect of Mental Disorders on Inflammatory Processes

The mechanisms by which depression influences pain and disability are also poorly understood. Depression, psychological stress, and sleep disturbance have all been shown to result in increases in cellular and molecular markers of inflammation, including increases in inflammatory signaling pathways such as nuclear factor kappa-B (Irwin et al. 2006, 2008; Pace et al. 2006). Furthermore, increases in the cellular production of inflammatory cytokines correlate with self-reported fatigue in RA patients, independent of pain (Davis et al. 2008). Finally, behavioral interventions that target negative affective and emotion regulation have been found to produce improvements in depression and pain outcomes, which are coupled with a downregulation of cellular production of inflammatory markers (Zautra et al. 2008). Moreover, in another controlled trial of a CBT intervention for patients in an early stage of RA, those receiving adjunctive CBT showed improvement in C reactive protein (but not ESR) immediately after therapy compared with those receiving the control condition, but this effect was lost by 6 months (Sharpe et al. 2001). It remains unclear whether this improvement was a direct effect of the CBT on inflammatory activity or a result of behavior-mediating factors, which seems more likely, such as improved compliance with treatment in the intensively followed-up group. Indeed, depression in patients with rheumatological disorders is a strong predictor of poor medication and treatment adherence (Julian et al. 2009).

Psychiatric disorders, particularly anxiety and depression, are associated with more negative illness cognitions in RA. As a result of these negative illness cognitions, health-seeking behaviors and health care use may increase as they do in other medical patients. Depressed RA patients are more likely to report physical symptoms (H. Murphy et al. 1999), less likely to be reassured by a doctor, and less likely to comply with medications (DiMatteo et al. 2000). We know that there is an immense variation in the health care costs among subjects that is not directly related to the severity of RA (Lubeck et al. 1986). Depression has been shown to contribute to these hitherto unexplained costs (Joyce et al. 2009). The effect of depression on indirect (social) costs is likely to be even greater (Yelin et al. 1979).

Osteoarthritis

Osteoarthritis is the most common joint disease, with the idiopathic form being the most prevalent. Secondary osteoarthritis arises most frequently as the result of trauma (acute or chronic), although it also may occur in a variety of metabolic and endocrine disorders. The prevalence of osteoarthritis increases sharply with age: fewer than 2% of women younger than 45 years are affected, compared with 30% of those between 45 and 64 years of age and 68% of those older than 65 years.

The pattern of joint involvement varies with age and sex; osteoarthritis involving the hip is more common in older men, whereas involvement of the interphalangeal joints and of the first metacarpophalangeal joint is more common in elderly women. Previous joint overload—in particular, repetitive incidences, as in vocational injuries—has a considerable influence on the distribution of joint involvement. Clinically affected joints are painful, especially on movement, and are stiff after a period of inactivity. In later stages of the disease, movements are limited, and joint instability may occur, which is exacerbated by atrophy of muscles adjacent to the affected joint.

There has been less research interest in the causes, prevalence, and effect of psychological disorders in osteoarthritis compared with RA and SLE. Because direct involvement of the CNS is not a feature of primary osteoarthritis, one can conclude that psychological disorders in patients with this disorder arise either as a reaction to the pain, disability, and life difficulties related to the osteoarthritis or for reasons independent of the osteoarthritis. Nevertheless, data implicate psychological stress in worsening the severity of pain symptoms in osteoarthritis patients, particularly among those who report higher levels of depressive symptoms (Zautra et al. 2004).

Research on depression in osteoarthritis has shown findings very similar to those in RA. The prevalence of depression is significantly increased in patients with osteoarthritis, and increased pain, poor social support, and stressful life events are predictors of more depression in patients with osteoarthritis (Rosemann et al. 2007a; Sale et al. 2008). Depression in osteoarthritis patients leads to greater activity limitations, poorer quality of life, and increased health care utilization (Machado et al. 2008; Rosemann et al. 2007b).

Few intervention studies have examined the efficacy of antidepressants and psychological therapies in osteoarthritis. Those that have been performed suggest that both antidepressants and CBT are efficacious in the treatment of depression in patients with osteoarthritis and that improvement in depression is associated with reduced pain and disability from the disease (Lin et al. 2003). A random-

ized trial is ongoing to evaluate the effectiveness of combined pharmacological and nonpharmacological therapies to target depression and pain in osteoarthritis (Lin 2008).

Systemic Lupus Erythematosus

SLE is an autoimmune disorder of unknown cause characterized by immune dysregulation with tissue damage caused by pathogenic autoantibodies, immune complexes, and T lymphocytes. Approximately 90% of cases are in women, usually of childbearing age. The incidence is 2.4 per 100,000 across genders and race, 9.2 for black women, and 3.5 for white women; and prevalence rates are 90 per 100,000 for white women and 280 per 100,000 for black women. Asian people are also more often affected than white people. At onset, SLE may involve one or multiple organ systems. Common clinical manifestations include cutaneous lesions (e.g., photosensitivity, malar or discoid rash, oral ulcers), constitutional symptoms (e.g., fatigue, weight loss, fevers), arthralgias and frank arthritis, serositis (e.g., pericarditis or pleuritis), renal disease, neuropsychiatric disorders, and hematological disorders (e.g., anemia, leukopenia). Autoantibodies are detectable at presentation in most cases.

The spectrum of treatment options in SLE is similar to that in RA: namely, NSAIDs, antimalarials (e.g., hydroxychloroquine), corticosteroids, and other immunosuppressants (e.g., azathioprine, mycophenolate mofetil, methotrexate, cyclophosphamide). The role of biological response modifiers is currently under investigation, but none is currently approved for this indication. In addition, anticoagulants are used in SLE patients who have antiphospholipid antibodies if the patients have a history of arterial or venous thrombosis. The rate of 20-year survival has been reported to be 50%–70% (Lahita 2004) but is improving with newer immunosuppressive treatments.

Neuropsychiatric Manifestations in Systemic Lupus Erythematosus

Neuropsychiatric symptoms of SLE were first reported in 1872 by Kaposi (1872). Depending on the diagnostic methodology used, neuropsychiatric manifestations have a prevalence of up to 90% (Ainiala et al. 2001b), ranging from stroke, seizures, headaches, neuropathy, transverse myelitis, and movement disorders to cognitive deficits, depression, mania, anxiety, psychosis, and delirium. CNS involvement is a major cause of morbidity in SLE, second only to renal failure as a cause of mortality. The pathogenesis of neuropsychiatric syndromes in SLE is complex. For a more detailed review of psychiatric aspects of SLE, see Cohen et al. (2004).

Pathogenesis of Neuropsychiatric Syndromes in SLE

Psychiatric syndromes in SLE can be caused by 1) direct CNS involvement; 2) infection, other systemic illness, or drug-induced side effects; 3) reaction to chronic illness; or 4) comorbid primary psychiatric illness.

Direct pathophysiological central nervous system effects. Two major antibody-mediated mechanisms of CNS injury have been proposed: neuronal injury and microvasculopathy (Scolding and Joseph 2002). Autoantibodies may directly damage neurons by either causing cell death or transiently and reversibly impairing neuronal function. Antibody-mediated microvasculopathy seems to involve two processes: either endothelial damage (Wierzbicki 2000) or coagulation disturbances resulting from the prothrombotic effects of antiphospholipid (including anticardiolipin) antibodies (Gharavi 2001), both culminating in ischemia or infarction. These two pathogenic mechanisms may be mutually reinforcing, perpetuating the disease process. Microvascular endothelial injury in the CNS may increase the permeability of the blood–brain barrier, leading to influx of autoantibodies and further CNS damage. In addition, antibodies against the *N*-methyl-D-aspartate (NMDA) receptor may play a role in some manifestations of CNS lupus (Kowal et al. 2006).

Autoimmune antibodies seem to play a much larger role in direct CNS involvement (Jennekens and Kater 2002) than does immune complex deposition. Antiribosomal-P antibodies have been associated with psychosis (Isshi and Hirohata 1998) and severe depression (Arnett et al. 1996), but not consistently (Gerli et al. 2002). Antibodies against endothelial cells have been associated with psychosis and mood disorders (Conti et al. 2004). Antineuronal antibodies have been associated with psychosis, depression, delirium, coma, and cognitive dysfunction (West et al. 1995). However, these are not proven causal relationships. In contrast, antiphospholipid antibodies (e.g., anticardiolipin) cause focal deficits (strokes) and cognitive dysfunction (Levine et al. 2002; West et al. 1995). Cytokines also appear to be involved in the pathogenesis of neuropsychiatric SLE, although their role remains unclear.

With the possible exception of cognitive dysfunction, all the major psychiatric manifestations of SLE (i.e., psychosis, depression, mania, anxiety, and delirium) show a degree of reversibility, as does coma. Even the cognitive deficits sometimes respond to corticosteroids (Denburg et al. 1994; Hanly et al. 1997). Because psychiatric syndromes tend to resolve within 2–3 weeks with corticosteroid treatment (Denburg et al. 1994), they are probably caused by reversible or transient mechanisms rather than irreversible neuronal death. The reversibility of psychiatric dysfunction stands in contrast to most focal neurological events,

which often have no more reversibility than atherosclerotic stroke and are associated with fixed lesions on neuroimaging. Similarly, in some individuals, the progressive nature of the cognitive impairment (Hanly et al. 1997), often with cerebral atrophy, suggests cumulative irreversible CNS damage.

Risk factors for direct CNS involvement in SLE include cutaneous vasculitis and antiphospholipid syndrome and its manifestations, especially arterial thromboses (Karassa et al. 2000). Patients with mainly articular manifestations or discoid rash have a much lower risk of neuropsychiatric lupus, as do those few who are antinuclear antibody (ANA)-negative and those with drug-induced SLE. Antiphospholipid antibodies may be the single strongest marker of CNS risk because they are associated with stroke, cognitive dysfunction, and epilepsy (Herranz et al. 1994; Sabet et al. 1998).

Psychological effects of coping with SLE. Coping with SLE is particularly challenging because lupus is a chronic, often debilitating multisystem illness, and its course is unpredictable. Because SLE can involve almost any organ system or include vague systemic symptoms, the diagnosis is often elusive. The inability to make a diagnosis may erode the patient's confidence in the medical system, and when no etiology can be found, the physician may deem the illness psychogenic. Given that SLE can affect many organ systems, patients may worry that the illness pervades their entire body, even when the disease is limited. The diffuse nature of SLE distinguishes it from most other chronic, recurrent diseases, such as asthma or inflammatory bowel disease, which are primarily limited to one organ. SLE patients are often under the care of an entourage of specialists, which may fragment care. One of the most stressful aspects of SLE is its unpredictable course, with sudden exacerbations, remissions, and variable prognoses, resulting in a profound loss of control, as well as a loss of ability to plan for the future.

Psychological reactions to having SLE are common and include grief, depression, anxiety, regression, denial, and invalidism. A feeling of isolation is reinforced by public ignorance about lupus. People with SLE may become socially withdrawn, especially if they are self-conscious about their appearance. Women with a malar rash or discoid lesions may feel branded as if by the "scarlet letter." The most prevalent fears of SLE patients are worsening disease, disability, and death. In particular, patients fear cognitive impairment, stroke, renal failure, and becoming a burden on their families (Liang et al. 1984). Although negative reactions to having SLE are common, at least 50% of patients experience positive reactions at some point during their illness (Liang et al. 1984).

Stress and SLE. Although stress may cause a lupus flare, it is also likely, if not inevitable, that lupus flares cause stress. Several studies have provided support for stress-induced immune dysregulation in SLE (for review, see Cohen et al. 2004). Daily stress in patients with SLE has been correlated positively with ANAs and anti-double-stranded DNA antibodies (Pawlak et al. 2003) and resulted in worsening of SLE symptoms (Peralta-Ramírez et al. 2004) and cognitive dysfunction (Peralta-Ramírez et al. 2006).

Whether stress precipitates onset or exacerbation of SLE symptoms has received relatively little study. Only one controlled study has reported that 20 patients hospitalized for SLE had significantly greater stress prior to the onset of their illness than did the seriously ill hospitalized control subjects (Otto and Mackay 1967). A more recent prospective study found no effect of stressful life events on SLE disease activity of symptoms (Peralta-Ramírez et al. 2004).

Classification of Neuropsychiatric Disorders in SLE

The literature on neuropsychiatric SLE has been plagued by terminology that has been imprecise and unstandardized. Terms such as *lupus cerebritis* have obfuscated our understanding because they imply a pathogenesis (inflammation) that remains unproven. Furthermore, because there is no gold standard for the diagnosis of neuropsychiatric SLE, ascertaining which conditions are direct CNS manifestations of SLE and which are a reaction to illness or a coincidental disorder has been controversial. To rectify these problems, the American College of Rheumatology (ACR) convened a committee to develop a standardized nomenclature for neuropsychiatric SLE, and guidelines were published in 1999 (American College of Rheumatology Ad Hoc Committee 1999). The guidelines defined neuropsychiatric lupus as "the neurological syndromes of the central, peripheral, and autonomic nervous systems, and the psychiatric syndromes observed in patients with SLE in which other causes have been excluded." Psychiatric disorders included psychosis, acute confusional state, cognitive dysfunction, anxiety disorder, and mood disorders. Overall, the ACR criteria significantly broadened the spectrum of syndromes that can be considered neuropsychiatric SLE (American College of Rheumatology Ad Hoc Committee 1999). The criteria have good sensitivity but low specificity (Ainiala et al. 2001a), making them better suited for identifying all possible cases of neuropsychiatric SLE. A large international collaborative cohort study of 572 patients newly diagnosed with SLE reported that whereas 28% of patients experienced at least one ACR-defined neuropsychiatric event around the time of diagnosis, only a minority of these events were attributable to SLE (Hanly et al. 2007). A more fundamental problem with the ACR classification system is

that it is difficult to apply clinically. To diagnose neuropsychiatric SLE as the cause of the psychiatric symptoms, one must exclude a primary psychiatric disorder. In contrast, in DSM-IV-TR (American Psychiatric Association 2000), a primary psychiatric disorder cannot be diagnosed unless medical disorders and substance use are ruled out as etiologies. Whereas medical disorders and substance use can be easily excluded, no clinical criteria or laboratory tests are available for excluding primary psychiatric disorders. For example, if a patient with SLE becomes depressed, it is unclear how one would rule out primary depression as the cause.

Cognitive dysfunction is the most common neuropsychiatric disorder in patients with SLE, occurring in up to 80% of patients (Ainiala et al. 2001a; Denburg et al. 1994). On neuropsychological testing, even patients who have never had overt neuropsychiatric symptoms are often found to have cognitive impairment. Patients with anticardiolipin antibodies have a three- to fourfold increased risk of cognitive impairment, which is often progressive (Hanly et al. 1997). Cognitive impairment may be associated with lymphocytotoxic antibodies, CSF antineuronal antibodies, and pathological findings such as microinfarcts and cortical atrophy. Although cognitive dysfunction often fluctuates and is reversible (Hanly et al. 1997), presumably when attributable to edema and inflammation, it tends to be irreversible when secondary to multiple infarcts and may culminate in dementia.

Depression is the second most common neuropsychiatric disorder in SLE. The reported prevalence of depression has varied widely, depending on the diagnostic criteria, patient population, and study design. When structured interviews were used, the prevalence of depression in SLE was approximately 50% (Bachen et al. 2009). Depression may be a preexisting primary psychiatric disorder; an iatrogenically induced illness, particularly from corticosteroids; a reaction to having a chronic disease; and, possibly, a direct CNS manifestation of lupus. Kozora et al. (2006) found that patients with SLE (both those with neuropsychiatric SLE and those with nonneuropsychiatric SLE) showed higher symptoms of depression, higher levels of fatigue, greater pain, and more perceived cognitive problems. However, only patients with neuropsychiatric SLE had significant correlations among depression, fatigue, and pain. Neither the nonneuropsychiatric SLE patients nor the control subjects showed significant associations among these behavioral measures. One study has suggested that psychiatric symptoms (e.g., depression) are correlated with a reduction in regional cerebral blood flow in the posterior cingulate gyrus and thalamus (gross structural lesions were ruled out by brain MRI) (Oda et al. 2005). Nevertheless, the question of whether depression is a direct manifestation of CNS SLE or a reaction to the stress and multiple losses associated with

having a chronic debilitating illness remains unresolved (for a review of the evidence, see Cohen et al. 2004). Diagnosing depression in SLE is confounded by the overlap between depressive symptoms and those associated with SLE or its treatment. Hypothyroidism should be ruled out because it can mimic depression and is more common in SLE than in the general population.

Anxiety is quite common in SLE patients, often as a reaction to the illness. The question of whether anxiety is attributable to direct CNS involvement in SLE or simply a reaction to chronic illness remains controversial, as with depression. In patients with SLE, the most common cause of mania is corticosteroid therapy. Psychosis in SLE patients can be a manifestation of direct CNS involvement, and in some but not all studies, it has been linked to anti-ribosomal-P antibodies. Distinguishing psychosis caused by CNS lupus from corticosteroid-induced psychosis presents a major diagnostic challenge (see section titled “Corticosteroid-Induced Psychiatric Symptoms” below). Delirium, referred to as “acute confusional state” in the ACR criteria, is common in severe SLE and is a result of CNS lupus, medication, or medical disorders, as shown in Table 25-1. Personality changes have been reported in SLE patients whose disease has damaged the frontal or temporal lobes, and symptoms are typical of those resulting from pathology in those brain regions.

TABLE 25-1. Secondary medical and psychiatric causes of neuropsychiatric symptoms in systemic lupus erythematosus and other rheumatological disorders

CNS infections
Systemic infections
Renal failure (e.g., due to lupus nephritis or vasculitis involving the renal artery)
Fluid or electrolyte disturbance
Hypertensive encephalopathy
Hypoxemia
Fever
CNS tumor (e.g., cerebral lymphoma because of immunosuppression)
Medication side effects (see Tables 25-2 and 25-3)
Comorbid medical illness
Psychiatric symptoms in reaction to illness
Comorbid psychiatric illness

Note. CNS = central nervous system.

Prevalence of Neuropsychiatric Disorders in SLE

Estimates of the prevalence of neuropsychiatric disorders in SLE have ranged from 17% to 91% (Ainiala et al. 2001a; Bachen et al. 2009; Brey et al. 2002; Cohen et al. 2004). This variation is a consequence of multiple factors: 1) lack of standardized terminology, 2) changing terminology over time, 3) differences in diagnostic methods, 4) variations in which disease entities are considered direct manifestations of CNS SLE versus reactions to a chronic unpredictable illness, 5) differences in study populations, 6) differences in specialties of the investigators, 7) inclusion or exclusion of mild psychiatric symptoms, and 8) inclusion or exclusion of particular CNS neurological disorders, as well as the arbitrariness of separating these disorders from psychiatric disorders.

The ACR nomenclature was used in two studies—a cross-sectional Finnish population-based study (Ainiala et al. 2001a) and a cohort study of predominantly Mexican American persons (Brey et al. 2002)—that examined the prevalence of neuropsychiatric syndromes in outpatients with SLE. Overall, 80%–91% of patients had at least one neuropsychiatric disorder, and the prevalence rates in the two studies were similar for individual neuropsychiatric syndromes. Cognitive dysfunction was the most common neuropsychiatric condition, occurring in 79%–80% of patients; however, fewer than a third of those patients had moderate to severe impairment. Indeed, in a nationwide study from Sweden with a follow-up for more than three decades, patients with SLE showed a significantly increased risk for subsequent psychiatric disorder (e.g., standardized incidence ratio = 2.38), which was primarily due to an increased risk of dementia and delirium (Sundquist et al. 2008). In the Finnish (Ainiala et al. 2001a) and Mexican American (Brey et al. 2002) studies, major depression occurred in 28%–39%, mania or mixed episodes in 3%–4%, anxiety in 13%–24%, and psychosis in 0%–5%. A recent U.S. cohort study that used the Composite International Diagnostic Interview in white women with SLE found that 65% of the participants received a lifetime mood or anxiety diagnosis. Major depression (47%), specific phobia (24%), panic disorder (16%), obsessive-compulsive disorder (9%), and bipolar I disorder (6%) were all more common than in other white women (Bachen et al. 2009). Acute confusional state occurred in 7% of the Finnish patients with SLE; it was not reported in the Mexican American cohort. Although comparable prevalence studies have not been reported for acutely ill inpatients with neuropsychiatric SLE, the incidence of psychosis and delirium is likely to be substantially higher.

Laboratory Detection of Central Nervous System Disease Activity in Systemic Lupus Erythematosus

The general principles of treatment discussed earlier in this chapter are applicable to neuropsychiatric SLE, but relevant laboratory tests are specific to SLE. In SLE, complement levels (C3, C4, CH₅₀) and anti-DNA antibodies are elevated during disease flares (West et al. 1995). Serum ANA titers need not be obtained in SLE because they do not seem to correlate with systemic or CNS lupus activity. Testing for antiphospholipid antibodies (including lupus anticoagulant and anticardiolipin) is crucial, particularly in patients with focal symptoms, because the results may determine treatment and prognosis (Levine et al. 2002). Unlike antiphospholipid antibody-negative patients, those with antiphospholipid syndrome are treated primarily with anticoagulation rather than corticosteroid or cytotoxic therapy. As noted earlier, antiribosomal-P, antineuronal, and antiendothelial cell antibodies have been linked to psychosis and/or depression, but their usefulness is limited by their low positive predictive value (Arnett et al. 1996; Gerli et al. 2002).

Corticosteroid-Induced Psychiatric Symptoms in Systemic Lupus Erythematosus

Corticosteroids have been shown to cause a variety of psychiatric syndromes. However, such symptoms in SLE patients are usually not attributable to corticosteroids. First, severe psychiatric syndromes were reported historically in SLE prior to the introduction of corticosteroids and occur in SLE patients who have not received corticosteroids. Second, psychiatric symptoms in SLE are more frequent and severe than in other disorders treated with comparable doses of corticosteroids. Third, psychiatric symptoms in SLE are often ameliorated, not worsened, by maintenance or an increase in high-dose corticosteroids. In contrast, a reduction in steroid dosage often does not alleviate psychiatric symptoms and may exacerbate them.

Distinguishing corticosteroid-induced psychiatric reactions from flares of CNS lupus is one of the most challenging aspects of treating SLE. Helpful distinguishing features are summarized in Table 25-2 (Kohen et al. 1993). Given the risk of untreated CNS lupus and the likelihood that corticosteroids will alleviate such flares and only temporarily exacerbate corticosteroid-induced psychiatric reactions, an empirical initiation or increase of corticosteroids is often the most prudent intervention (Denburg et al. 1994). (Corticosteroid-induced psychiatric reactions are discussed later in this chapter in the section “Secondary Causes of Neuropsychiatric Symptoms in Rheumatological Disorders.”)

TABLE 25–2. Differentiation of CNS lupus flares from corticosteroid-induced psychiatric reactions

	Active primary CNS lupus	Corticosteroid-induced psychiatric reaction
Onset	After decrease in corticosteroid dosage or during ongoing low-dose treatment	Generally <2 weeks after increase in corticosteroid dosage (~90% within 6 weeks)
Corticosteroid dosage	Variable	Rare if <40 mg/day, common if >60 mg/day
Psychiatric symptoms	Psychosis, delirium > mood disorders, cognitive impairment (new onset)	Mania, mixed states, or depression (often with psychotic features) >> delirium, psychosis
SLE symptoms	Often present; may coincide with onset of psychiatric symptoms	Often present but precede onset of psychiatric symptoms
Laboratory tests	Increases in indices of inflammation	No specific laboratory findings
Response to corticosteroids	Improvement	Exacerbation of symptoms
Response to decreased corticosteroid dosage	Exacerbation	Improvement

Note. CNS = central nervous system; SLE = systemic lupus erythematosus.

Differential Diagnosis of Psychiatric Disorders in Systemic Lupus Erythematosus

Other Medical Disorders

A wide variety of diseases can mimic neuropsychiatric SLE. One group of diseases, associated with a medium to high ANA titer (>1:160), includes Sjögren's syndrome and mixed or undifferentiated connective tissue disease. A second group of diseases, associated with a low ANA titer (<1:160), includes multiple sclerosis and, less commonly, ANA-positive RA, sarcoidosis, and hepatitis C. A third group of diseases, characterized by a negative ANA, also may be mistaken for CNS lupus. This group includes polyarteritis nodosa, microscopic angiitis, Wegener's granulomatosis, chronic fatigue syndrome, fibromyalgia, temporal arteritis, and Behçet's syndrome.

Psychotropic Drug–Induced Lupus

Patients who are receiving antipsychotic drugs, particularly chlorpromazine, may have positive ANAs and antiphospholipid antibodies; most of these patients do not develop signs of an autoantibody-associated disease. Compared with other (nonpsychiatric) drugs known to cause a symptomatic lupuslike syndrome, chlorpromazine and carbamazepine carry low risk, and several other psychotropics (divalproex, other anticonvulsants, and lithium) have very low risk. CNS involvement is usually absent in drug-induced lupus. Laboratory findings may include mild cytopenia and elevated ESR and ANA titers. Antihistone antibodies are positive in up to 95% but are not pathognomonic of drug-induced lupus. After discontinuation of the drug, symp-

toms and antibody titers decline usually over a period of weeks; however, the recovery can be relatively slow and may require a year (Vedove et al. 2009).

Somatization Disorder ("Psychogenic Pseudolupus")

SLE can be misdiagnosed in "somatizing" patients with multisystem complaints and mildly positive tests for ANAs, which are common in young women.

Factitious SLE

Factitious SLE appears to be rare, but several cases have been reported (Tlacuilo-Parra et al. 2000). Patients have simulated hematuria by pricking a finger surreptitiously to add trace amounts of blood to urine specimens, injected themselves with feces or other contaminants to cause infections, or applied rouge to their cheeks to simulate a malar rash. One patient feigned proteinuria by inserting a packet of protein into her bladder. These patients had no serological evidence of an autoimmune disorder.

Pregnancy in Women With Systemic Lupus Erythematosus

Pregnancy is safe for both mother and fetus in most women with inactive and stable SLE. Pregnancy is considered high risk if the woman has active disease (especially nephritis), hypertension, or specific antibodies (Khamashta 2006). Some patients with antiphospholipid syndrome have been advised to forgo reproduction because of the risk of thrombosis, preeclampsia, and fetal demise (now much less common because of anticoagulation therapy). Family tension may escalate when a patient wants to (or her partner wants

her to) risk jeopardizing her health by becoming pregnant, despite admonitions about possible worsening renal or heart failure, hypertension, or stroke.

Sjögren's Syndrome

Sjögren's syndrome is characterized by lymphocytic infiltration of the exocrine glands. It can occur alone (primary Sjögren's) or in association with another autoimmune rheumatic disease. It is associated with a medium to high ANA titer (>1:160) and positive anti-SSA and/or anti-SSB antibodies. Many patients with primary Sjögren's make multiple autoantibodies, including rheumatoid factor and antiphospholipid antibodies. Some will go on to develop lymphoma. Although Sjögren's syndrome may be difficult to distinguish from CNS SLE (and the two syndromes may overlap), establishing a specific diagnosis is less crucial clinically because the treatment is the same. The most common symptoms result from drying of the eyes, mouth, and upper respiratory and urogenital tracts, but systemic manifestations can occur in up to one-third of patients. In general, these extraglandular manifestations are rare in secondary Sjögren's syndrome but relatively common in primary Sjögren's syndrome.

Neurological involvement has been reported in 20%–40% of cases, with both CNS and peripheral manifestations common (Delalande et al. 2004; Lafitte et al. 2001; Segal et al. 2008). Unlike SLE, CNS involvement is not correlated with titers of autoantibodies (Delalande et al. 2004). The nature of CNS involvement can be focal (e.g., cerebellar ataxia, vertigo, ophthalmoplegia, cranial nerve involvement) or diffuse (e.g., encephalopathy, aseptic meningoencephalitis, dementia, or psychiatric manifestations). Focal lesions may be visible on MRI. CNS involvement is most often manifested in subcortical dysfunction (Lafitte et al. 2001). A relatively high rate of affective and cognitive symptoms, as well as abnormal fatigue, headache, and poorly characterized pain, is noted in patients with Sjögren's syndrome (Harboe et al. 2009; Segal et al. 2008). The exact prevalence of psychiatric complications is not clear because most studies have investigated small populations with limited questionnaire methods. Psychological distress and quality of life in Sjögren's syndrome appear to be a function of the amount of fatigue and pain rather than degree of dryness (Champey et al. 2006).

Systemic Sclerosis (Scleroderma)

Systemic sclerosis is a chronic disorder of unknown etiology. The condition is characterized by thickening of the skin as a result of the accumulation of fibrotic connective tissue and damage to the microvasculature. Multiple body

systems can be involved, including the gastrointestinal tract, heart, lungs, and kidneys. Of all the connective tissue disorders, systemic sclerosis is considered to be the least likely to cause CNS damage. CNS involvement in systemic sclerosis is rare, and most neurological complications of scleroderma are peripheral neuropathies.

Psychiatric symptoms are common, with between one-third and two-thirds reporting symptoms of depression (Thombs et al. 2007). Depression and anxiety symptoms are common (Mozzetta et al. 2008). High rates of depressive symptoms in systemic sclerosis are not a result of bias related to the reporting of somatic symptoms (Thombs et al. 2008). Symptoms of anxiety, hostility, somatization, and sensitivity have been shown to be higher in those with systemic sclerosis than in healthy control subjects (Angelopoulos et al. 2001). Body image dissatisfaction is common and in one study was greater than in patients with severe burn injuries (Benrud-Larson et al. 2003), but psychological distress has not always been found related to the extent of skin involvement (van Lankveld et al. 2007). As in many other chronic diseases, impaired psychological functioning is associated with poorer health-related quality of life (Hyphantis et al. 2007).

No known treatment is available to prevent progression of scleroderma (although some medications alleviate symptoms), and the prognosis can be poor because of renal failure and pulmonary hypertension. Some patients have severe pain secondary to digital ischemia. Fatigue, pain, and concern about prognosis and disfigurement (skin thickening, discoloration, and telangiectasias on face) are common in patients with scleroderma.

Temporal (Giant Cell) Arteritis

Temporal (giant cell) arteritis, a granulomatous arteritis of unknown etiology, predominantly affects those older than 60 years. Although almost any large artery may be involved, most of the clinical features arise because of involvement of the carotid artery and its branches. Extradural arteries are most commonly involved, leading to the typical clinical picture of headache, superficial pain, or sensitivity in skin overlying inflamed vessels (e.g., pain on combing hair). Pain overlying the temporal artery with loss of pulsations is characteristic of temporal arteritis. Pain in the face, mouth, and jaw may occur, the latter characteristically being worse on eating (jaw claudication). Visual problems occur in 25% of untreated patients, and avoidable blindness may occur if treatment with corticosteroids is delayed. In 50% of patients, pain and tenderness occur in the proximal limb muscles without signs of joint effusion, which constitutes the diagnosis of polymyalgia rheumatica. Systemic features such as weight loss and malaise can

occur. Such patients may be given the misdiagnosis of fibromyalgia, but new onset later in life and an elevated ESR point toward polymyalgia rheumatica.

Neuropsychiatric manifestations of temporal arteritis arise because of the involvement of arteries supplying blood to the CNS. The insults to the CNS in temporal arteritis can be ischemic (either permanent or transient) or hemorrhagic. The clinical characteristics of the presentation depend on the nature and extent of the brain areas affected. Resultant impairments can be focal (e.g., cerebrovascular accidents leading to specific motor or sensory deficit) or diffuse, resulting in impairment of consciousness. Visual hallucinations (Charles Bonnet syndrome) are a sign of optic ischemia and if not quickly treated progress to permanent visual loss (Nesher et al. 2001). Most psychiatric symptoms in patients with temporal arteritis are a result of corticosteroid therapy (Fauchais et al. 2002).

Treatment with high-dose corticosteroids is commenced as soon as the diagnosis has been made on clinical grounds, before results of arterial biopsy are available, to prevent progression of the disease, resulting in irreversible blindness or other serious CNS damage.

Polymyositis

Polymyositis is a disease of unknown etiology that results in inflammation of the muscles. Dermatomyositis is a related condition that includes inflammation of the skin as well. The disease can occur on its own or as part of other rheumatological diseases. The clinical picture is typically that of symmetrical, proximal muscle weakness. Involvement of heart (arrhythmias, cardiac failure), gastrointestinal tract (dysphagia, reflux, constipation), and respiratory muscles (breathlessness and respiratory failure) can occur. Vasculitis can occur, rarely affecting the CNS and resulting in neuropsychiatric manifestations, including seizures, cognitive dysfunction, and depression (Ramanan et al. 2001). As with SLE and temporal arteritis, the clinical features of neuropsychiatric involvement secondary to vasculitis depend on the site and extent of the vasculitic lesions. In 20% of patients, an underlying malignancy is present (most commonly, bronchus, breast, stomach, or ovary). Thus, neuropsychiatric manifestations also may occur as the result of secondary spread of malignancy to the CNS.

Polyarteritis Nodosa

Polyarteritis nodosa is a necrotizing arteritis affecting small and medium-sized vessels, often related to hepatitis B virus

infection, typically presenting with systemic symptoms (e.g., fatigue, fever, arthralgias) and signs of multisystem involvement (e.g., hypertension, renal insufficiency, neurological dysfunction, abdominal pain). Asymmetric polyneuropathy is common. Direct involvement of the CNS is less rare than previously thought. Small cerebral infarcts are the most common neuroradiological findings, although intracranial aneurysms and intracranial hemorrhage have been reported. There have been case reports of psychosis in polyarteritis nodosa with cerebral vasculitis (e.g., Kohlhaas et al. 2007).

Behçet's Syndrome

Behçet's syndrome is an idiopathic inflammatory disorder with incidence primarily in Asia and highest incidence in Turkey. In Europe, most cases are in Turkish immigrants. The most common symptoms include oral and genital ulcers, uveitis, and skin lesions. Behçet's can be life-threatening. Neuropsychiatric involvement occurs in 10%–25% of cases (Houman et al. 2007; Tohmé et al. 2009). The most common neurological manifestations include meningoencephalitis (and/or myelitis), brain stem syndromes, and vascular thrombosis. Personality change, psychiatric disorders, movement disorders, and dementia may develop. Depression and anxiety are very common, with one study finding significant symptoms of depression in half of the patients (Taner et al. 2007). Cognitive dysfunction has been found in patients with Behçet's syndrome without overt neurological involvement (Erberk-Ozen et al. 2006; Monastero et al. 2004). Differential diagnosis includes other autoimmune disorders, multiple sclerosis, and herpes simplex infections. Brain imaging and CSF studies have abnormal but not specific results. Acute neuropsychiatric symptoms respond to corticosteroids, but chronic progressive CNS disease does not.

Wegener's Granulomatosis

Wegener's granulomatosis, an uncommon disorder of unknown etiology, is characterized by a granulomatous vasculitis, predominantly affecting the upper and lower respiratory tracts together with glomerulonephritis. Necrotizing vasculitis is the hallmark of this disorder, involving both small arteries and veins. As the result of vasculitis and granuloma formation, virtually any organ in the body can be involved, including the brain and CNS. Literature relating to the neuropsychiatric manifestations is sparse.

Secondary Causes of Neuropsychiatric Symptoms in Rheumatological Disorders

Infection, Other Central Nervous System or Systemic Illness, and Drug-Induced Side Effects

Neuropsychiatric symptoms are often secondary to complications of the rheumatological disorder or its treatment, especially infection. Because some rheumatological disorders or their treatments can be associated with immune dysregulation or immunosuppression, these disorders predispose individuals to CNS and systemic infections. These infections can simulate direct involvement of the CNS by the primary disease process as in, for example, neuropsychiatric lupus. Infections causing these secondary neuropsychiatric complications include cryptococcal, tubercular, and meningococcal infections and *Listeria* meningitis; herpes encephalitis; neurosyphilis; CNS nocardiosis; toxoplasmosis; brain abscesses; and progressive multifocal leukoencephalopathy (see also Chapter 27, "Infectious Diseases"). Other etiologies of neuropsychiatric manifestations in rheumatological disorders include uremia, hypertensive encephalopathy, cerebral lymphoma,

and medication side effects, as well as comorbid medical or psychiatric disorders and psychological reactions to illness (see Tables 25–1 and 25–3).

Corticosteroid-Induced Psychiatric Syndromes

Corticosteroids have psychiatric adverse effects, including mania, depression, mixed states, psychosis, anxiety, insomnia, and delirium. A previous psychiatric reaction to corticosteroids does not necessarily predict recurrent reactions with subsequent steroids. Mild psychiatric side effects include insomnia, hyperexcitability, mood lability, mild euphoria, irritability, anxiety, agitation, and racing thoughts. Mood disorders, including depression and mania, are the most common psychiatric reaction to corticosteroids. Patients may experience both mania and depression during a single course of corticosteroid therapy. Affective symptoms are often accompanied by psychotic symptoms. The psychiatric symptoms induced by corticosteroids most often resemble those of bipolar disorder, with manic symptoms most often encountered with high-dose, short-term administration and depression most often seen with chronic therapy (Bolanos et al. 2004). Delirium and psychosis (without mood symptoms) are less common. Cognitive dysfunction also has been reported. The most common

TABLE 25–3. Psychiatric side effects of medications used in treating rheumatological disorders

Medication	Psychiatric side effects
NSAIDs (high dose)	Depression, anxiety, paranoia, hallucinations, hostility, confusion, delirium, reduced concentration
Sulfasalazine	Insomnia, depression, hallucinations
Corticosteroids	Mood lability, euphoria, irritability, anxiety, insomnia, mania, depression, psychosis, delirium, cognitive disturbance
Gold	None reported
Penicillamine	None reported
Leflunomide	Anxiety
Azathioprine	Delirium
Mycophenolate mofetil	Anxiety, depression, sedation (all rare)
Cyclophosphamide	Delirium (at high doses) (rare)
Methotrexate	Delirium (at high doses) (rare)
Cyclosporine	Anxiety, delirium, visual hallucinations
Tacrolimus	Anxiety, delirium, insomnia, restlessness
Immunoglobulin (intravenous)	Delirium, agitation
LJP-394 ^a	None reported
Hydroxychloroquine	Confusion, psychosis, mania, depression, nightmares, anxiety, aggression, delirium

Note. NSAIDs = nonsteroidal anti-inflammatory drugs.

^aB-cell tolerogen-anti-double-stranded DNA antibodies.

symptoms in children are agitation and sleep disturbances (Tavassoli et al. 2008).

The incidence of corticosteroid-induced psychiatric symptoms is dose related: 1.3% in patients receiving less than 40 mg/day of prednisone, 4.6% in those receiving 41–80 mg/day, and 18.4% in those receiving greater than 80 mg/day (Boston Collaborative Drug Surveillance Program 1972). For most patients, the onset of psychiatric symptoms is within the first 2 weeks (and in 90%, within the first 6 weeks) of initiating or increasing corticosteroid treatment. In children, psychiatric side effects are also dose related, most often occurring at either prescribed or inadvertent high doses (Tavassoli et al. 2008).

The preferred treatment for corticosteroid-induced psychiatric reactions is tapering of corticosteroids, if possible, resulting in greater than 90% response rate. However, rapid tapering or discontinuation of corticosteroids also can induce psychiatric reactions by precipitating a flare of the rheumatological disease, iatrogenic adrenal insufficiency, or possibly corticosteroid-withdrawal syndrome. Corticosteroid-withdrawal syndrome is manifested by headache, fever, myalgias, arthralgias, weakness, anorexia, nausea, weight loss, and orthostatic hypotension and sometimes depression, anxiety, agitation, or psychosis (Margolin et al. 2007; Mercadante et al. 2007). Symptoms respond to an increase or a resumption of corticosteroid dosage. Adjunctive treatment with antipsychotics, antidepressants, and mood stabilizers can be helpful, depending on the particular psychiatric symptom constellation.

Other drugs used in treating rheumatological disorders may cause psychiatric side effects, especially hydroxychloroquine (see Table 25–3).

Chronic Fatigue and Fibromyalgia Syndromes

Michael C. Sharpe, M.A., M.D., F.R.C.P., F.R.C.Psych.

Patrick G. O'Malley, M.D., M.P.H., F.A.C.P.

IN THIS CHAPTER, WE REVIEW two symptom-defined somatic syndromes: chronic fatigue syndrome (CFS) and fibromyalgia syndrome (FMS). The central feature of CFS is the symptom of severe chronic, disabling fatigue that is typically exacerbated by exertion and unexplained by any other medical condition. The central feature of FMS is widespread pain with localized tenderness that is similarly unexplained by any other diagnosis. Although these syndromes have different historical origins, it is increasingly recognized that they have much in common (Sullivan et al. 2002). Therefore, in this chapter we will consider them together.

CFS, FMS, and other symptom-defined somatic syndromes are conditions whose homes both in medicine (as functional syndromes) and in psychiatry (as somatoform disorders) are rather temporary structures located in unfashionable areas of their respective communities. These so-called functional somatic syndromes (Wessely et al. 1999) are, however, of central concern to psychosomatic medicine. Other functional or medically unexplained syndromes covered elsewhere in this volume include noncardiac chest pain (see Chapter 18, "Heart Disease"), hyperventilation syndrome (see Chapter 19, "Lung Disease"), irritable bowel and functional upper gastrointestinal disorders (see Chapter 20, "Gastrointestinal Disorders"), idiopathic pruritus (see Chapter 29, "Dermatology"), migraine (see Chapter 32, "Neurology and Neurosurgery"), chronic pelvic pain and vulvodynia (see Chapter 33, "Obstetrics and Gynecology"),

and several other pain syndromes (see Chapter 36, "Pain"). Somatization is also discussed in Chapter 12, "Somatization and Somatoform Disorders."

General Issues

Symptom or Disorder?

Although CFS and FMS are often regarded as discrete conditions, the severity of their core symptoms of fatigue and pain is continuously distributed in the general population (Croft et al. 1996; Pawlikowska et al. 1994); the case definitions can therefore be regarded as simply defining clinically significant cutoff points on these severity continua.

Organic or Psychogenic?

The history of CFS and FMS has been notorious for sometimes bitter disputes about whether these disorders are "organic" or "psychogenic" (Asbring and Narvanen 2003). The extreme organic position argues that they eventually will be found to be as firmly based in disease pathology as any other medical condition, whereas the extreme psychogenic view is that these syndromes are really pseudodiseases, not rooted in biology but rather mere social constructions based on the psychological amplification of normal somatic sensations such as tiredness and pain. Neither of these extreme positions can be satisfactorily sustained by

the evidence or indeed is helpful in managing patients. The extreme organic view encourages the doctor to endlessly seek pathology while the patient adopts the life of the helpless invalid. The extreme psychological view encourages the doctor to dismiss the patient's physical symptoms and paradoxically can also lead to a defensive entrenchment of the patient's belief that he or she has an untreatable disease (Hadler 1996b). An etiologically neutral and integrated perspective that both recognizes the reality of the physical symptoms and acknowledges the contribution of biological, psychological, and social factors offers the best basis for effective clinical practice (Engel 1977).

Medical or Psychiatric?

In parallel with the debate about etiology is an argument about whether these conditions are most appropriately regarded as "medical" or as "psychiatric" illnesses. For a given set of symptoms, the appropriate medical diagnosis might be CFS (chronic fatigue and immune dysfunction syndrome; myalgic encephalomyelitis or encephalopathy—see "History" subsection in the following section, "The Syndromes") or FMS, whereas for the very same symptoms the appropriate psychiatric diagnosis might be an anxiety, mood, or somatoform disorder. Which is correct? We argue that neither alone is an adequate description of the illness and that both should be used. Proper use of the DSM-IV-TR (American Psychiatric Association 2000) axes allows the patient to be given both a medical (Axis III) and a psychiatric (Axis I) diagnosis. Consequently, the best diagnosis may be, for example, FMS and generalized anxiety disorder (GAD). Ultimately, however, a classification that avoids the need for two separate diagnoses for the same symptoms is desirable. Achieving this will be a challenge for the authors of the forthcoming DSM-V (Mayou et al. 2003).

The Syndromes

Chronic Fatigue Syndrome

History

CFS is not a new illness. A very similar, if not identical, condition was described as *neurasthenia* over 100 years ago and probably existed long before that (Wessely 1990). However, the term *chronic fatigue syndrome* was coined as recently as 1988 to describe a condition characterized by chronic disabling fatigue accompanied by many other somatic symptoms (Holmes et al. 1988). The authors of this early definition anticipated that a specific disease cause, possibly infectious, would be found, but an etiology has so far not been established.

CFS has subsumed a multitude of previous terms used to describe patients with similar symptoms. These include

chronic Epstein-Barr virus infection (see Chapter 27, "Infectious Diseases"), *myalgic encephalomyelitis*, *neurasthenia* (still a specific diagnosis in ICD-10 [World Health Organization 1992]), and *postviral fatigue syndrome*. Arguments persist about the appropriateness of subsuming all of these diagnoses under the umbrella term CFS. Patient advocacy groups in particular have been very vocal in arguing that the name CFS is an inadequate description of their illness and that a name such as *myalgic encephalomyelitis* or *encephalopathy* or *chronic fatigue and immune dysfunction syndrome*, which emphasizes a biological pathology, is more appropriate. The introduction of the new terminology of CFS has, however, had the important advantage for researchers of being clearly operationally defined and consequently has provided a firm basis for replicable scientific research.

Definition

Several operational diagnostic criteria for CFS have been published. The first case definition (noted in the preceding subsection, "History"), by Holmes et al. (1988), was excessively cumbersome and restrictive. Furthermore, it was found that requiring multiple somatic symptoms selected patients who were more—rather than less—likely to also meet criteria for a psychiatric diagnoses, which, combined with the strict psychiatric exclusions, made the condition very rare. Consequently, simpler and less exclusive Australian (Lloyd et al. 1988) and British (Oxford) (Sharpe et al. 1991) case definitions were constructed. The currently most widely used criteria (shown in Table 26-1) are based on an international consensus case definition published in 1994 (Fukuda et al. 1994) that has since been further clarified (Reeves et al. 2003). Finally, it should be remembered that all of these definitions have been constructed by committees with the primary aim of aiding research. Consequently, clinical practice should not be too rigidly bound by them.

Clinical Features

The core symptoms of CFS are fatigue exacerbated by exercise, and subjective cognitive impairment; in addition, disrupted and unrefreshing sleep is almost universally described, with some degree of widespread pain also common (Prins et al. 2006). Patients often report marked fluctuations in their fatigue that occur from week to week and even from day to day. Few patients are so disabled that they cannot attend an outpatient consultation, although some describe difficulty walking and require the aid of wheelchairs and other appliances. A minority remain bedridden, unable to visit the clinic, and represent an important and neglected group.

The symptom of fatigue is subjective. The correlation between the feeling of fatigue and objectively measured decrements in performance has long been known to be

TABLE 26-1. Diagnostic criteria for chronic fatigue syndrome**Inclusion criteria**

1. Clinically evaluated, medically unexplained fatigue of at least 6 months' duration that is
 - ♦ Of new onset (not lifelong)
 - ♦ Not the result of ongoing exertion
 - ♦ Not substantially alleviated by rest
 - ♦ Associated with a substantial reduction in previous level of activities
2. Presence of four or more of the following symptoms:
 - ♦ Subjective memory impairment
 - ♦ Sore throat
 - ♦ Tender lymph nodes
 - ♦ Muscle pain
 - ♦ Joint pain
 - ♦ Headache
 - ♦ Unrefreshing sleep
 - ♦ Postexertional malaise lasting more than 24 hours

Exclusion criteria

Active, unresolved, or suspected medical disease

Psychotic, melancholic, or bipolar depression (but not uncomplicated major depression)

Psychotic disorders

Dementia, anorexia or bulimia nervosa

Alcohol or other substance misuse

Severe obesity

Source. Adapted from Fukuda et al. 1994.

weak (Welford 1953). Hence, if a patient with CFS is asked to perform exercise tests, he or she may not show the expected objective decrement in performance but instead may report greater subjective effort and increased fatigue, both at the time of the test and over the following days (Wallman and Sacco 2007). Similarly, standard neuropsychological testing usually yields normal results but is often accompanied by a report of greater effort (Vercoulen et al. 1998). Some evidence indicates that more complex cognitive tests do show deficits in functioning, including reduced attention, motor speed, and working memory, although these usually appear less severe than expected from the severity of the patient's subjective complaints (Dickson et al. 2009; Majer et al. 2008; Wearden and Appleby 1996).

In summary, the core clinical features of CFS are subjective physical and mental fatigue exacerbated by physical and mental effort. Although some may interpret this sub-

jectivity as evidence of exaggeration of disability, it can also be seen as reflecting the essentially sensory nature of this condition.

Fibromyalgia**History**

More than 100 years ago, Gowers (1904) coined the term *fibrositis* to describe a chronic widespread pain thought to be caused by inflammation of muscles. However, as with CFS, specific disease pathology in muscle has not subsequently been confirmed. Other terms, such as *chronic widespread pain* (CWP) and *myofascial pain syndrome*, have been used to describe the condition. In 1990, the American College of Rheumatology adopted the operationally defined and descriptive term *fibromyalgia* as an alternative to *fibrositis* (Wolfe et al. 1990). As with CFS, the new case definition has facilitated replicable research and has been widely adopted.

Definition

The American College of Rheumatology criteria specify widespread pain of at least 3 months' duration and tenderness at 11 or more of 18 specific sites on the body. They are shown in Table 26-2.

A particular feature of the FMS criteria is the specification of specific examination findings as well as of symptoms. A standardized method of eliciting these "tender points" has been defined (i.e., the application of pressure with the thumb pad perpendicular to each defined site with increasing force by approximately 1 kg/second until 4 kg of pressure is achieved, which usually leads to whitening of the thumbnail bed). Despite the apparent precision of this clinical sign, both the specificity of the locations and the uniqueness of the proposed tender points to FMS have been questioned (Croft et al. 1996; Wolfe 1997).

Clinical Features

The core features of fibromyalgia are chronic widespread pain and musculoskeletal tenderness (muscles; ligaments and tendons). Pain occurs typically in all four quadrants of the body and the axial skeleton but also can be regional. Fatigue, sleep disturbance, and subjective cognitive impairment (memory and concentration) are common associations. As with CFS, the report of pain is essentially a subjective phenomenon and may not be reflected in attempts to assess physical and mental performance objectively.

Patients have a range of associated disability, although most patients are able to attend outpatient services. The symptoms of FMS overlap considerably with those of other rheumatological conditions, creating a diagnostic dilemma for the clinician faced with a patient who has an

TABLE 26–2. American College of Rheumatology 1990 criteria for fibromyalgia

1. History of widespread pain. Pain in the right and left sides of the body, pain above and below the waist, axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back). In this definition, shoulder and buttock pain is considered as pain for each involved side. Low back pain is considered lower-segment pain.
2. Pain, on digital palpation, must be present in at least 11 of 18 specified tender point sites. Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered positive, the patient must state that the palpation was painful. Tender is not to be considered painful.

undifferentiated constellation of chronic musculoskeletal symptoms (see subsection “Identification of Medical and Psychiatric Conditions” later in this chapter).

Primary or Secondary?

Both CFS and FMS are typically diagnosed when the patient has no evidence of another general medical condition. This makes it easy to define the symptoms as unexplained by another condition. However, similar symptoms are also found in patients with other medical diagnoses. For example, symptoms of FMS have been reported in patients with systemic lupus erythematosus (Buskila et al. 2003) and rheumatoid arthritis (Wolfe et al. 1984), and symptoms of CFS have been reported in disease-free cancer patients (Servaes et al. 2002) and in patients with multiple sclerosis (Vercoulen et al. 1996a). The terms *primary* (occurring in the absence of another condition) and *secondary* (accompanying a medical condition) have been used to describe these findings. The terminology is, however, confusing and arguably more a matter of differential diagnosis than of comorbidity (see subsection “Association With Other Symptom-Defined Syndromes” later in this section). It is best avoided.

Same or Different?

Pain and fatigue tend to co-occur in the general population (Creavin et al. 2010). Furthermore, there is an overlap in the symptoms of patients with a diagnosis of FMS and those with a diagnosis of CFS. Put simply, CFS is fatigue with pain, and FMS is pain with fatigue. A latent class analysis of the symptoms of more than 600 patients failed to identify separate syndromes (Sullivan et al. 2002). Not only are the symptoms similar, but a patient who has received the diagnosis of one of these conditions is also likely to meet the diagnostic criteria for the other. Of 163 consecutive female

patients with CFS enrolled at a tertiary care clinic, more than a third also met criteria for FMS (Ciccone and Natelson 2003). Consequently, most authorities now accept that important similarities exist between CFS and FMS (Aaron and Buchwald 2003; Wessely et al. 1999). One potential difference between CFS and FMS is the presence of so-called tender points in the former. However, tender points also are often found in patients with CFS. Whether these conditions will be found ultimately to be distinct entities, overlapping conditions, or just aspects of the same condition currently remains both unclear and controversial.

Association With Other Symptom-Defined Syndromes

Studies that have assessed the comorbidity of CFS and FMS with other symptom-defined syndromes (also known as medically unexplained symptoms or functional somatic syndromes) also have found high rates of migraine, irritable bowel syndrome, pelvic pain, and temporomandibular joint pain (Aggarwal et al. 2006; Kanaan et al. 2007; Kato et al. 2006). These syndromes, like CFS and FMS, are also associated with high lifetime rates of comorbid mood and anxiety disorders (Hudson and Pope 1994). Other similarities are also seen between CFS, FMS, and these disorders, such as a female predominance, association with childhood abuse, and response to similar treatments. This observation raises the possibility not only that CFS and FMS are similar but also that all the functional syndromes have more in common than previously thought by the specialists who diagnose them (Sullivan et al. 2002; Wessely et al. 1999). It has been further suggested that these syndromes, along with mood and anxiety disorders, share a common psychological and central nervous system (CNS) pathophysiology (Clauw and Chrousos 1997) and indeed genes (Kato et al. 2009).

Association With Psychiatric Disorders

In clinical practice, many (but not all) patients who have received a diagnosis of CFS or FMS also meet criteria for a psychiatric diagnosis. Most will meet criteria for a depression or an anxiety syndrome. Those who do not are likely to meet DSM criteria for a somatoform disorder or for the ICD-10 diagnosis of neurasthenia (Sharpe 1996). The more somatic symptoms the patient has, the more likely is a diagnosis of depression or anxiety disorder (Skapinakis et al. 2003). However, the precise prevalence rates of psychiatric disorders reported vary and will depend on a number of factors: compared with a community sample, patients attending clinics are likely to be more disabled and distressed and therefore to have more depression and anxiety. Some symptoms (such as fatigue, sleep disturbance, and poor concentration) overlap with the symptoms of depression and anx-

ity, and the observed prevalence of psychiatric disorders will depend on whether all symptoms are counted toward a diagnosis of psychiatric disorder or whether those considered medically explained by CFS or FMS are excluded. Finally, it has been argued that atypical presentations of depression (Van Hoof et al. 2003) and anxiety (Kushner and Beitman 1990) are common in these groups, adding further uncertainty to the estimates quoted in the following subsections.

Depression

Fatigue is strongly associated with depression. The international World Health Organization (WHO) study of more than 5,000 primary care patients in several countries (Sartorius et al. 1993) found that 67% of the patients meeting criteria for CFS (defined from survey data) also had an ICD-10 depressive syndrome (Skapinakis 2000). A study of clinic attenders with CFS reported that more than 25% had a current DSM major depression diagnosis and 50%–75% had a lifetime diagnosis (Afari and Buchwald 2003). Population studies have also found an elevated prevalence, although a lower rate than in some clinic-based studies (Taylor et al. 2003).

Chronic pain is also strongly associated with depression in the general population (Ohayon and Schatzberg 2003; see also Chapter 36, “Pain”). In FMS, a study of attenders at a specialist clinic reported that 32% had a depressive disorder (22% with major depression) (Epstein et al. 1999). An increased prevalence of lifetime and family history of major depression also has been reported in FMS (Hudson and Pope 1996). As with CFS, the prevalence of depression is probably lower in patients with FMS in the general population (Clauw and Crofford 2003).

Generalized Anxiety Disorder, Panic Disorder, and Posttraumatic Stress Disorder

Anxiety disorders have been relatively neglected as associations with CFS and FMS. One study reported finding GAD in as many as half of the clinic patients with CFS or FMS when the hierarchical rules that subsume it under major depression were suspended (Fischler et al. 1997).

Panic disorder is especially common in patients with medically unexplained symptoms. A prevalence of 13% was reported in one study of CFS (Manu et al. 1991), and the prevalence was 7% in clinic patients with FMS (Epstein et al. 1999). Panic disorder, which may present with predominantly somatic symptoms (Chen et al. 2009), should be suspected when the reported somatic symptoms are markedly episodic.

The prevalence of posttraumatic stress disorder (PTSD) has been reported to be higher in patients with CFS (Taylor and Jason 2001), and much higher in those with FMS (Roy-

Byrne et al. 2004), than in the general population. PTSD is associated with reports of previous abuse (see “Abuse” under the “Etiology” section later in this chapter).

Somatoform Disorders

Somatoform disorders are descriptive diagnoses primarily defined by somatic symptoms that are not explained by a medical condition. Hence, replacing a diagnosis of CFS or FMS with a somatoform one may simply be to relabel it. Furthermore, the choice of diagnosis depends on one's beliefs about the nature of these conditions. If one regards CFS and FMS as medical conditions, then the symptoms will not be counted toward a diagnosis of a somatoform disorder, whereas if one regards CFS and FMS as medically unexplained syndromes, then they will be (Johnson et al. 1996). Some patients will meet the criteria for hypochondriasis because of persistent anxious concern about the nature of their illness. Others may meet the criteria for somatization disorder because of a long history of multiple symptoms (Martin et al. 2007). Patients with FMS are likely to meet criteria for pain disorder as described in DSM-IV. Finally, most of the patients with CFS or FMS who do not meet the criteria for anxiety, depression, or these more specific disorders will fit the undemanding criteria for a diagnosis of undifferentiated somatoform disorder.

Summary

If sought, diagnoses of depressive and anxiety disorders can be commonly made in patients with CFS and FMS. There is some suggestion that anxiety is associated more with pain, and depression with fatigue (Kurtze and Svebak 2001). This association with psychiatric disorders appears not to be explained simply by overlapping symptoms, because it remains high even when fatigue is excluded from the diagnostic criteria for major depression (Kruesi et al. 1989). Neither can the occurrence of depression or anxiety disorders be attributed entirely to referral bias because the rate is still elevated, although less so, in community cases (Kato et al. 2006; Nater et al. 2009). It does not appear that depression can be explained entirely as a reaction to disability, because it has been found to be more common than in patients with disabling rheumatoid arthritis (Katon et al. 1991; Walker et al. 1997). However, despite the robustness of the association, many patients with CFS and FMS are not found to have depressive and anxiety syndromes, even after detailed assessment (Henningsen et al. 2003). Whether it is appropriate to give these people a diagnosis of a somatoform disorder rather than CFS or FMS is controversial.

It has been proposed that depression, anxiety, CFS, and FMS have shared risk factors. These may include both genetics (Kato et al. 2009) and adverse experiences such as abuse and victimization (Van Houdenhove et al. 2001a).

The lack of acceptance by others of the suffering associated with these medically ambiguous conditions may also contribute to emotional distress (Lehman et al. 2002).

The relation between symptom syndromes defined by psychiatry and those of CFS and FMS defined by general medicine is an intimate and complex one. It can be conceived of either as psychiatric comorbidity with a general medical condition or alternatively as different perspectives on the same condition. Whichever view one takes, the importance of making the psychiatric diagnosis lies in its implications for treatment.

Epidemiology

Prevalence of Fatigue and Chronic Fatigue Syndrome

Fatigue is common, but CFS as currently defined is relatively rare. A large survey of 90,000 residents in Wichita, Kansas, which used rigorous assessment and exclusion criteria, found that 6% of the population reported fatigue of more than 1 month's duration, but only 235 per 100,000 (or 0.2%) met criteria for CFS (Reyes et al. 2003). It should be noted, however, that the application of the current diagnostic criteria (Fukuda et al. 1994) excluded numerous patients, mainly because of diagnoses of rheumatoid arthritis and psychiatric disorder. A more recent study found that 1% of the Dutch population endorsed symptoms of CFS on a self-report measure, most of whom had not sought medical attention (van't Leven et al. 2010).

Prevalence of Pain and Fibromyalgia Syndrome

Studies of the prevalence of pain and FMS have reported similar findings (Makela 1999). Chronic pain is common and has been reported in as much as 10% of the general population (Croft et al. 1993), whereas FMS defined according to the American College of Rheumatology criteria has an estimated prevalence of only 2% (Wolfe et al. 1995) to 4% (K.P. White et al. 1999). The observation that FMS appears to be more common than CFS (Bazelmans et al. 1997) may indicate that chronic pain states are more common than chronic fatigue states or, alternatively, may simply reflect the requirement in the CFS diagnostic criteria for a longer duration and greater disability (see Tables 26-1 and 26-2).

Associations

Gender

Both CFS and FMS are more common in women. The female-to-male ratio for CFS has been reported to be about 4:1 (Reyes et al. 2003) and for FMS, 8:1 (Wolfe et al. 1995),

although this increased female preponderance in FMS may reflect a greater frequency of tender points rather than more frequent pain (Clauw and Crofford 2003).

Age

The most common age at onset for both CFS and FMS is between 30 and 50 years, although patients who present with FMS are on average 10 years older (Reyes et al. 2003; K.P. White et al. 1999). These syndromes are also diagnosed, although controversially, in children. An epidemiological study from the United Kingdom found a prevalence of CFS of only 0.002% in 5- to 15-year-olds (Chalder et al. 2003). CFS and FMS are also diagnosed in the elderly, but the frequency of other chronic medical conditions complicates the differential diagnosis.

Socioeconomic Status

Both CFS and FMS are more prevalent in persons who are of lower socioeconomic status and in those who have received less education (Jason et al. 1999; K.P. White et al. 1999). CFS is 50% more common in semiskilled and unskilled workers than in professionals.

International and Cross-Cultural Studies

It is often noted that the diagnoses of CFS and FMS are almost entirely restricted to Western nations, whereas the symptoms of fatigue and pain are universal. It is unclear to what extent this reflects differing epidemiology or simply different diagnostic practice. For example, in France fatigue may be diagnosed as a condition called *spasmophilia*. In the Far East, neurasthenia remains a popular diagnosis and accordingly is still listed in the ICD-10 diagnostic classification. The WHO Collaborative Study of Psychological Problems in General Health Care conducted in 14 countries reported wide variations in the prevalence of both persistent pain (including both medically explained and medically unexplained pain) and fatigue (Gureje et al. 2001; World Health Organization 1995).

Disability and Work

CFS and FMS are both associated with substantial self-reported loss of function and substantial work disability (Assefi et al. 2003). Unemployment in patients with CFS and FMS attending specialist services in the United States is as high as 50% (Bombardier and Buchwald 1996).

Prognosis

The prognosis for patients with CFS or FMS is variable; these illnesses typically have a chronic but fluctuating course. Rehabilitative therapy improves the outcome,

however (see subsection “Specialist Nonpharmacological Treatments” later in this chapter).

Prospective studies of CFS and FMS in the general population have reported that in about half the cases, the syndrome is in partial or complete remission by 2–3 years after diagnosis (Granges et al. 1994; Nisenbaum et al. 2003). Poor outcome in CFS and FMS is predicted by longer illness duration, more severe symptoms, older age, depression, and lack of social support (van der Werf et al. 2002), and in CFS by a strong belief in physical causes (Cairns and Hotopf 2005). Severely disabled patients attending specialist clinics have a particularly poor prognosis for recovery (Hill et al. 1999; Wolfe et al. 1997).

Etiology

The etiology of CFS and FMS remains unknown. While a wide range of etiological factors have been proposed, none has been unequivocally established. The available evidence may be summarized as suggesting that a combination of environmental factors and individual vulnerability initiates a series of biological, psychological, and social processes that lead to the development of CFS or FMS (Table 26–3). These factors are discussed in the following subsections as predisposing, precipitating, and perpetuating factors. It is worth mentioning that, with notable exceptions, the preponderance of research in this area is based on small case-control studies (typically 10–20 patients per case and control group) with insufficient power to control for confounding variables, thereby limiting our ability to draw strong causal inferences about any of the findings reported below.

Predisposing Factors

Biological Factors: Genetics

Modest evidence from family and twin studies suggests that genetic factors play a part in predisposing individuals to CFS and to FMS. In a study of 146 female–female twins, one of whom had CFS, the concordance was 55% in monozygotic and 20% in dizygotic twins (Buchwald et al. 2001), suggesting both moderate heritability and the importance of environmental factors. In FMS, a similar familial clustering has been reported (Buskila and Neumann 1997). Claims for the role of specific genes in the etiology of these conditions remain unproven (Kaiser 2006).

Psychological and Social Factors

Personality and activity. Clinicians often claim a predisposing “obsessional” personality type, but this theory has been little studied. The clinical observation that CFS and FMS patients lead abnormally active lives or have high levels

of exercise before becoming ill does have some empirical support (Harvey et al. 2008a; Van Houdenhove et al. 2001b).

Previous psychiatric illness. A long-term cohort study has confirmed that persons with a prior history of depression or anxiety are more likely to develop CFS (Harvey et al. 2008b), suggesting that either the psychiatric illness itself or a shared risk factor such as genetics (Kato et al. 2009) predisposes individuals to CFS.

Abuse. Childhood and adult neglect, abuse, and maltreatment have been reported to be more common in CFS and FMS (Heim et al. 2006; Paras et al. 2009) than in comparison groups. A recent study found that people who reported abuse had six times the risk of CFS (Paras et al. 2009). Both psychological and biological etiological mechanisms for the etiological role of trauma have been suggested.

Social status. Low social status and lower levels of education are risk factors for both CFS and FMS (see subsection “Socioeconomic Status” in the “Epidemiology” section earlier in this chapter).

Precipitating Factors

Precipitating factors trigger the illness in vulnerable persons.

Biological Factors

Infection. There is some evidence that infection can precipitate CFS, and some, but less, evidence indicates that infection also may trigger FMS (Rea et al. 1999). Specific infections have been found to be associated with the subsequent development of CFS in 10%–40% of patients. These infections are Epstein-Barr virus (P.D. White et al. 2001), Q fever (Ayres et al. 1998), viral meningitis (Hotopf et al. 1996), viral hepatitis (Berelowitz et al. 1995), and parvovirus (Kerr and Matthey 2008). The etiological mechanism to explain this association remains unclear but may include stress, immunological factors, and an acute reduction in activity (P.D. White et al. 2001) (see “Perpetuating Factors” later in this section).

Injury. The role of physical injury in the etiology of CFS and FMS has been controversial, in part because of the implications for legal liability and compensation. Limited evidence indicates that both conditions may be precipitated by injury, particularly to the neck. If a link exists, it is stronger for FMS (Al Allaf et al. 2002).

Psychological and Social Factors: Life Stress

Clinical experience indicates that patients often report the onset of CFS and FMS as occurring during or after a stress-

TABLE 26-3. Possible etiological factors to consider in a formulation of chronic fatigue syndrome or fibromyalgia syndrome

	Predisposing	Precipitating	Perpetuating
Biological	Genetics	Acute infection, disease, or injury	Neuroendocrine changes Immunological changes Deconditioning Sleep disorder
Psychological	Personality Depression or anxiety	Perceived stress	Depression Fixed disease attribution Catastrophizing Low self-efficacy Avoidance of activity
Social	Lack of support	Life events	Illness-reinforcing information Lack of legitimacy of illness Social or work stress Occupational and financial factors

ful period in their lives. The evidence for life stress or life events being a precipitant of FMS and CFS is, however, both limited and retrospective (Anderberg et al. 2000; Theorell et al. 1999). One of the best studies so far published examined 64 patients and a similar number of matched control subjects. An excess of severe life events and difficulties was found in the CFS patients for the year prior to onset. More specifically, a certain type of life event called a *dilemma* (defined as an event when the person had to choose between two equally undesirable responses to circumstances) was found in one-third of the patients with CFS and none of the control subjects (Hatcher and House 2003).

Perpetuating Factors

Perpetuating factors are those that maintain a condition once it is established. They are clinically the most important because they are potential targets for treatment.

Biological Factors

Chronic infection. There has been much interest in the potential role of ongoing infection and in associated immunological factors, especially in CFS. It was previously thought that chronic Epstein-Barr virus was a cause of CFS, but that hypothesis has been rejected. There have been numerous reports of evidence of chronic infection with other agents in both CFS and FMS, the most recent being with a xenotropic murine leukemia-related virus (XMRV) (Lombardi et al. 2009). None has so far been substantiated.

Immunological factors. Immunological factors, especially cytokines, also have been much investigated in CFS and FMS, not only because of the possible triggering effect of infection but also because administration of immune active agents, such as interferons, is recognized as a cause of fatigue and myalgia (Vial and Descotes 1994) and because similar symptoms in conditions such as hepatitis C have been associated with changes in measured cytokines (Thompson and Barkhuizen 2003). Various minor immune abnormalities, mainly mild degrees of activation, have been reported in patients with CFS and FMS. However, a systematic review found no evidence of any consistent immune abnormality in CFS (Lyll et al. 2003). The hypothesis that CFS is associated with immune activation therefore remains tantalizing but unproven.

Myopathic or biochemical abnormalities and physiological deconditioning. The bulk of evidence indicates that there are no proven pathological or biochemical abnormalities of muscle or muscle metabolism, either at rest or with exercise, other than those expected with deconditioning. *Deconditioning* describes the physiological changes that lead to the loss of tolerance of activity after prolonged rest (e.g., as a result of pain). It has been found in many, but not all, patients with CFS (Bazelmans et al. 2001; Fulcher and White 2000) and also in those with FMS (Valim et al. 2002). Deconditioning offers one biological explanation for exercise-induced fatigue and worsening or persistent muscle pain in patients with CFS and FMS and also provides a rationale for treatment with graded activity (see sub-

section “Specialist Nonpharmacological Treatments” later in this chapter).

Sleep abnormalities. Patients with CFS and FMS typically complain of unrefreshing and broken sleep, a symptom that has been objectively confirmed with polysomnography. Abnormalities in sleep have been claimed to be of major etiological importance, especially in FMS. Early work (Moldofsky et al. 1975) reported a specific sleep electroencephalogram abnormality of alpha wave intrusion into slow-wave sleep (so-called alpha-delta sleep) and suggested that this was a cause of the myalgia. However, attempts to replicate this finding in both CFS and FMS have produced inconsistent results, and its specificity to chronic pain remains unclear (Rains and Penzien 2003). A number of other abnormalities in sleep variables have been reported in recent years in CFS and FMS, but no clear and consistent differences are apparent.

Neuroendocrine changes. One of the best-supported biological abnormalities associated with both CFS and FMS is changes in the level and response of neuroendocrine stress hormones. A repeated observation has been of a tendency to low blood levels of cortisol and a poor cortisol response to stress (Parker et al. 2001). This finding differs from what would be expected in depression (in which blood levels of cortisol are typically elevated) but is similar to that reported in other stress-induced and anxiety states. It is not known whether this is a primary abnormality or merely a consequence of inactivity or sleep disruption. Low cortisol has been reported to be associated with a history of childhood trauma (Heim et al. 2009). Although there is evidence that cortisol levels can be raised by successful cognitive-behavioral therapy (CBT) treatment (Roberts et al. 2009), low cortisol at baseline predicts a poorer response to CBT (Roberts et al. 2010).

Patients with FMS may also have an elevated level of substance P in their cerebrospinal fluid (Russell et al. 1994). A similar finding has been made in patients with other chronic pain syndromes such as osteoarthritis. However, elevated substance P has not been found in CFS patients (Evengard et al. 1998).

Blood pressure regulation. Failure to maintain blood pressure when assuming erect posture (orthostatic intolerance) and particularly a pattern in which the heart rate increases abnormally (postural orthostatic tachycardia syndrome) have been reported in both CFS (Rowe et al. 1995) and FMS (Bou-Holaiigah et al. 1997). These findings have been interpreted as indicating abnormal autonomic nervous system function (Newton et al. 2009). However, postural hypotension commonly occurs in healthy persons af-

ter prolonged inactivity (Sandler and Vernikos 1986), and its specificity to CFS and FMS remains unclear.

CNS structure. The brains of patients with CFS and FMS are probably structurally normal, although a reduction in gray matter has been reported in both CFS (de Lange et al. 2005) and FMS (Burgmer et al. 2009). However, this apparent difference in amount of gray matter has been reported to disappear after controlling for depression (Hsu et al. 2009). Interestingly, the reduction in gray matter also appears to be at least partially reversed by treatment with CBT (de Lange et al. 2008).

CNS function. The use of functional brain imaging has great potential to elucidate the biology of these conditions but remains in its infancy. There is, however, accumulating evidence of abnormally increased activation of pain systems in patients with fibromyalgia in response to painful stimuli (Pujol et al. 2009) and even with only the anticipation of a painful stimulus (Schweinhart et al. 2008). These findings are consistent with a “symptom amplification” model of these syndromes.

An early single photon emission computed tomography (SPECT) study (Costa et al. 1995) and a positron emission tomography (PET) study (Tirelli et al. 1998) reported reduced brain stem perfusion in patients with CFS. However, another study that found fewer differences when CFS patients were compared with depressed patients reminds us of the need for careful control for variables such as depression (Machale et al. 2000). As with pain, more widespread cerebral activation is seen in CFS patients than in control subjects when performing a fatiguing cognitive task (Cook et al. 2007).

Although tantalizing, these imaging findings must be regarded as preliminary. Furthermore, evidence of changes in brain activation or brain reorganization must not be taken to mean that the symptoms are necessarily based in fixed neurological pathology; behavioral rehabilitation and drug therapy can potentially reverse such changes (Flor 2003).

Psychological and Social Factors

There is strong evidence that psychological and behavioral factors play a major role in perpetuating CFS and FMS.

Illness beliefs. One of the most striking aspects of the presentation of CFS and FMS to clinicians involves the often strong beliefs many patients hold about the cause of their illness. Three categories of illness beliefs are considered here: 1) cause of symptoms (attributions), 2) significance of symptoms (catastrophizing), and 3) what one can do despite having symptoms (self-efficacy).

Although the causes of CFS and FMS are unknown, many patients, and especially those seen in specialist clinics, often strongly attribute their symptoms to a physical disease (Neerincx et al. 2000). A systematic review of prognostic studies in CFS found that such strong attributions predicted a poorer outcome (Cairns and Hotopf 2005). The mechanism of this effect is unclear. It may be that such an attribution favors a focusing of attention on symptoms, more passive coping, and greater inactivity (Heijmans 1998) or, alternatively, that such an attribution leads to nonparticipation in potentially effective psychological and behavioral treatment.

Catastrophizing is a tendency to make excessively negative predictions about symptoms, such as "If I do more, my pain or fatigue will keep getting worse and worse." Catastrophizing has been observed in patients with CFS (Nijs et al. 2008) and FMS (Hassett et al. 2000) and is associated with increased symptom vigilance, avoidance of activity, and more severe disability. Furthermore, a reduction in the belief that activity is damaging is associated with recovery during rehabilitative therapy (Deale et al. 1998), suggesting that it may be a critical psychological target for effective rehabilitation.

Self-efficacy—the belief that one can do something, despite symptoms—has been found both to be low and to be associated with more severe disability in patients with CFS (Findley et al. 1998), FMS (Buckelew et al. 1996), and chronic pain (Asghari and Nicholas 2001). Self-efficacy is therefore another potential target for treatment that aims to improve function.

Behavioral factors. Patients cope with their symptoms in different ways. The way in which a patient copes will be influenced by his or her illness beliefs (Silver et al. 2002). Of particular interest is a style of coping through avoidance of any activity that the patient fears will lead to an exacerbation of symptoms. This fear-avoidance phenomenon is well described in chronic pain patients (Philips 1987) and also has been observed in patients with CFS (Afari et al. 2000; Nater et al. 2006) and FMS (Davis et al. 2001). Objective assessment also confirms that patients with CFS and FMS show reduced overall activity, with most patients oscillating between activity and rest, and a quarter being more pervasively inactive. This reduced activity produces deconditioning; gradually increasing activity is a target for treatment.

Another potentially important coping behavior is the focusing of attention on symptoms—so-called symptom focusing or symptom vigilance (Roelofs et al. 2003). This behavior is, not surprisingly, associated with catastrophizing beliefs and greater perceived symptom intensity; it offers another target for treatment.

Social factors. Patients' beliefs about their illness and associated coping behavior will be influenced by the information they receive. One striking social aspect of CFS and FMS is the high level of activity of patient support and advocacy organizations, which communicate mainly over the Internet (Ross 1999). Studies from the United Kingdom have reported that patients who are members of a self-help group have poorer outcomes than those who are not, despite similar illness duration and disability (Sharpe et al. 1992), as well as a poorer response to rehabilitation (Bentall et al. 2002). It is not known whether this association reflects self-selection into such groups or the effect of the group on patients' beliefs, coping, and willingness to engage in rehabilitation. Some patients reported negative experiences related to having the legitimacy of their illness repeatedly questioned by doctors and others, a process that probably drives some patients to join defensively focused advocacy organizations. Perhaps unsurprisingly, the acquisition of a disability pension is also associated with a worse prognosis (Wigers 1996).

Summary

The available evidence suggests that patients are predisposed to develop CFS and FMS by some combination of genetics, previous experience including childhood trauma, and possibly lack of social support. Many patients with CFS have a history of preceding infection, and many patients with FMS point to an accident, injury, or trauma as the triggering event. Others can identify no precipitant. Most research has been into those factors associated with established illness, so-called perpetuating factors, because these are both clearly more accessible to study and more relevant to treatment of established cases. Many biological factors have been investigated, with interest initially being directed at peripheral nerves and muscles and subsequently focusing on the functioning of the CNS and its neuroendocrine and autonomic outputs. Tantalizing findings have suggested—but have not yet established—a role for immune factors and possibly for ongoing infection. The physiological effects of inactivity seem to be important. Substantial evidence indicates the importance of psychological and behavioral factors, especially the fear of exacerbating symptoms and the associated avoidance of activity in both CFS and FMS. Social factors are more difficult to study but often are of striking importance clinically.

Models of Chronic Fatigue and Fibromyalgia Syndromes

The findings discussed in the previous section can be amalgamated into explanatory models. Three main mod-

els can be discerned that correspond approximately to biological, psychological, and social perspectives, although, in reality, all three are probably relevant.

Biological Model

It is well known that the immune system, the CNS, and the endocrine system interact and also have reciprocal relations with sleep and activity. It is thus possible to construct a tentative biological model in which these systems interact to perpetuate the illness (Moldofsky 1995). There seems to be stronger evidence for the role of infection in triggering CFS and for the role of trauma in FMS. However, it is unclear whether these represent real differences or simply differences in the hypotheses pursued by researchers.

Psychological Model

Whatever the biological aspects of these conditions, psychological models assume that the symptoms and disability are perpetuated, at least in part, by psychological and behavioral factors (Deary et al. 2007). Biological factors are not excluded from this model but are assumed to be either only partially responsible for the illness or largely reversible (Surawy et al. 1995). The cognitive-behavioral models for chronic pain and CFS have much in common (Philips 1987). Both emphasize the importance of fear of symptoms leading to a focusing on the symptoms, helplessness, and avoidance of activity. This model provides the rationale for behavioral and cognitive-behavioral approaches to rehabilitation (see section "Management" later in this chapter).

Social Model

The social model emphasizes the role of social factors in shaping illness. A fight for the legitimacy of the syndrome as a chronic medical condition is central (Banks and Prior 2001). Patient advocacy has been strongly hostile to psychological and psychiatric involvement, probably because it is seen as undermining legitimacy. The social model proposes that patient organizations, while providing valuable social support, can also reinforce patients' illness beliefs, medical care, and disability payment seeking in ways that are not conducive to recovery (Shorter 1997).

Diagnostic Evaluation

Effective management of patients with possible CFS or FMS requires that 1) alternative medical and psychiatric diagnoses are considered and 2) all patients receive an adequately comprehensive assessment.

Identification of Medical and Psychiatric Conditions

Medical Differential Diagnosis

The medical differential diagnosis for CFS and FMS is a long one because so many diseases can present with pain and/or fatigue (Sharpe and Wilks 2002; Yunus 2002; Table 26-4). Both a physical and a mental status examination must be performed in every case to determine the presence of alternative medical and psychiatric diagnoses. As with many chronic diseases, particularly rheumatological conditions, time is often the principal arbiter because these conditions evolve clinically. For symptoms in general, 75% of the patients presenting to primary care improve within 2-4 weeks (Kroenke 2003). Thus, it makes sense to rely on an initial 4- to 6-week wait to clarify whether the symptoms will persist (Kroenke and Jackson 1998). For persistent symptoms, most of the common medical disorders can be diagnosed from a standard history, physical examination, and basic laboratory studies.

Routine investigations. Initial investigation depends on the clinical signs, symptoms, and temporal nature of symptoms. When symptom duration exceeds 4-6 weeks, an initial basic screening workup is appropriate. If there are no specific indications for special investigations, the following have been found to be adequate as screening tests: thyrotropin, erythrocyte sedimentation rate (sensitive for any condition with systemic inflammation), complete blood count, basic chemistries, and withdrawal of some medications (particularly statins or 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors; typical resolution of symptoms in 4-6 weeks).

Special investigations. Special investigations should be carried out only if clearly indicated by the history or examination. Immunological and virological tests are generally unhelpful as routine investigations and remain research tools. Sleep studies can be useful in excluding other diagnoses (especially when the fatigue is characterized by sleepiness), including sleep apnea, narcolepsy, nocturnal myoclonus, and periodic leg movements during sleep (see Chapter 15, "Sleep Disorders"). Once symptoms become chronic (duration greater than 3 months) and remain unexplained, the general approach is to avoid excessive testing, establish regular follow-up, screen for depressive and anxiety disorders, and focus on symptom management.

Medical misdiagnosis. Physicians who are concerned about missing a serious medical diagnosis can be reassured that in most cases, the primary care physician's initial judgment in this regard is likely to be accurate (Khan et

TABLE 26-4. Medical differential diagnosis for patients with chronic fatigue syndrome (CFS) and fibromyalgia syndrome (FMS)

Relative frequency	Diagnoses	Syndrome	Differentiating clinical features	Initial workup
Very common (~1 per 100)	Thyroid disorders	CFS, FMS	Hypothyroidism: cold intolerance, slowed relaxation phase of reflexes, weight gain, elevated cholesterol Hyperthyroidism: heat intolerance, tremor, weight loss	Thyrotropin
	Medications (statins)	CFS, FMS	Symptom resolution with withdrawal of medication	Creatine kinase, aldolase
	Sleep apnea	CFS, FMS	Daytime somnolence, motor vehicle accidents, witnessed nighttime apnea and snoring, hypertension	Sleep study
	Spinal stenosis	FMS	History of osteoarthritis, degenerative disc disease, back pain with radiculopathy, sensory and/or motor deficits, pseudoclaudication	Nerve conduction study, electromyogram, magnetic resonance imaging of spine if neurological deficits
Common (~1 per 1,000)	Anemia	CFS	Pallor	Complete blood cell count
	Chronic infection: HIV, hepatitis C, endocarditis, osteomyelitis, Lyme disease, occult abscess	CFS, FMS	Infection-specific risk factors and signs (e.g., sexual habits, diabetes, fevers, murmur)	Serology, erythrocyte sedimentation rate, liver function tests, serial blood cultures, bone scan, indium scan
	Polymyalgia rheumatica	FMS	Age >60 years	Erythrocyte sedimentation rate
	Cancer	CFS	Pallor, anemia, anorexia, weight loss, cachexia	Complete blood cell count, albumin, age-appropriate cancer screening studies
	Pulmonary condition: asthma, obstructive lung disease, interstitial lung disease	CFS	Shortness of breath, prominent exertional symptoms, smoking history, hypoxia	Chest X ray, pulmonary function tests, oxygenation saturation with exercise
	Rheumatoid arthritis	FMS	Symmetric synovitis, morning stiffness	Rheumatoid factor
	Inflammatory bowel disease (Crohn's)	CFS	Diarrhea, weight loss, fever, anemia	Serial fecal occult blood with endoscopy if positive
Uncommon (~1 per 2,500-100,000)	Systemic lupus	FMS	Malar rash, joint pain	Antinuclear antibody, double-stranded DNA
	Polymyositis, dermatomyositis, myopathy	CFS, FMS	Proximal muscle weakness	Antinuclear antibody, creatine kinase, aldolase

TABLE 26-4. Medical differential diagnosis for patients with chronic fatigue syndrome (CFS) and fibromyalgia syndrome (FMS) (continued)

Relative frequency	Diagnoses	Syndrome	Differentiating clinical features	Initial workup
	Myasthenia gravis, multiple sclerosis	CFS	Neurological findings: extinguishing strength with repetitive movements, ptosis, swallowing difficulties, optic neuritis, sensory deficits	Tensilon test, acetylcholine receptor antibodies, magnetic resonance imaging of brain
	Narcolepsy	CFS	Drop attacks, falling asleep during daily activities	Sleep study
	Symptomatic hyperparathyroidism	CFS	Bone pain, nephrolithiasis, pancreatitis, renal insufficiency	Serum calcium and parathyroid hormone

al. 2003). However, there is some evidence that CFS and FMS may be overdiagnosed by primary care physicians (Fitzcharles and Boulous 2003); evaluating psychiatrists should feel able to request second medical opinions.

Psychiatric Differential Diagnosis

Underdiagnosis and undertreatment of psychiatric disorders are common (Torres-Harding et al. 2002), probably reflecting a focus of the initial medical assessment on the patient's somatic symptoms and a tendency to disregard mood changes as a consequence of those symptoms. The most important psychiatric diagnoses to consider are depressive and anxiety disorders because of their frequency and their implications for treatment. Depression may be masked and require an expert assessment if it is to be detected. Panic attacks with agoraphobia may cause intermittent severe fatigue and disability. Somatoform disorders are common but have fewer implications for management. A diagnosis of somatization disorder indicates a poorer prognosis, and hypochondriasis indicates special attention to repeated reassurance seeking, which may perpetuate fears of undiagnosed disease (Sharpe and Williams 2001).

Assessment of the Illness

Other than to make diagnoses, the aims of the assessment are to 1) establish a collaborative relationship with the patient, 2) elicit the patient's own understanding of his or her illness and how he or she copes with it and 3) identify current family and social factors such as employment and litigation that may complicate management. It is important to inquire fully about the patient's understanding of his or her illness (e.g., "What do you think is wrong with you?" or "What do you think the cause is?"). Patients may be fearful that their symptoms indicate a progressive, not-yet-diagnosed disease or that exertion will cause a long-term wors-

ening of their condition. A formulation that identifies potential predisposing, precipitating, and perpetuating factors (see Table 26-3) is valuable both in providing an individualized explanation to the patient and for targeting interventions.

Management

Diagnosis, Formulation, and Management Plan

Forming a Therapeutic Relationship With the Patient

It is important to see the consultation from the patient's perspective. He or she may have already seen many other doctors and may have experienced problematic interactions with them (Asbring and Narvanen 2003). These doctors may have offered overly biomedical or overly psychological explanations or even dismissed the patient completely.

Explaining Psychiatric Involvement

It is helpful to explain to the patient why he or she is seeing a psychiatrist. A psychiatrist's involvement in management may be interpreted by the patient as indicating that his or her condition is considered to be "all in his or her head." It is therefore often best to begin with an assessment of the physical symptoms and only then to introduce a discussion of psychological factors. This can be done in a nonblaming and normalizing way; for example: "You have clearly had a terrible time that has been made worse by not being believed. It is entirely understandable that this has gotten you down." It is generally unhelpful to force a psychiatric diagnosis on an unwilling patient. It is also important to explain that treatments commonly associated with psychiatry (particularly antidepressants and CBT) do not necessarily imply that the person is mentally ill; rather, they can be seen as ways of normalizing brain and bodily

functions in conditions that are exacerbated by stress (Sharpe and Carson 2001).

Giving the Diagnosis

Some controversy exists about whether giving patients a diagnosis of CFS or FMS is helpful or harmful (Huibers and Wessely 2006). Some who believe that a positive diagnosis is helpful argue that it enables patients to both conceptualize their illness and communicate about it (Sharpe 1998). Others who are concerned about the potentially harmful effect of diagnosis argue that it medicalizes and pathologizes symptoms in a way that can exacerbate social and occupational disability (Hadler 1996a). It is our clinical experience that a positive diagnosis, linked to a clear explanation of the potential reversibility of symptoms and a management plan to achieve this, is not only a positive intervention but also an essential starting point from which to plan effective management.

Offering an Explanation

The explanation offered should ideally be scientifically accurate, acceptable to the patient, and congruent with the management plan. It can be explained that although the specific causes of CFS or FMS remain unknown, a combination of vulnerability and environmental stress that have changed the function of the brain and endocrine system is most likely. One such explanation is that the illness is a disorder of brain *function* rather than *structure*—that is, a functional nervous disorder (Stone et al. 2002).

Explaining the Management Plan

The management plan should be explained to the patient as following from the etiological formulation, focusing on illness-perpetuating factors and consisting of elements intended to 1) relieve symptoms such as depression, pain, and sleep disturbance with agents such as antidepressants; 2) assist the patient's efforts at coping by stabilizing activity and retraining the body to function effectively (graded exercise, CBT); and 3) assist the patient in managing the social and financial aspects of his or her illness and, when possible, remaining in or returning to employment (problem solving).

General Measures

Providing Advice on Symptom Management

One of the most important interventions the clinician can make is to encourage and guide patients in the active self-management of the illness. Such advice will include the importance of being realistic about what they are able to accomplish right now without giving up hope for improvement in the future. It should involve advice on the pros

and cons of self-medication, particularly with analgesics, and also might require a discussion of the potential benefits and risks associated with seeking treatment from other practitioners, both conventional and alternative. The overall aim is to encourage patients to feel that they can do things to manage the condition themselves, to accept the reality of their illness while still planning positively for the future, and to be cautious about seeking potentially harmful and expensive treatments.

Managing Activity and Avoidance

Once a patient's pattern of activity has been stabilized and large fluctuations between excessive rest and unsustainable activity reduced, very gradual increases in activity can be advised. It is critical, however, to distinguish between carefully graded increases carried out in collaboration with the patient and a forced or overambitious exercise regimen.

Managing Occupational and Social Factors

Patients who continue working despite illness may become overstressed by the effort of doing this. Those who have left work because of illness may have become inactive and demoralized. These situations require a problem-solving approach to consider how to manage work demands, achieve a graded return to work, or plan an alternative career. Ongoing litigation regarding the illness is potentially a complicating factor because it reinforces (and may reward) the patient for remaining symptomatic and disabled.

Pharmacotherapy

Most pharmacological treatment studies in CFS and FMS have focused on antidepressants, although various other agents have been advocated.

Antidepressants

Antidepressant drug treatment is indicated by the fact that 1) many patients with CFS or FMS have depressive and anxiety syndromes and 2) these agents can reduce pain and improve sleep, even in the absence of depression. Overall there is good evidence for the short-term efficacy of antidepressants in FMS (Hauser et al. 2009a) but less evidence in CFS.

The tricyclic antidepressants (TCAs) are more effective than the selective serotonin reuptake inhibitors (SSRIs) for relieving pain and for inducing sleep. Small doses (e.g., 25–50 mg of amitriptyline) are often adequate for these purposes, whereas full doses are required to treat major depression.

Cyclobenzaprine, a tricyclic agent chemically similar to amitriptyline but used as a "muscle relaxant" rather than as an antidepressant, has been found to be effective in im-

proving symptoms in FMS, especially pain and sleep disturbance (Tofferi et al. 2004).

SSRIs are generally better tolerated than TCAs. However, in CFS, fluoxetine was found in a large trial to be no more effective than placebo (Vercoulen et al. 1996b), and in FMS, the benefit of SSRIs was reported to be small (Hauser et al. 2009a).

The dual-action serotonin-norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine, duloxetine, and milnacipran are also of benefit in fibromyalgia but may be less effective than TCAs in relieving pain (Hauser et al. 2009a). Other antidepressant agents may also be of value. For example, there is some evidence for the value of mirtazapine in CFS (Stubhaug et al. 2008).

Other Pharmacological Agents

Patients with CFS or FMS frequently take nonsteroidal anti-inflammatory drugs (NSAIDs) to relieve pain. No evidence from clinical trials indicates that NSAIDs are effective when used alone, although they may be of some benefit in FMS when combined with amitriptyline (Kroenke et al. 2009).

Opiates are occasionally used for pain relief in CFS and FMS. There is some evidence for the efficacy of tramadol (Bennett et al. 2003) but not for other opiates. Adverse effects, including dependence, are major concerns with opiate use.

As with opiates, great caution is required with benzodiazepines because of the risk of dependence in patients with chronic conditions. TCAs are probably preferable to benzodiazepines for treating insomnia, and the chronic use of benzodiazepines should be reserved for patients with intractable anxiety.

Given the finding of low serum cortisol, it is not surprising that corticosteroids have been tried as a treatment. Prednisone was found to be ineffective in FMS (Clark et al. 1985). Hydrocortisone was reported to produce some benefit in CFS but was not recommended because of the long-term risks of adrenal suppression (Cleare et al. 1999). In CFS, fludrocortisone has been used in patients with orthostatic hypotension but has not been found to be of value (Rowe et al. 2001).

Serotonin₃ receptor antagonists (e.g., ondansetron, tropisetron) have analgesic effects (Kranzler et al. 2002). A randomized, placebo-controlled double-blind trial in FMS found short-term benefit only with the lowest dosage (5 mg/day) (Farber et al. 2001). Trials of longer duration are needed.

Gabapentin and pregabalin both appear to be effective in reducing pain and other symptoms in fibromyalgia but do not suit all patients (Hauser et al. 2009b).

Stimulating medications such as bupropion, methylphenidate, dextroamphetamine, modafinil, and amantadine have all been reported to have value for other fatigue states (e.g., in multiple sclerosis) and have been advocated for use in CFS, but the evidence for their efficacy in CFS is very limited. Like opiates and benzodiazepines, stimulants pose a risk of dependence and abuse.

Summary

Caution is required when prescribing pharmacological therapy for CFS and FMS. The mainstay of drug treatment continues to be the so-called antidepressant drugs, which may be helpful for mood, pain, and sleep (but not fatigue), and which have limited effect on overall outcome. TCAs are preferred for nighttime sedation and pain, but greater tolerability may mean that an SSRI or an SNRI is preferable as first-line treatment. Although patients often receive low doses of antidepressants, higher doses may be required to achieve a therapeutic response. The increased interest in pharmacological treatment of functional syndromes in the past few years will likely expand future treatment options. However, the available evidence suggests that drug therapy currently has a limited role in the management of these conditions.

Specialist Nonpharmacological Treatments

If the patient does not respond to or requires a more active treatment than that described above, referral for specialist therapy should be considered. For most patients, a rehabilitative outpatient program based on appropriately planned increases in activity, either as graded exercise therapy (GET) or as CBT, is indicated. Some patients may require inpatient multidisciplinary rehabilitation, although evidence of its efficacy is inadequate (Karjalainen et al. 2000).

Graded Exercise Therapy

GET is a structured progressive exercise program administered and carefully monitored by an exercise therapist. It also may be given in individual or group form, but the evidence is best for individually administered treatment (Fulcher and White 1998).

GET follows the basic principles of exercise prescription for healthy individuals, adapted to the patient's current capacity. The initial exercise intensity and duration are determined on an individual basis and may be done by heart rate monitoring. Most patients can begin at an intensity of 40% of their maximum aerobic capacity, which approximately equates to 50% of their estimated individual heart rate reserve added to their resting heart rate (e.g., if the maximum heart rate is 180 beats per minute [bpm] and the resting heart rate is 80 bpm, the heart rate reserve is 100 bpm, and

the exercise target heart rate is $80 + (0.5 \times 100) = 130$ bpm). This heart rate should not be exceeded; if it is, the patient should stop exercising for 1–2 minutes and then resume. Patients who are very disabled, or who have extremely low exercise tolerance to begin with, should begin with 2 weeks of stretching alone without aerobic activity and then should adopt alternate-day aerobic exercise before building up frequency, duration, and then intensity. The important principle is to calculate exercise capacity conservatively to start with, as well as to ensure that the patient will try that which is proposed.

At each clinic visit, joint planning of the exercise prescription for the following 1–2 weeks is completed. The initial aim is to establish a regular pattern of exercise (usually walking), with exercise 5 days/week. Home exercise sessions should initially last between 5 and 15 minutes, depending on ability and exercise tolerance. The duration is increased by 1–2 minutes/week up to a maximum of 30 minutes per homework session. Then the intensity of exercise can be increased to a target heart rate of 60% and then 70% of the patient's heart rate reserve added to his or her resting heart rate. Patients will respond differently; some will take a lot longer to adapt to each new level, whereas others will have to be held back, particularly those who have been active sports participants in the past. Those patients who are inclined to overexert themselves in an attempt to speed up the recovery process should be monitored carefully because this can be a contributing factor in nonrecovery or relapse.

GET has been found in systematic reviews to be of benefit in both CFS and FMS. In FMS, there is strong evidence (from a systematic review of 34 studies) that supervised aerobic exercise is of value in relieving symptoms and disability (Busch et al. 2007). In CFS, a systematic review of five studies found exercise to be better than comparison treatments in improving fatigue and disability. However, there were a number of dropouts from treatment, suggesting that exercise approaches may have limited acceptability (Edmonds et al. 2004). Of particular interest was a trial of brief simple education about the physiology and rationale of exercise that found this intervention to be as effective as CBT (Powell et al. 2001). A subsequent trial of this approach found that the benefit was not sustained, however (Wearden et al. 2010).

Cognitive-Behavioral Therapy

CBT is not a single treatment, and there are a variety of types (Williams 2003). Here, we refer to a collaborative psychologically informed type of rehabilitation that aims to achieve both graded increases in activity and changes in unhelpful beliefs and concerns about symptoms. It also may include problem solving for life and occupational di-

lemmas. It can be given in an individual or a group form, although more evidence exists for the efficacy of individual therapy (Sharpe 1997).

The procedure is 1) to elicit the patient's own illness model, appraisal of his or her situation and the ways in which he or she copes; 2) to introduce the possibility of alternatives; and 3) to help the patient select the beliefs and coping behaviors that are most helpful to him or her by conducting behavioral experiments. The key question for the behavioral experiment is "Is it possible for me to make changes in my behavior that will allow me to achieve my goals?" The patient is encouraged to think of the illness as a real one but one that is reversible by his or her own efforts rather than (as many patients do) as a fixed disease only alterable by medical intervention. The evidence that the patient can make changes and achieve goals acts as a test of these alternative hypotheses. Problem solving is used to address relevant occupational and interpersonal difficulties. A typical therapy takes place over 14 sessions (the first 90 minutes, the rest 50 minutes), the first 4 sessions being weekly and thereafter biweekly over 5 months.

In CFS, individually administered CBT has been tested in trials that together have included more than 1,000 patients. CBT has been found to be moderately effective and safe (Price et al. 2008). It is acceptable to most patients if explained adequately, but early dropouts may occur in routine practice (Scheeres et al. 2008).

Although CBT is an established treatment for chronic pain, a systematic review suggests that its efficacy is modest (Eccleston et al. 2009; see also Chapter 36, "Pain"). While it is reported to be of value in clinical practice (Bennett and Nelson 2006), randomized evaluations of the type of intensive individual CBT shown to be effective in CFS are required in FMS.

Patients Who Do Not Respond to Treatment

Most patients respond to some degree to rehabilitative therapies, but many will achieve only partial improvement, and some will fail to improve at all. In such cases, the management is the same as that for other chronic conditions—to maximize functioning and quality of life while minimizing the risk of iatrogenic harm. Although it is desirable that all patients should have a trial of rehabilitative treatment, a balance has to be struck between treatment and acceptance of chronic illness. Many physicians are reluctant to accept chronic disability in these patients, perhaps because the physicians do not regard these conditions as true diseases. However, pushing patients beyond their capabilities may only demoralize them and may even cause them to retreat further into invalidism. For such patients, regular supportive long-term follow-up from a single physician is often the best form of management.

Conclusion

Although peripheral to both internal medicine and psychiatry, functional somatic syndromes such as CFS and FMS are both common and core to the practice of psychosomatic medicine. A willingness and an ability to integrate biological, psychological, and social factors are essential in order to achieve an adequate understanding of these syndromes and to implement effective management. The challenge that these syndromes present to narrow biomedical and psychopathological perspectives of illness makes them a potential Trojan horse for those who seek to persuade others of the benefits of a much greater integration of medical and psychiatric theory and practice in achieving our core aim: to help our patients.

Infectious Diseases

James L. Levenson, M.D.

PSYCHIATRIC SYMPTOMS ARE part of the clinical presentation of many systemic and central nervous system (CNS) infectious processes. Rapid cultural and economic changes affecting regional and international mobility, sexuality, and other behaviors have led to worldwide spread of new epidemics (e.g., human immunodeficiency virus [HIV], severe acute respiratory syndrome [SARS]; Cheng et al. 2004) and more limited spread of previously geographically isolated diseases (e.g., cysticercosis). Infectious diseases have been considered as contributing to the pathogenesis of psychiatric disorders (e.g., viral antibodies in schizophrenia). Associations between specific infections and a subset of psychiatric syndromes (e.g., pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection [PANDAS]) provide intriguing models of etiology. Controversy surrounds some attributions of psychopathology to infectious pathophysiology (e.g., Lyme disease).

Consulting psychiatrists should carefully consider relevant aspects of patients' histories, including immune status, regions of origin and residence, travel, high-risk sexual behaviors, occupation, and recreational activities. Physicians must consider which infectious diseases are endemic in the practice area and in the areas where the patient has traveled or resided. Similar neuropsychiatric symptoms might suggest possible Lyme disease in a hiker in the northeastern United States and neurocysticercosis in an immigrant from Central America.

Many brain diseases or injuries, as well as the effects of aging, render patients more vulnerable to neuropsychiatric effects of even minor metabolic or toxic insults and similarly to adverse effects of even limited infectious diseases. For example, a simple upper respiratory or bladder infection may cause only discomfort in an otherwise healthy individual but agitation, irritability, and frank delirium in the elderly, especially in patients who also have

dementia. The reasons that older age and brain disease would make patients vulnerable to delirium with minor infections are not understood but may involve changes in immune function and the blood-brain barrier.

Psychological factors may significantly affect the risk for and course of infectious diseases, with HIV as the most studied example (see Chapter 28, "HIV/AIDS"). Psychological factors have been shown to influence other infectious diseases as well, from the common cold (Takkouche et al. 2001) to hepatitis B and C infection (Osher et al. 2003). One mechanism for such effects is through poor sleep (Cohen et al. 2009).

This chapter is divided into bacterial, viral, fungal, and parasitic infections, followed by psychiatric side effects of antimicrobial drugs and their interactions with psychotropic medications, and finally a discussion of fears of infectious disease and psychiatric aspects of immunization. HIV and AIDS are covered in Chapter 28. In the current chapter, we focus on psychiatric aspects of all other infectious diseases.

Occult Infections

Occult infections, irrespective of location, by definition are concealed or mysterious, often requiring diligent detective work. Such infections may occur essentially anywhere in the body (Table 27-1). Psychiatric symptoms may result from even a small focus of chronic infection. The psychiatric symptoms most likely to be present are subtle cognitive dysfunction or mood change (e.g., irritability) consistent with a mild encephalopathy, but depression, psychosis, and delirium also may occur.

The diagnosis is suggested by secondary signs of infection, specifically temperature dysregulation, or increases

TABLE 27-1. Occult infections that may cause psychiatric symptoms

Sinusitis
Chronic otitis
Abscess (e.g., dental, lung, intra-abdominal, retroperitoneal, perirectal)
Bronchiectasis
Endocarditis
Cholecystitis
Parasitosis
Urinary tract infection
Pelvic inflammatory disease
Osteomyelitis
Subclinical systemic infections (e.g., HIV, tuberculosis)

in white blood cell count, granulocyte count, or sedimentation rate. A careful history and physical examination may identify overlooked clues to guide the search (e.g., chronic toothache or lymphadenopathy). If repeat history and physical examination are not fruitful, other studies may be needed (e.g., chest X rays, computed tomography [CT] scans, ultrasounds).

Bacterial Infections

Bacteremia and Sepsis

Bacteremia literally means entry of bacteria into the bloodstream, whereas *sepsis* refers to the systemic inflammatory response to bacteremia. Systemic symptoms of sepsis, including CNS symptoms, result from many different mechanisms, including bacterial toxins, release of cytokines, hyperthermia, shock (poor perfusion), acute renal insufficiency, pulmonary failure ("shock lung"), coagulopathy, disruption of the blood-brain barrier, and spread of the organism into the CNS and other organs. An acute change in mental status may be the first sign of impending sepsis and may precede the development of fever. Any patient who has an abrupt change in mental status in concert with a shaking chill should be presumed to have a high risk for impending sepsis.

Septic encephalopathy occurs more frequently than is generally assumed. Its severity is associated with the severity of overall illness, and it is often part of multiorgan failure (Siami et al. 2008). Standard treatment is broad-spectrum antibiotics at first and is then tailored to the identified organism and its antimicrobial susceptibilities. Symptoms of

posttraumatic stress disorder recently have been recognized as very common following septic shock. Although the role of corticosteroids in septic shock remains controversial, one group has reported studies showing that stress doses of hydrocortisone lead to a significant reduction of posttraumatic stress disorder symptoms in long-term survivors (Schelling et al. 2006).

Toxic Shock Syndrome

Toxic shock syndrome (TSS) typically occurs in otherwise healthy people with intact immune systems, caused by either *Streptococcus pyogenes* (most often) or *Staphylococcus aureus*. TSS generally manifests with rapid onset of fever, rash, and hypotension (shock). There may be a prodromal period of 2–3 days of malaise, myalgia, and chills followed by confusion and lethargy. TSS should be suspected in any patient with a recent wound who acutely develops unexplained pain, lethargy, and confusion and may occur even when a surgical wound appears not to be inflamed.

Pediatric Autoimmune Neuropsychiatric Disorder Associated With Streptococcal Infection

PANDAS is not a diagnosis but an acronym for the clinical characteristics of a subgroup of children whose obsessive-compulsive and tic disorders seem to have been triggered by an infection with group A beta-hemolytic streptococci (GABHS). The syndrome is defined by early childhood onset of symptoms; an episodic course characterized by abrupt onset of symptoms with frequent relapses and remissions; association with neurological signs, especially tics; and temporal association with GABHS infections (most commonly pharyngitis). The best way to show the association between recent GABHS infection and PANDAS symptoms is to document a rapid rise in antistreptococcal (ASO) titers associated with symptom onset or exacerbation and a decrease in titers associated with symptom resolution or improvement. Children with PANDAS also may have behavioral symptoms (e.g., attention deficits and hyperactivity) (Swedo et al. 1998). GABHS may play a role in some cases of Tourette's syndrome as well.

In addition to ASO titers, a throat culture should be obtained, keeping in mind that some children who have GABHS infection may not have a sore throat (Swedo et al. 1998). Prompt antibiotic treatment may prevent the expected rise in ASO titers, and children with uncomplicated streptococcal infections treated with antibiotics appear to have no increased risk for PANDAS (Perrin et al. 2004). In children with recurrent streptococcal infections, antibiotic prophylaxis to prevent neuropsychiatric symptoms has yielded mixed results. One double-blind, placebo-con-

trolled trial found no benefit over placebo in preventing PANDAS exacerbations (Garvey et al. 1999), but another trial found that either penicillin or azithromycin was able to lower rates of recurrent streptococcal infections and to decrease PANDAS exacerbations (Snider et al. 2005). Even though one study found that the severity of obsessive-compulsive symptoms diminished by 45%–58% following treatment with either plasma exchange or intravenous immunoglobulin (Perlmutter et al. 1999), immunomodulatory therapies are not recommended as routine treatment of PANDAS.

PANDAS has been and remains a controversial concept (Shulman 2009). It must be emphasized that most cases of obsessive-compulsive disorder (OCD) and tic disorders in children are unrelated to streptococcal infection. Even in children meeting PANDAS criteria, most exacerbations of OCD or tic symptoms are not due to GABHS infection (Kurlan et al. 2008). The failure of immune markers to correlate with clinical exacerbations of PANDAS challenges the autoimmune theory of its etiology (Singer et al. 2008). Outside of specialty centers, inadequate diagnostic evaluation has led to unwarranted antibiotic and immunomodulatory medications in children with OCD or tics (Gabbay et al. 2008).

Bacterial Endocarditis

Bacterial endocarditis may cause neuropsychiatric symptoms at all stages of the disease via focal, systemic, and CNS disease processes. Endocardial infections are focal infections that usually occur on one of the valves of the heart. Rheumatic heart disease was originally the typical cause of the predisposing cardiac abnormality. Its incidence has decreased, whereas the incidence of senescent valvular disease, prosthetic valve placement, and intravenous drug use has increased, thus changing the risk factors in the developed world. Malaise and fatigue may represent early symptoms before progression of the infection is evident. CNS symptoms are related to 1) occlusion of cerebral arteries by septic emboli; 2) expansion, leakage, or rupture of mycotic aneurysms; and 3) direct infection of meninges or brain abscess. Neuropsychiatric deficits resulting from septic emboli will reflect which cerebral vessels have been affected. The most common psychiatric symptoms are those of diffuse encephalopathy, which may occur at any stage of infection. Their onset may be insidious to acute, paralleling the course of the endocarditis (chronic, subacute, acute).

Diagnosis is based on clinical history and physical examination, particularly looking for new or changing heart murmurs, signs of microembolism (splinter hemorrhages, retinal hemorrhages, microscopic hematuria), and posi-

tive blood cultures in a patient with fever. Cardiac echocardiography is important for evaluation of valvular abnormalities.

Rocky Mountain Spotted Fever

The etiological agent for Rocky Mountain spotted fever (RMSF) is *Rickettsia rickettsii*. RMSF is a tickborne disease with a seasonal distribution paralleling human contact with ticks, peaking May through September. Its name is misleading because half of the U.S. cases are in the South Atlantic region, and rickettsial spotted fevers occur worldwide. RMSF typically (although not invariably) includes fever and a rash characterized by erythematous macules that later progress to maculopapular lesions with central petechiae. Initially appearing as a nonspecific severe febrile illness, the diagnosis is seldom suspected until the rash appears. Only half of RMSF patients report exposure to ticks. *R. rickettsii* causes a diffuse vasculitis in many organs. CNS involvement occurs in 25% of cases and includes lethargy, confusion, and occasionally fulminant delirium. Subtle changes such as irritability, personality changes, and apathy may occur before the rash, particularly in children. Abnormalities on brain imaging may show focal lesions, but 80% of RMSF patients with normal scans have symptoms of encephalopathy as well (Bonawitz et al. 1997). Because mortality is high in untreated patients, a provisional clinical diagnosis (e.g., fever, rash in the appropriate season, and geographic setting) is sufficient to initiate definitive antimicrobial therapy.

Typhus Fevers

Typhus fevers are caused by two species of *Rickettsia*. *R. prowazekii* is the cause of mouseborne and squirrelborne typhus. *R. typhi* is the cause of fleaborne typhus. Mouseborne typhus usually occurs in epidemics related to war or famine when communal hygiene deteriorates. Fleaborne typhus is associated with fleas found on rodents. The annual disease frequency in the United States was 2,000–5,000 cases in the 1940s. It is now fewer than 100, with most in Texas. This dramatic change is a result of rat control programs. Clinical manifestations, diagnosis, and treatment of typhus are similar to those of RMSF. The psychiatric manifestations are confusion, lethargy, and particularly headache in a febrile illness with rash. The delirium of typhus and typhoid has been classically described as having a peculiar preoccupied nature, with patients picking at the bedclothes and imaginary objects (Verghese 1985). In fact, the word *typhus* in Greek means “cloud” or “mist,” a term Hippocrates used to describe clouded mental status in patients with unremitting fevers.

Typhoid Fever

Typhoid fever is an enteric fever caused by salmonellae. The incidence of typhoid fever has steadily declined in the United States over the last century primarily because of improved sanitation. Typhoid fever is still endemic in many places in the world. Most of the cases in the United States are acquired outside the country, most often in Mexico and India.

Abdominal pain, headache, and fever are the classic presentation. However, when typhoid fever is endemic or not treated promptly, psychiatric symptoms may appear. *Salmonella typhi* enters a bacteremic phase, and the typhoid bacilli can localize in the CNS. The high fever and electrolyte imbalances also may cause encephalopathy, with delirium reported in up to 75% of the cases in some parts of the world (Aghanwa and Morakinyo 2001) and very infrequently (2%) in others (Parry et al. 2002). Mental symptoms such as indifference, listlessness, and dullness are common at presentation. Published cases have described persistent psychiatric symptoms, including irritability, personality change, and psychosis (Parry et al. 2002), but most survivors completely recover following treatment.

Tetanus

Tetanus is uncommon in the United States but remains internationally significant. *Clostridium tetani* produces a potent neurotoxin called *tetanospasmin*, which is the cause of tetanus. The greatest risk factor for tetanus remains lack of up-to-date immunization. Infections generally occur because an open wound comes into contact with soil contaminated with spores from *C. tetani*. After initial inoculation, tetanospasmin is disseminated via blood, lymph, and nerves and produces symptoms by binding to receptors at the neuromuscular junction.

The classic symptom is muscle stiffness, particularly in the muscles of mastication, thus the descriptive term *lock-jaw*. If the muscle stiffness extends across the entire face, risus sardonicus occurs, an expression of continuous grimace. Also, stiffness may progress to the entire body if left untreated.

Tetanospasmin may enter the CNS, causing encephalopathic symptoms. Diagnosis is based on the clinical manifestations and a history of likely exposure. On initial presentation, patients with tetanus have been given misdiagnoses of an anxiety disorder or a conversion disorder (Treadway and Prange 1967), although more commonly, a conversion disorder is mistakenly thought to be possible tetanus (Barnes and Ware 1993). If the patient had received neuroleptics or antiemetics, one could easily mistake the symptoms as drug-induced acute dystonia.

Brucellosis

Brucellosis is a worldwide zoonosis caused by species of *Brucella*, gram-negative intracellular coccobacilli. They infect many animals, but most human cases are acquired from consumption of unpasteurized dairy products from sheep or goats. It has become rare in developed countries (about 100 cases per year in the United States) but is likely underdiagnosed because of the nonspecificity of symptoms. Brucellosis can occur at any age, with insidious or abrupt onset, affecting any organ system, and hence is notorious for mimicking other diseases. Signs of acute brucellosis include fever, diaphoresis, headache, and myalgia. Chronic brucellosis is not always preceded by acute symptoms. Its manifestations include fatigue, depression, subtle cognitive dysfunction, and multiple chronic pains (Eren et al. 2006), so it is not surprising that patients' symptoms are frequently misdiagnosed as primary psychiatric illness (Sacks and Van Rensburg 1976). Protean complications in many different organs have been reported. CNS involvement occurs in 5%–18% of cases and may present as meningitis, psychosis, or cranial nerve dysfunction (Bodur et al. 2003; Yetkin et al. 2006). Diagnosis is confirmed by isolation of the organism or serological testing.

Syphilis

Syphilis is a chronic systemic disease caused by the spirochetal bacterium *Treponema pallidum*. Although *T. pallidum* was not identified until 1905, syphilis was described in the medical literature before the sixteenth century. A hundred years ago, syphilis was the leading diagnosis in psychiatric inpatients; the incidence declined as the antibiotic era began. The rates of syphilis have been increasing over the past decade, in part related to the global pandemic of HIV infection.

The clinical manifestations are varied and mimic those of other diseases. Syphilis was the original "great imitator." In adults, syphilis passes through several stages. *Primary syphilis* develops first as a small papule at the site of inoculation that develops into an ulcer called a chancre. If left untreated, the chancre will disappear, but about 6–24 weeks after the initial infection, *secondary syphilis* occurs with a variety of symptoms. During this stage, multiple organ systems, including the CNS, may become involved. Most symptoms are constitutional (malaise, fatigue, anorexia, and weight loss). Skin, gastrointestinal tract, lymphatics, bones, kidneys, and eyes all may be affected. Most syphilitic meningitis occurs within the first year of infection. Symptoms of headache, stiff neck, nausea, and vomiting prevail, and focal neurological findings may be present. Often, signs and symptoms of secondary syphilis disappear, and the infection becomes latent.

Tertiary syphilis refers to infection years to decades after initial infection. It has been divided into three types: late benign syphilis (gummatous), cardiovascular syphilis, and neurosyphilis. Gummatous and cardiovascular forms were very prevalent before antibiotics; neurosyphilis is now the predominant form of tertiary syphilis (Gliatto and Caroff 2001).

Neurosyphilis is divided into asymptomatic, meningeal, meningovascular, and parenchymatous forms. Meningeal syphilis may occur early in the course (as noted earlier in this subsection) or late. Meningovascular syphilis typically occurs 4–7 years after infection. Presenting symptoms of neurosyphilis include changes in memory and personality, dizziness, and other encephalopathic symptoms that can mimic atherosclerotic disease (e.g., transient ischemic attack, multi-infarct dementia). Parenchymatous neurosyphilis syndromes are tabes dorsalis and general paresis. Tabes dorsalis occurs 20–25 years after infection and results from demyelination of the posterior columns and dorsal roots. Paresthesias, Argyll Robertson pupils (pupils that accommodate but do not react to light), impotence, incontinence, and truncal ataxia may develop. General paresis is an insidious dementia that can include seizures and personality deterioration. This form of syphilis presents 15–20 years after infection and—if untreated—may be fatal.

Diagnosis relies on serological testing. However, in primary and secondary syphilis, dark-field microscopy of material from chancres, condylomata, and mucous patches usually identifies many organisms.

Except in populations in which syphilis is common, it is not cost-effective to screen all new psychiatric patients for syphilis (Roberts et al. 1992); screening should focus on patients with unexplained cognitive dysfunction or other neurological symptoms accompanying the psychopathology. The most frequently used tests and their sensitivities are shown in Table 27–2.

Serological testing is based on two types of antibody response to the syphilitic infection: nontreponemal antibodies and antitreponemal antibodies. The Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) are the most commonly used tests that detect nontreponemal (nonspecific) antibodies. The reactivity of these tests depends on the stage of the disease. In secondary syphilis and early latent syphilis, the nontreponemal tests show reactivity 95%–100% of the time. However, the reactivity in primary syphilis and tertiary syphilis is 76% and 70%, respectively. The fluorescent treponemal antibody absorption (FTA-ABS) test is more sensitive and more specific. This test is used to confirm the diagnosis when syphilis is suspected and a nontreponemal test was nonreactive and to confirm a positive nontreponemal test

result. The FTA-ABS test is not used as a screening test because its false-positive rate is as high as 1%. Another treponemal test is the microhemagglutination assay of *T. pallidum* (MHA-TP). This assay is used as a confirmatory test, typically after a positive RPR test result (Hicks 2004).

False-positive nontreponemal tests (i.e., positive VDRL or RPR and negative FTA-ABS and no clinical evidence of disease) are divided into acute (those that revert to normal in less than 6 months) and chronic (those that persist for longer than 6 months). Acute false-positive results occur after some immunizations, during acute infections, and during pregnancy. Chronic false-positive results occur in individuals with autoimmune disease (e.g., lupus), in narcotic-addicted persons, in persons with leprosy, and in the elderly.

Intravenous penicillin G is the recommended treatment for all forms of neurosyphilis (Jay 2006). If a definitive diagnosis cannot be made, it is prudent to treat presumptively. In some patients with dementia due to neurosyphilis, the infection appears to have “burned out,” and they show no clinical response to penicillin G. Multiple case reports but no controlled trials have addressed treatment of psychiatric symptoms associated with neurosyphilis. A recent review (Sanchez and Zisselman 2007) and case reports (Taycan et al. 2006; Turan et al. 2007) recommended use of a typical or an atypical antipsychotic to treat psychosis in patients with neurosyphilis. An anticonvulsant such as divalproex sodium also was recommended for agitation and mood stabilization.

Lyme Disease

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which is transmitted by deer ticks. The risk of contracting Lyme disease from a single tick bite is 3% (Nadelman et al. 2001). Lyme disease occurs worldwide; it is the most common tickborne disease in the United States, with four times as many cases as reported in Europe. Disease onset is marked by erythema migrans, a characteristic (more than 90% of cases) large spreading rash with central clearing. Acute disseminated disease includes fatigue, arthralgia, headache, fever, and stiff neck. If untreated, Lyme disease may disseminate to other organs and produce subacute or chronic disease. Neurological symptoms occur in about 15% and may include cranial neuropathies (most often, the facial nerve), meningitis, or painful radiculopathy. If still untreated, patients may develop chronic neuroborreliosis, including a mild sensory radiculopathy, cognitive dysfunction, or depression. Typical symptoms of chronic Lyme encephalopathy include difficulty with concentration and memory, fatigue, daytime hypersomnolence, irritability, and depression. Very rarely, Lyme disease has included chronic encephalomyelitis. Although these chronic syn-

TABLE 27-2. Sensitivity (%) of diagnostic tests of serum^a in different stages of syphilis

Stage of disease	Screening ^b		Confirmatory ^c	
	RPR or VDRL	FTA-ABS	TPI	MHA-TP
Primary	75	85	40	80
Secondary and early latent	95-100	100	98	100
Late latent and tertiary	70	99	95	98

Note. FTA-ABS = fluorescent treponemal antibody absorption; MHA-TP = microhemagglutination assay of *Treponema pallidum*; RPR = rapid plasma reagin; TPI = *Treponema pallidum* immunofluorescence assay; VDRL = Venereal Disease Research Laboratory.

^aSensitivity and specificity cannot be determined on cerebrospinal fluid because no gold standard exists.

^bDetects nontreponemal antibodies.

^cDetects treponemal antibodies. Typically, a laboratory performs one of these tests when a screening test result is positive.

dromes are not distinctive, they are almost always preceded by the classic early symptoms of Lyme disease, such as erythema migrans, arthritis, cranial neuropathy, or radiculopathy (Feder et al. 2007).

The clear relation between another spirochetal disease, syphilis, and psychopathology makes the possibility that *B. burgdorferi* can cause psychiatric syndromes an area of interest and controversy. Many different psychiatric symptoms have been reported to be associated with Lyme disease, including depression, mania, delirium, dementia, psychosis, obsessions or compulsions, panic attacks, catatonia, and personality change (Tager and Fallon 2001). However, association does not allow one to infer causation by Lyme. Evaluation of patients with Lyme disease at 10- to 20-year follow-up showed no significant differences in symptoms or neuropsychological testing compared with control subjects without Lyme disease. Although symptoms such as pain, fatigue, and difficulty with daily activities are common in patients who received treatment for Lyme disease years earlier, the frequencies of such symptoms are similar in control subjects without Lyme disease (Seltzer et al. 2000). Studies of whether children have cognitive sequelae after treated Lyme disease have had mixed results (McAuliffe et al. 2008; Vázquez et al. 2003).

The differential diagnosis of neuroborreliosis in a patient presenting with fatigue, depression, and/or impaired cognition includes fibromyalgia, chronic fatigue syndrome, other infections (e.g., babesiosis or ehrlichiosis), somatoform disorders, depression, autoimmune diseases, and multiple sclerosis (Tager and Fallon 2001).

Unfortunately, Lyme disease has been grossly overdiagnosed in patients with nonspecific cognitive, affective, or other psychiatric symptoms. As noted earlier in this section, numerous reports in the literature attribute a wide variety of psychiatric symptoms to neuroborreliosis on the basis of positive serological testing. As explained later in this section, this is inappropriate. Adverse consequences of overdiagnosis include reinforcement of somatization and

creation of invalidism. Overdiagnosis leads to overtreatment. The diagnosis of an infection that can be treated with antibiotics can be very appealing to patients for whom depression or somatoform disorder is an unacceptable diagnosis, but this leads to inappropriate diagnostic procedures and inappropriate extended prescription of antibiotics for a putative chronic CNS infection. Chronic antibiotic prescription is not benign and may lead to secondary infections, antibiotic resistance, and drug toxicity (Feder et al. 2007). Even in patients with classic symptomatic Lyme disease confirmed by serological testing, persisting symptoms are usually explained by some illness other than chronic borreliosis if these patients have received adequate antibiotic therapy (Kalish et al. 2001; Seltzer et al. 2000).

Diagnosis is based on the characteristic clinical features. Serological testing (enzyme-linked immunosorbent assay followed by Western blot) can support the diagnosis but should never be the primary basis. False-negative and false-positive results are common with serological testing. Even a true-positive test result simply indicates that the patient has had Lyme disease at some point in life, but no conclusion about current disease activity or extent of infection can be drawn on that basis alone. In chronic neuroborreliosis, increased cerebrospinal fluid (CSF) protein and antibody to the organism occur in more than 50% of the patients. Electroencephalogram (EEG) findings are typically normal, whereas magnetic resonance imaging (MRI) shows nonspecific white matter lesions in about 25%. Neuropsychological assessment is useful in measuring cognitive dysfunction, but the findings are not specific (Ravdin et al. 1996).

Treatment is straightforward for acute Lyme disease (see Wormser et al. 2006). Neither serological testing nor antibiotic treatment is cost-effective in patients who have a low probability of having the disease (e.g., nonspecific symptoms, low incidence region) (Nichol et al. 1998). Multiple controlled trials have found no benefit of extended intravenous or oral antibiotics in patients with well-documented, previously treated Lyme disease who had persistent

pain, neurocognitive symptoms, dysesthesias, or fatigue (Kaplan et al. 2003; Klemmner et al. 2001; Krupp et al. 2003; Oksi et al. 2007). The only exception is a recent, very small placebo-controlled trial ($n=37$) of 10 weeks of intravenous ceftriaxone in patients with at least 3 weeks of prior intravenous antibiotics, which showed moderate generalized cognitive improvement at week 12, but it was not sustained to week 24 (Fallon et al. 2008). The consensus of experts is that chronic antibiotic therapy is not indicated for persistent neuropsychiatric symptoms in patients who received adequate treatment for Lyme disease (Feder et al. 2007).

Leptospirosis

Leptospirosis is another protean spirochetal disease. It was previously thought of as a rural tropical disease, but it occurs globally in rural and urban areas. The organism is spread through the urine of many species of mammals. Most leptospirosis infections resemble influenza and are relatively benign. The more severe form of leptospirosis is a multiorgan disease affecting liver, kidneys, lung, and brain (meningoencephalitis, aseptic meningitis). Confusion and delirium are common, and leptospirosis has presented with mania and psychosis (Semiz et al. 2005).

Bacterial Meningitis

Bacterial meningitis is an acute illness associated with significant morbidity and mortality. Psychiatric symptoms play an important role in its presentation. Irrespective of the organism, most cases of bacterial meningitis result from hematogenous spread of bacteria from a primary site to the subarachnoid space. Once the organism crosses the blood–brain barrier at the choroid plexus and enters the subarachnoid space, host defenses become activated. Psychiatric symptoms may result by several mechanisms, including toxic effects of the organism, mediators of inflammation, cerebral edema, and hypoxia.

The classic sign of meningeal inflammation is nuchal rigidity. Headache, nausea, vomiting, confusion, lethargy, and apathy also may occur. Psychiatric symptoms are the result of encephalopathy. As in other infections, encephalopathy may initially present as subtle changes in personality, mood, motivation, or mentation. Symptom severity generally correlates with the magnitude of the host's immune response. When the patient cannot mount a full inflammatory response, the classic symptoms may not occur. In infants, the elderly, or immunocompromised patients, the only clinical signs may be irritability or minor changes in mentation or personality. Even after good recovery from bacterial meningitis, some patients may have subtle cognitive impairment (van de Beek et al. 2002).

Once clinically suspected, the diagnosis is usually confirmed by examination of the CSF, which typically shows

pleocytosis, low glucose, high protein, and evidence of the offending organism on appropriate staining. Although neuroimaging is routinely performed to rule out other CNS processes, it rarely establishes the diagnosis of bacterial meningitis.

Cat-Scratch Disease

Cat-scratch disease (CSD), which is caused by *Bartonella henselae*, usually presents as self-limiting lymphadenopathy in young people following a cat scratch or bite. Encephalopathy is one of the common complications, with almost all cases reported in children. Patients with CSD encephalopathy present with combative behavior, lethargy, and seizures, and significant fever may be absent. Diagnosis is made by serology and/or biopsy of skin or lymph node.

Bacterial Brain Abscess

The portals of entry for organisms causing brain abscesses are similar to those in bacterial meningitis. In fact, brain abscesses frequently occur as a complication of bacterial meningitis, although they also are a frequent complication of infective endocarditis. The classic triad of headache, fever, and focal neurological deficits has been described for the diagnosis of brain abscess, but these symptoms occur in fewer than half of the patients who have a brain abscess. Seizures are common. Various psychiatric symptoms may occur, depending on the size and location of the abscess, the degree of irritation of the organism, and the extent of the inflammatory response.

Mortality rates have markedly declined as a result of improved neuroimaging and antimicrobials, but morbidity remains high. Neuroimaging can show focal abscesses in the CNS with very good sensitivity. Effective treatment includes empirical antibiotics that cross the blood–brain barrier, with primary excision or aspiration of the abscess usually required. After successful treatment of the infection, psychiatric symptoms may persist.

Tuberculous Meningitis

Tuberculosis (TB) incidence is at an all-time low in the United States but remains a major world health problem, endemic in many developing countries. Extensively drug-resistant TB has been reported in 49 countries worldwide. Where AIDS is prevalent, the epidemiology of TB has markedly changed. TB now represents the most common serious HIV-related complication worldwide. In countries where TB is not endemic, the diagnosis of tuberculous meningitis is often not considered because the clinical manifestations are often nonspecific. Early diagnosis of tuberculous meningitis is essential because delay in treatment is associated with high morbidity and mortality. Tuberculous menin-

tis is caused by bacilli discharged from small tuberculous lesions adjacent to the meninges. These small tuberculous lesions arise early via hematogenous spread following a primary pulmonary infection or as a consequence of reactivation.

Early symptoms of tuberculous meningitis are nonspecific and include low-grade fever, generalized malaise, fatigue, and mild headache. Over the course of a week, progression to high-grade fever, severe nuchal rigidity, confusion, and delirium occurs. Persons with HIV, the elderly, substance abusers, and others with impaired immunity are more likely to present without nuchal rigidity and headache. In such patients, the symptoms will tend to be most nonspecific, with a higher risk of missing the correct diagnosis while attributing the symptoms to more common diagnoses such as alcohol withdrawal.

Confirming the diagnosis can be difficult. The organisms are difficult to detect in the CSF, so diligent search is needed to identify them when present. Early in the course when symptoms are mild, CSF glucose may be unchanged and protein only marginally elevated. As the disease progresses, glucose declines drastically, and protein becomes markedly elevated, with white blood cell counts typically between 50 and 200 cells/mm³ (predominantly lymphocytes). Later complications include cerebral vasculitis and cranial nerve involvement. Diffuse meningeal involvement by TB may be seen on MRI.

Strong suspicion of tuberculous meningitis calls for early multidrug treatment. In many parts of the world today, including the United States, multidrug-resistant TB is present, requiring different drug combinations.

Whipple's Disease

Whipple's disease is a rare infection, caused by the bacterium *Tropheryma whippelii*. Most patients experience arthralgia, diarrhea, and weight loss. Neurological involvement has been reported in 6%–63% of patients, may occur without intestinal involvement, and can mimic almost any neurological syndrome. Psychiatric symptoms (e.g., depression, personality change) are present in about half of the patients with neurological involvement. Cognitive deficits are even more common and may extend to dementia. Whipple's disease is treated with antibiotics, but patients with neurological involvement have a poor prognosis (Fenollar et al. 2007).

Viral Infections

The overwhelming majority of viral infections are asymptomatic or mild and do not receive medical attention.

Many viruses are difficult to detect, most infections are difficult to treat, and none are cured by treatment. Viruses can produce psychiatric symptoms by primary CNS involvement, from secondary effects of immune activation, or indirectly from systemic effects. One serious sequela of several viral infections is acute disseminated encephalomyelitis; patients with this condition can present with encephalopathy, acute psychosis, seizures, and other CNS dysfunction. Active demyelination is widespread, and the disease may be difficult to distinguish from multiple sclerosis. Residual cognitive dysfunction may occur (Jacobs et al. 2004). Despite viral syndromes' ubiquity and frequent nonspecificity, it is important for psychiatrists to know particular viral syndromes.

Epstein-Barr Virus

Epstein-Barr virus (EBV), one of the herpesviruses, commonly causes infectious mononucleosis ("mono") in children and young adults. The prodromal stage of infectious mononucleosis is characterized by headache, fatigue, and malaise, with progression to fever, sore throat, and lymphadenopathy. Diagnosis is based on the combination of typical clinical symptoms and a positive heterophil antibody test (Monospot) result. Because the Monospot test is an antibody measure, it may have false-negative results in immunosuppressed patients. Most cases completely resolve, although some may take several months. Fatigue commonly persists for a few months, but this can occur with other viral infections as well (Hickie et al. 2006). In the rare, more severe form of infectious mononucleosis, anemia, leukopenia, eosinophilia, thrombocytopenia, pneumonitis, hepatosplenomegaly, uveitis, and an abnormal pattern of serum globulins may occur. EBV also can cause acute encephalitis and other neurological syndromes.

Because EBV may persist lifelong in a latent state following acute infection, periodic reactivation may occur. Patients with reactivated EBV infection typically report overwhelming fatigue, malaise, depression, low-grade fever, lymphadenopathy, and other nonspecific symptoms, essentially the picture of the chronic fatigue syndrome. However, only a small fraction of chronic fatigue symptoms are attributable to EBV infection. In the past, patients with chronic fatigue and depression (and sometimes their physicians) pursued an explanation in chronic EBV infection, erroneously confirming this after a positive Monospot test result. It was erroneous because the test result remains positive long after complete resolution of uncomplicated infectious mononucleosis in youths, and most adults have had the infection. (See analogous discussion in "Lyme Disease" earlier in this chapter.)

Cytomegalovirus

Like EBV, cytomegalovirus (CMV) is a herpesvirus with the ability to develop a lifelong latency in the host with possible reactivation. Seroprevalence in adults has been reported to be between 40% and 100%. Most CMV infections are subclinical and occur across a broader age group than does EBV. In adults, CMV can produce a syndrome identical to infectious mononucleosis, except that heterophil antibody testing is negative in CMV, and a sore throat is usually absent. CMV also may cause hepatitis, retinitis, colonitis, and pneumonitis. CMV can cause encephalitis in immunocompromised patients (especially posttransplant and AIDS) and rarely in immunocompetent patients. Following patient recovery, CMV has been implicated as a cause of depression or dementia. Seropositive transplant recipients are at risk for reactivation of infection, and seronegative transplant recipients are at risk for a more serious primary CMV infection if the graft is seropositive. Prophylactic therapy has reduced posttransplant CMV infections but also delayed their appearance. Without prophylaxis, the symptoms of CMV reactivation usually occur between the first and fourth month after transplantation.

Viral Meningoencephalitis

Most viruses that cause encephalitis cause meningitis as well. Enteroviruses, mumps, and lymphocytic choriomeningitis primarily affect the meninges, with enteroviruses responsible for most identifiable cases. Patients with viral meningitis (often referred to as aseptic meningitis) present with headache, fever, nuchal rigidity, malaise, drowsiness, nausea, and photophobia. Typically, the CSF shows pleocytosis, elevated protein, and no evidence of an organism. Treatment for aseptic meningitis is generally supportive.

In viral encephalitis, psychiatric symptoms are very common in the acute phase and frequent after recovery (Arciniegas and Anderson 2004; Caroff et al. 2001). Occasionally, patients with viral encephalitis may initially present with psychopathology without neurological symptoms. Caroff et al. (2001) reviewed 108 published cases of psychiatric presentation, classified as psychosis (35%), catatonia (33%), psychotic depression (16%), or mania (11%). Patients in such cases often receive misdiagnosis and inappropriate treatment, and Caroff et al. (2001) noted that patients with viral encephalitis are more vulnerable to adverse effects of neuroleptics, including extrapyramidal side effects, catatonia, and neuroleptic malignant syndrome.

For those who survive viral encephalitis, outcomes vary from complete recovery to serious neuropsychiatric sequelae. Psychiatric sequelae, especially mood disorders, are common following recovery from acute viral encephalitis and constitute a major cause of disability. Depression,

hypomania, irritability, and disinhibition of anger, aggression, or sexuality have been frequently noted months after recovery, and psychosis occurs rarely. Depressive symptoms may respond to treatment with antidepressants or stimulants (Neel 2000). Hypomania, irritability, and disinhibition have benefited from neuroleptics, mood stabilizers including lithium, and electroconvulsive therapy (Ferrando et al. 2010; Monnet 2003). Specific viruses are discussed below.

Arboviruses

Arboviruses (short for arthropod-borne viruses) are the most common cause of viral encephalitis worldwide. Of the arbovirus diseases, Japanese encephalitis is the most common worldwide and annually causes 10,000 deaths in Asia. In the United States, the major types are St. Louis encephalitis, eastern equine encephalomyelitis, western equine encephalomyelitis, California encephalitis, and West Nile virus. Most arboviruses are mosquito-borne. Arboviral encephalitis typically appears in the summer or fall in children (Japanese encephalitis) or young adults (West Nile virus and St. Louis encephalitis), with abrupt onset of fever, headache, nausea, photophobia, and vomiting, and may be fatal. Reduced level of consciousness, flaccid paralysis resembling poliomyelitis, parkinsonism, and seizures are common (Solomon 2004). Persistent depression is very common after West Nile infection (Murray et al. 2007). Although no specific treatment is available for arboviral encephalitis, rapid diagnosis is important for public health measures, mosquito control, and, ideally, vaccines.

Dengue. Dengue, another disease caused by an arbovirus, is transmitted by mosquitoes, endemic in 100 countries, and encountered in temperate developed countries mainly in travelers and new immigrants (Castleberry and Mahon 2003). The virus causes three syndromes: the relatively more benign dengue fever, which is a painful influenza-like illness, and the serious forms, hemorrhagic dengue and dengue shock syndrome, which are rare in travelers. Neuropsychiatric symptoms were noted in 14% of the tourists who returned to France with dengue (Badiaga et al. 2003). CNS involvement has been reported in 3%–21% of cases of dengue, and in the more serious endemic dengue infections, encephalitis is common, with confusion, delirium, and seizures (Domingues et al. 2008; Wasay et al. 2008).

Herpes Simplex Virus

Herpes encephalitis is the most common cause of sporadic fatal encephalitis worldwide, with more than 90% caused by herpes simplex type 1 virus. Symptoms may include hypomania, personality change, dysphasia, seizures, autonomic

dysfunction, ataxia, delirium, psychosis, and focal neurological symptoms. Herpes simplex virus (HSV) encephalitis differs from arboviral encephalitis by causing more unilateral and focal findings, with a predilection for temporoparietal areas of the brain. HSV encephalitis is more likely to cause focal seizures, olfactory hallucinations, and personality change. HSV is the most common identified cause of viral encephalitis simulating a primary psychiatric disorder (Arciniegas and Anderson 2004; Caroff et al. 2001). One possible sequela of HSV encephalitis is the Klüver-Bucy syndrome, which includes oral touching compulsions, hypersexuality, amnesia, placidity, agnosia, and hyperphagia. CSF typically shows pleocytosis, red blood cells (because of the hemorrhagic nature of HSV encephalitis), and elevated protein. Glucose is usually normal. EEG is a sensitive (but not specific) diagnostic test, showing periodic temporal spikes and slow waves as opposed to more diffuse changes usually seen in other forms of viral encephalitis. MRI may show diffuse inflammation, particularly in the temporoparietal areas. The gold standard for diagnosis had been brain biopsy, but detection of HSV DNA by polymerase chain reaction is now the standard. Diagnosis based on symptoms and signs alone misses 50% of the cases.

Rapid diagnosis is essential because only early treatment improves outcome. HSV encephalitis is treated with intravenous acyclovir, which itself can cause neuropsychiatric adverse effects (see Table 27-3 later in this chapter). No well-defined treatments are available for the associated cognitive and neuropsychiatric symptoms, but case reports describe success with anticonvulsants such as carbamazepine (especially in patients with comorbid seizures), atypical antipsychotics, selective serotonin reuptake inhibitors, stimulants, clonidine, and cholinesterase inhibitors (Ferrando et al. 2010).

Varicella/Herpes Zoster

The varicella/herpes zoster virus causes chickenpox in children and herpes zoster in adults. Most cases of encephalopathy in children with varicella infection have been due to Reye's syndrome, although the virus itself can cause encephalitis. Zoster-associated encephalitis typically presents in adults with delirium within days after the appearance of the rash. The most common neurological sequela of herpes zoster is postherpetic neuralgia (see Chapter 36, "Pain"). Depression and anxiety are common in postherpetic neuralgia (Volpi et al. 2008) and may influence the choice of treatment for the neuropathic pain (e.g., tricyclic or serotonin-norepinephrine reuptake inhibitor antidepressant vs. anticonvulsant). Weeks or months after recovery from herpes zoster, encephalitis or arteritis may appear (mostly in immunosuppressed patients). The arteritis may affect large vessels, producing strokelike symptoms, or

small vessels, producing headache, altered mental status, fever, seizures, and focal deficits (Gilden et al. 2000).

Measles

Measles can cause postinfectious encephalomyelitis, subacute measles encephalitis, and subacute sclerosing panencephalitis (SSPE). SSPE typically occurs 7–10 years after measles infection, presenting with cognitive dysfunction, behavior change, headache, and myoclonic jerks (Garg 2008). Most cases are in children or adolescents, but cases beginning in middle age have been reported.

Tickborne Encephalitis

Tickborne encephalitis (TBE) is an important human infection of the CNS throughout Europe and parts of Asia, caused by a virus (TBEV) mainly transmitted by tick bites and rarely by unpasteurized milk (Kaiser 2008). TBE presents as meningitis or meningoencephalitis. Neurological and psychiatric sequelae, including motor, affective, cognitive, and personality changes, are common in adults. No specific treatment for TBE is known, but it can be prevented by active immunization.

Postencephalitis Syndromes

Following recovery from acute viral encephalitis, psychiatric sequelae are common and constitute a major cause of disability, especially mood disorders. Depression, amnesic disorders, hypomania, irritability, and disinhibition of anger, aggression, or sexuality have been frequently noted months after recovery, and psychosis occurs rarely. Depressive symptoms may respond to treatment with antidepressants or stimulants. Hypomania, irritability, and disinhibition have benefited from mood stabilizers and antipsychotics, and behavior modification also may be helpful for aggressive and sexual behaviors.

The global pandemic encephalitis in 1917–1929 known as *encephalitis lethargica* (von Economo's disease) had an acute encephalitic phase during which lethargy, psychosis, and catatonia were common. This period was followed by a chronic postencephalitic syndrome, including parkinsonism, mania, depression, and apathy in adults and conduct disorder, emotional lability, and tics in children, with relatively little cognitive impairment (Cummings et al. 2001; Vilensky et al. 2007). Sporadic similar cases continue to be reported (Dale et al. 2007; Raghav et al. 2007). Whether encephalitis lethargica was a postinfluenzal phenomenon remains controversial (Mortimer 2009).

Viral Hepatitis

Some viruses—including hepatitis A, B, and C; EBV; and CMV—cause acute or chronic hepatitis (see also Chapter 20, "Gastrointestinal Disorders"). Hepatitis C infection is

very common in the chronically mentally ill (Himelhoch et al. 2009). Fatigue, malaise, and anorexia are usually prominent in viral hepatitis and may lead to a misdiagnosis of depression. However, fatigue in chronic hepatitis is more closely correlated with depression and other psychological factors than is severity of hepatitis (McDonald et al. 2002). Depression is frequently comorbid, especially in the chronic forms of hepatitis B (Kunkel et al. 2000) and hepatitis C infection (Nelligan et al. 2008), but whether the etiology of depression in hepatitis C infection is really viral has been questioned (Wessely and Pariante 2002). Subtle cognitive dysfunction not attributable to depression, substance abuse, or hepatic encephalopathy has been documented in hepatitis C infection, and the virus has been identified in brain, suggesting that cerebral infection also may occur (Weissenborn et al. 2009).

Complicating the diagnostic picture further, treatment with interferon causes depression itself in 20%–40% of patients and depressive symptoms in as many as two-thirds receiving long-term interferon treatment (Neri et al. 2006). Depression has been the most common adverse effect leading to cessation of interferon treatment. Depression reduces adherence to antiviral therapy (Martín-Santos et al. 2008) and is associated with a poorer antiviral response (Fontana et al. 2008). Depression associated with hepatitis or interferon is amenable to treatment with antidepressants (Kraus et al. 2008), allowing continuation of interferon in most patients. Therefore, depression should not be considered a contraindication to interferon therapy. Dosing should be adjusted downward if the patient has impaired liver function.

Rabies

Rabies is a viral infection of mammals transmitted by bite. In the United States, nondomesticated animals (i.e., bats, raccoons) account for most cases of rabies because domesticated animals are vaccinated. Worldwide, human mortality from endemic canine rabies is estimated to be about 55,000 deaths annually, with more than 31,000 deaths in Asia alone, mostly children (Dodet et al. 2008). Transmission to humans is rare in developed countries, but rabies has been misdiagnosed as an anxiety disorder (Centers for Disease Control 1991) or alcohol withdrawal (Centers for Disease Control and Prevention 1998).

The usual incubation period is 20–60 days but can vary from several days to years. Initial symptoms are nonspecific and include generalized anxiety, fever, depression, hyperesthesia, and dysesthesia, especially at the site of inoculation. In one U.S. case, “mild personality changes” preceded more suggestive symptoms such as unsteady gait and slurred speech by more than a week (Centers for Disease Control and Prevention 2003). The rabies virus has a proclivity for

attacking the limbic system; thus, delusions may result. The initial phase is followed by an excitatory phase, when the classic symptom of hydrophobia may occur. Hydrophobia is an aversion to swallowing liquids (not a phobia of water) secondary to the spasmodic contractions of the muscles of swallowing and respiration, resulting in pain and aspiration. The final phase is a progressive, general flaccid paralysis that progresses relentlessly to death. Both rabies and the rabies vaccine may cause delirium (Leung et al. 2003).

No effective treatment exists for rabies once symptoms are evident. After a bite by an infected animal, the rabies vaccine should be given as soon as possible because outcome is related to the proximity in time to the bite.

Prion Diseases

Prions are proteinaceous agents that cause spongiform changes in the brain. Prion diseases are rare and universally fatal, with an incubation period of months to years—hence the term *slow viruses* (see also Chapter 32, “Neurology and Neurosurgery”). Kuru occurs only in Papua, New Guinea. It is spread by the cannibalistic consumption of dead relatives during mourning rituals. Scrapie is a spongiform encephalopathy found in sheep. Although known to have been present in Great Britain for almost three centuries, scrapie has never been shown to cause disease in humans. Bovine spongiform encephalopathy (“mad cow disease”) appears to have been transmitted to cattle by the practice of feeding cattle recycled sheep by-products.

Creutzfeldt-Jakob disease (CJD) occurs sporadically (i.e., sporadic CJD [sCJD]) and sometimes familially in humans, with a mean age at onset around 60 years. It also has been transmitted by intracerebral electrodes, grafts of dura mater, corneal transplants, human growth hormone, and gonadotropin, but iatrogenic transmission is now rare. sCJD is a severe dementia accompanied by psychosis, affective lability, and dramatic myoclonus that rapidly progresses to rigid mutism and then death. A retrospective review of 126 cases of sCJD found that 26% had psychiatric symptoms at presentation and 80% within the first 100 days of illness—most commonly, sleep disturbances, psychotic symptoms, and depression (Wall et al. 2005). Young patients with sCJD present with psychiatric symptoms similar to those seen in patients with new-variant CJD (nvCJD) (see next paragraph) but progress more rapidly to severe dementia than in nvCJD (Boesenberg et al. 2005).

nvCJD was initially reported mainly in Great Britain but now has been found in many other countries and has distinct differences from CJD. nvCJD patients are considerably younger than sCJD patients, with an average age at onset of about 30, and the disease progresses less rapidly. In most cases of nvCJD, psychiatric symptoms, including depres-

sion, irritability, anxiety, and apathy, appear several months before any neurological symptoms (Spencer et al. 2002). Bovine spongiform encephalopathy and nvCJD are caused by the same prion strain, but the disease can be transmitted through the same iatrogenic routes as sCJD, years after initial exposure. Detection of the 14–3–3 protein in CSF supports the diagnosis of sCJD but is not as sensitive or specific as initially thought and is insensitive for nvCJD. The EEG usually has abnormal results in both forms of CJD, but definitive diagnosis requires brain biopsy.

Fatal familial insomnia is an even rarer prion disease in which progressive insomnia (and sometimes behavior change) (Raggi et al. 2009) appears months before any cognitive, autonomic, or motor symptoms develop. Despite its name, the disease also occurs through sporadic mutation. Patients with this disorder initially may be given misdiagnoses of mood, anxiety, or somatoform disorders.

Fungal Infections

The frequency of fungal infection has increased steadily over the last three decades, coincident with the growing number of immunocompromised patients who are surviving longer than in the past. An aging population, an increased number of malignancies, the spread of AIDS, the use of immunosuppressive and cytotoxic drugs, the use of intravenous catheters, hyperalimentation, illicit drug use, extensive surgery, and the development of burn units also have contributed to the increased frequency of fungal infection. CNS symptom development depends on the size and shape of the fungi. The smallest fungi have access to the cerebral microcirculation and infect the subarachnoid space. Large hyphae obstruct large and intermediate arteries, giving rise to extensive infarctions (e.g., aspergillosis). Fungi with pseudohyphae occlude small blood vessels, producing small infarctions and microabscesses (e.g., *Candida*). Most fungi are opportunistic (as in aspergillosis, mucormycosis, and candidiasis), whereas others are pathogenic (as in coccidioidomycosis and cryptococcosis) irrespective of the host's defenses. Most systemic fungal infections are treated with amphotericin B, which can cause neuropsychiatric side effects (see Table 27–3 later in this chapter).

Aspergillosis

Aspergillus, an opportunistic organism, infects only debilitated patients. *Aspergillus* genus is commonly found in soil. In aspergillosis, CNS involvement usually follows infection of the lungs or gastrointestinal tract. Symptoms of confusion, headache, and lethargy often accompany focal neurological signs.

Cryptococcosis

Cryptococcosis is an infection caused by *Cryptococcus* species, a pathogen distributed worldwide, found in bird excreta, the soil, and other animals. *Cryptococcus* may act as a solo pathogen, but in up to 85% of cases, it is associated with another illness, especially AIDS. The portal of entry is usually the respiratory tract from which hematogenous spread occurs, although at the time of presentation, pulmonary infection may not be evident.

Cryptococcus is the most common form of fungal meningitis. It is typically insidious in onset and slowly progressive. Headache is present in up to 75% of the cases, varying from mild and episodic to progressively incapacitating and constant. Other signs include cerebellar, cranial nerve, and motor deficits; irritability; psychosis; and lethargy, which may progress to coma. Remission and relapse are common in untreated patients. Isolation of the fungi provides definitive diagnosis. Serological testing of patients with cryptococcal meningitis identifies cryptococcal antigen in serum, CSF, or both 90% of the time. Treatment is typically a prolonged course of an antifungal agent.

Coccidioidomycosis

Coccidioidomycosis is restricted to warm, dry areas such as the southwestern United States, Mexico, and parts of South America (particularly Argentina and Paraguay). Its spores are inhaled in infected dust. Initial infection produces a mild febrile illness, often followed by pulmonary symptoms. Dissemination beyond the lung is relatively rare, and the CNS is not the most common extrapulmonary site. When it does occur, CNS infection is typically insidious in onset, 1–3 months after initial infection, with headache associated with confusion, restlessness, hallucinations, lethargy, and transient focal signs.

Histoplasmosis

Histoplasmosis is a common respiratory infection found throughout the world and is especially common in the central United States. *Histoplasma capsulatum* is inhaled with dust contaminated with chicken, bird, or bat excreta. Most infections are asymptomatic and involve the lungs or the reticuloendothelial system. The CNS is involved in 5%–10% of patients with progressive disseminated histoplasmosis. Most but not all are immunocompromised. CNS histoplasmosis may cause chronic meningitis, focal brain lesions, stroke due to infected emboli, and diffuse encephalitis (Saccante 2008).

Blastomycosis

Blastomyces dermatitidis is an uncommon mycotic infection that rarely causes CNS infections, mainly in immunocom-

promised patients. Blastomycosis is coendemic with histoplasmosis in the central United States. The most common CNS manifestations are stiff neck and headache, eventually progressing to confusion and lethargy.

Mucormycosis

Mucormycosis refers to any infection caused by a member of the family *Mucoraceae*, opportunistic fungi found in common bread and fruit molds. Mucormycosis is notorious for causing an acute fulminant infection in diabetic patients and patients with neutropenia. *Mucor* directly invades tissue and disseminates by attacking contiguous structures. Any diabetic patient with a purulent, febrile infection of the face or nose should be emergently evaluated for mucormycosis because it may rapidly erode into the orbit and cerebrum in a matter of hours. Early mild encephalopathy may quickly progress to severe delirium. Aggressive debridement and intravenous antifungal medication are required.

Candidiasis

Candida causes limited local infections (cutaneous, vaginal, oral) in immune-competent hosts, typically after broad-spectrum antibiotics. Disseminated candidiasis occurs only in immunocompromised patients. Psychiatric symptoms occur from the toxic effects of fungemia or from direct invasion of the CNS. Cerebral lesions generally occur late in the course of disseminated candidiasis. *Candida* may cause meningitis, microabscesses, macroabscesses, or vasculitis in the CNS. The nonspecific signs include confusion, drowsiness, lethargy, and headache. Sometimes *Candida* can be cultured from blood or CSF, but most cases of CNS candidiasis are not discovered until autopsy. Suggestive neuroimaging findings and isolation of *Candida* from a non-CNS site in an immunocompromised patient should prompt treatment with appropriate antifungal agents.

An alternative medicine belief is that occult systemic *Candida* infection is the cause of a wide array of somatic and psychological symptoms. There is no scientific support for this theory or its advocated treatments.

Parasitic Infections

Neurocysticercosis

One of the world's most common parasitic infections—neurocysticercosis—is an infection of the CNS caused by the larval form (cysticerci) of *Taenia solium*, also known as the pork tapeworm. For neurocysticercosis to occur, a human must ingest the tapeworm's eggs, from contact with infected swine or humans. Once ingested, the eggs he-

matogenously spread to the CNS and other sites. Cysticercosis is endemic in the developing nations. A Venezuelan study found that cysticercosis infection was much more common in psychiatric inpatients, especially those with mental retardation, than in healthy control subjects (Meza et al. 2005). In the United States, it is usually reported in immigrants from Latin America and has been reportedly found in 10% of the patients with seizures presenting to an emergency department in Los Angeles, California, and in 6% in an emergency department in New Mexico (Ong et al. 2002). However, infected food handlers may transmit it to people who have no contact with pork or other contaminated foods.

A high percentage of neurocysticercosis infections remain asymptomatic. Cerebral involvement may produce seizures, stroke, or hydrocephalus; neurocysticercosis is the leading cause of seizures in adults in endemic areas. Psychiatric symptoms are frequently reported and include depression and psychosis (Mahajan et al. 2004). Neurocysticercosis is a common cause of dementia in developing nations (Jha and Patel 2004), but the cognitive decline may be reversible (Ramirez-Bermudez et al. 2005).

Between clinical history, neuroimaging, and serology, a presumptive diagnosis of neurocysticercosis usually can be made. Definitive diagnosis of neurocysticercosis is through biopsy, but this is usually impractical. Treatment of neurocysticercosis has involved anticonvulsants, steroids, antihelminthics, and shunting for hydrocephalus. However, antihelminthic drugs in neurocysticercosis may actually aggravate neuropsychiatric symptoms, and their use in some forms of the disease is controversial.

Toxoplasmosis

Toxoplasmosis refers to the disease caused by *Toxoplasma gondii*, a parasite ubiquitously affecting all mammals, some birds, and probably some reptiles. Latent infection is common, but in immunosuppressed individuals, particularly those with AIDS, the parasite may preferentially infect the CNS, resulting in a wide range of clinical presentations. Mass lesions mimicking tumor or abscess are most common, but psychosis has been reported as a presenting symptom (Donnet et al. 1991). Effective antibiotic therapy can produce rapid remission of active infection but must be continued throughout life to prevent recurrence. Some data have supported the hypothesis that maternal or patient toxoplasmosis exposure might be a risk factor for schizophrenia (e.g., Niebuhr et al. 2008). However, one randomized trial found no benefits of trimethoprim as adjuvant treatment in Ethiopian schizophrenic patients, almost 90% of whom were positive for the *T. gondii* antibody (Shibre et al. 2009).

Trypanosomiasis

The family of protozoa *Trypanosomatidae* causes two different syndromes: African trypanosomiasis (sleeping sickness) and American trypanosomiasis (Chagas' disease). African trypanosomiasis, which occurs in several sub-Saharan African countries, is caused by a subspecies of *Trypanosoma brucei* and is transmitted to humans and animals by the bite of the tsetse fly. The illness begins with a lesion at the site of the fly bite, headache, fever, malaise, weight loss, and myalgia and is often misdiagnosed as malaria. Later, the parasite crosses the blood-brain barrier and causes encephalitis with neuropsychiatric, motor, and sensory abnormalities (Blum et al. 2006; Kennedy 2006), with usually fatal outcome. Sleeping sickness is a disturbance of the sleep-wake cycle with bouts of fatigue progressing to daytime somnolence and nighttime insomnia. Meningoencephalitis may develop with prominent somnolence—hence the name *sleeping sickness*. Africans living in other countries have received misdiagnoses of primary psychiatric disorders (Bedat-Millet et al. 2000). The drug used to treat late-stage disease is very toxic, with an often-fatal encephalopathy the most feared complication of treatment (Blum et al. 2001); for this reason, early detection—permitting less toxic treatment—is important.

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi*, which is carried by insects ("kissing bugs" or "assassin bugs") in Latin America. More than 100,000 persons chronically infected with Chagas' disease now live in the United States. Transmission is so inefficient that years of exposure are required to acquire the infection, and most infections are quiescent. Following immunosuppression, reactivated disease may present as meningoencephalitis. In immunocompetent patients, manifestations of CNS Chagas' disease are nonspecific and minor (Wackermann et al. 2008).

On brain imaging, the lesions are indistinguishable from those of toxoplasmosis, and the organism is often not identifiable in blood. Reactivated Chagas' disease should be suspected in immunosuppressed immigrants from endemic areas of Latin America, especially in presumed cases of toxoplasmosis not responsive to chemotherapy.

Malaria

Malaria remains a major cause of morbidity in tropical nations, especially in young children and pregnant women. In other parts of the world, cases occur in immigrants and travelers to malarial areas. *Plasmodium* species are transmitted to humans by the bite of mosquitoes.

Relapsing fever typifies malaria, and with temperatures commonly in excess of 41°C (105°F), delirium is

common. *Plasmodium falciparum* causes cerebral malaria, the most catastrophic complication of malaria, with a mortality rate of 15%–20%. Cerebral malaria begins with disorientation, mild stupor, agitation, and psychosis and rapidly progresses to seizures and coma (Mishra and Newton 2009). Some but not all children and adults who survive cerebral malaria have persistent cognitive deficits in attention, memory, visuospatial skills, language, and executive functions (Kihara et al. 2006). Anxiety and depression are common after recovery (Dugbartey et al. 1998), but they are more likely a result of psychological and social stress associated with severe illness (Weiss 1985). More severe neuropsychiatric signs, including psychosis in fully recovered (aparasitemic) cerebral malaria, are most likely attributable to pharmacotherapeutic agents. Antimalarial drugs commonly cause psychiatric side effects (see Table 27-3 later in this chapter). Mefloquine in chemoprophylaxis doses causes severe CNS side effects (e.g., psychosis, seizures) in 0.1% and other adverse psychiatric symptoms (e.g., nightmares, depression, irritability) in 0.02%–0.5%. Vivid dreams occur in 15%–25% (Freedman 2008). Mefloquine's psychiatric adverse effects are more common in patients who have had cerebral malaria.

Schistosomiasis

Schistosomiasis is an infection caused by blood flukes (trematodes) of the genus *Schistosoma*. Infection by the larval stage usually occurs while the individual is swimming in infected freshwater. The infection affects about 200 million people in 74 countries (*Schistosoma japonicum* in the Far East; *Schistosoma mansoni* and *Schistosoma haematobium* in Africa). Most infections are asymptomatic. CNS symptoms are uncommon, but once the worms mature and the eggs have been laid, CNS involvement may be observed with any of the clinical forms of schistosomal infection. Eggs in the CNS may induce a granulomatous reaction, but in most cases, eggs in the CNS are clinically silent. Neurological complications of cerebral schistosomiasis include delirium, seizures, dysphasia, visual field impairment, focal motor deficits, and ataxia. Brain tumor-like masses in neuroschistosomiasis can present with increased intracranial pressure, headache, nausea and vomiting, and seizures (Carod-Artal 2008). In advanced disease with *S. mansoni* or *S. haematobium*, portal hypertension is a serious complication, with hepatic encephalopathy.

Trichinosis

Trichinosis is a worldwide disease caused by the ingestion of *Trichinella* larvae encysted in the muscles of infected animals. They are most commonly found in pork in the United States and Europe, but 150 species of mammals from all

latitudes may acquire the infection. Trichinosis has become rare in most developed nations but still occurs in ethnic groups that prefer raw or undercooked pork or wild animals, such as boar, polar bear, or walrus. Typical symptoms of infection include a febrile illness with myalgias and diarrhea, accompanied by marked eosinophilia. CNS involvement occurs in 10%–20% through a variety of mechanisms, including obstruction, toxicity, inflammation, vasculitis, and allergic reactions such as headache, delirium, insomnia, meningoencephalitis, and seizures. Neuropsychiatric sequelae and chronic fatigue are common after infection (Nemet et al. 2009), and residual cognitive dysfunction may occur (Harms et al. 1993). CT or MRI scans show multiple small hypodense lesions with ringlike enhancement with contrast. A muscle biopsy is usually diagnostic. Treatment in severe cases requires corticosteroids for the inflammation and antihelminthic drugs to kill *Trichinella*.

Amebiasis

Several amebas cause human disease, and all are ubiquitous in the environment worldwide. CNS infection with amebas is rare in the United States. Primary amebic meningoencephalitis is produced by *Naegleria fowleri* in healthy young individuals engaged in water sports. Its course is acute and fulminant, with headache, nausea, confusion, and stiff neck followed by coma and death within days. Granulomatous amebic encephalitis, caused by *Balamuthia mandrillaris* and some species of *Acanthamoeba*, usually occurs in debilitated, immunosuppressed (especially in cases of AIDS), or malnourished individuals. The course is more chronic, with personality changes, confusion, and irritability, eventually progressing to seizures and death (Schuster et al. 2009).

Drugs for Infectious Diseases:
Adverse Psychiatric Effects and
Drug Interactions

That antibiotics can cause delirium and other psychiatric symptoms is not well appreciated. The best-documented psychiatric side effects of drugs for infectious diseases are listed in Table 27–3 (antiretroviral drugs are discussed in Chapter 28, “HIV/AIDS”). Delirium and psychosis have been particularly associated with quinolones (e.g., ciprofloxacin), procaine penicillin, antimalarial and other antiparasitic drugs (especially mefloquine), and the antituberculous drug cycloserine. The most common adverse effect causing discontinuation of interferon is depression. Metronidazole and tinidazole can cause disulfiram-like reactions after alcohol ingestion. More detailed review is available elsewhere (Ferrando et al. 2010).

Table 27–4 shows selected well-established interactions between antimicrobial and psychotropic drugs. Drug interactions between antibiotics and nonpsychiatric drugs also may present risk in psychiatric practice. Erythromycin (and similar antibiotics such as clarithromycin) and ketoconazole (and similar antifungals) may cause QT interval prolongation and ventricular arrhythmias when given to a patient taking other QT-prolonging drugs, including tricyclic antidepressants and many antipsychotics. Linezolid is an irreversible monoamine oxidase–A inhibitor and therefore may cause serotonin syndrome if taken with serotonergic antidepressants and hypertensive crisis if taken with sympathomimetics or meperidine. Isoniazid is a weaker monoamine oxidase inhibitor. Details regarding antibiotics’ effects on psychiatric drugs via cytochrome P450 interactions can be found elsewhere (Ferrando et al. 2010).

Fears of Infectious Disease

Infectious diseases historically have been, and remain, frightening. In the epidemic of SARS, both affected patients and health care workers experienced fears of the illness and fears of contagion to family and friends, sometimes resulting in posttraumatic stress disorder (Sim et al. 2004). Quarantined patients struggled with loneliness, isolation, and stigmatization, and they feared the effect of their absence on those who depend on them (Maunder et al. 2003). Feared, stigmatized infected individuals may delay seeking care and remain undetected (Person et al. 2004). Widespread panic may occur in the event of a human avian influenza outbreak, pointing to the need for psychologically informed public health measures (Lau et al. 2007).

Both individual and group reactions to real or imagined threats of infectious diseases also may include hysterical and phobic behaviors. Anxiety about acquiring a feared disease may lead to conversion symptoms, hypochondriacal preoccupation, and unnecessary avoidance behaviors. Contamination obsessions and washing compulsions are among the most frequent symptoms in OCD. Delusional fears or beliefs that one is infected also occur in psychotic disorders, including schizophrenia, psychotic depression, and delusional disorder, somatic type (e.g., delusions of intestinal parasitosis); however, it is important to consider that a patient with a delusion of infection may actually be infected. Unrealistic fears of infection are especially likely with venereal diseases (particularly HIV), serious outbreaks (e.g., meningococcal meningitis on campus), and infectious threats given heavy media coverage (e.g., bacterial food contamination, bovine spongiform encephalopathy, SARS, anthrax, smallpox). Of course, how much vigilance and which precautions are optimal may be uncertain even among experts, but the early years of the

TABLE 27-3. Psychiatric side effects of drugs for infectious diseases (excluding antiretroviral drugs)

Drug	Side effects
Antibacterial	
Cephalosporins	Euphoria, delusions, depersonalization, illusions
Dapsone	Insomnia, agitation, hallucinations, mania, depression
Procaine penicillin ^a	Delirium, psychosis, agitation, depersonalization, fear of imminent death, hallucinations (probably due to procaine)
Quinolones ^a	Psychosis, paranoia, mania, agitation, Tourette-like syndrome
Trimethoprim-sulfamethoxazole	Delirium, psychosis
Gentamicin	Delirium, psychosis
Clarithromycin	Delirium, mania
Antituberculous	
Cycloserine ^a	Agitation, depression, psychosis, anxiety
Isoniazid	Psychosis, mania
Ethionamide	Depression, hallucinations
Antiviral	
Acyclovir, ganciclovir	Psychosis, delirium, depression, anxiety
Amantadine ^a	Psychosis, delirium
Oseltamivir, zanamivir	Psychosis, delirium
Interferon-alpha ^a	Irritability, depression, agitation, paranoia
Interleukin-2	Psychosis, delirium
Antiparasitic	
Antimalarials ^a (especially mefloquine)	Confusion, psychosis, mania, depression, anxiety, aggression, delirium
Metronidazole	Depression, delirium, disulfiram-like reactions
Thiabendazole	Psychosis
Antifungal	
Amphotericin	Delirium, psychosis, depression

Note. See also Brown and Stoudemire 1998.

^aMore significant (more frequent and/or better established) effects.

Source. Adapted from Abouesh A, Stone C, Hobbs WR: "Antimicrobial-Induced Mania (Antimania): A Review of Spontaneous Reports." *Journal of Clinical Psychopharmacology* 22:71-81, 2002; "Drugs That May Cause Psychiatric Symptoms." *Medical Letter* 44:59-62, 2002.

AIDS epidemic were a clear example of the potential for widespread irrational behaviors among the public, health care professionals, and officials.

At times, mass outbreaks of symptoms occur, falsely attributed to a supposed toxic exposure (e.g., bacterial food poisoning or toxic fumes) or infectious disease. There have been hundreds of reports in the literature of such outbreaks of "mass psychogenic" or "mass sociogenic" illness, and they tend to follow trends in societal concerns (e.g., bioterrorism) (Bartholomew and Wessely 2002). They are most likely to occur in groups of young people in close quarters, such as students at schools or military recruits. Some aspects of "germ panic" have become socially normative (Tomes 2000)—for example, inappropriate use of

antibiotics such as ciprofloxacin during the anthrax scare and the widespread overuse of antiseptic soaps, mouthwashes, sprays, and cleaning agents. A related phobia of fever in their children remains prevalent among parents (Crocetti et al. 2001).

Psychiatric Aspects of Immunizations

A growing body of research has indicated that psychological factors can influence the antibody response to vaccination. Several studies have convincingly shown that psychological stress suppresses the secondary (but not primary) antibody response to immunization (Cohen et al. 2001). More recent studies have shown reduced antibody re-

TABLE 27-4. Selected antimicrobial-psychoactive drug interactions

Antimicrobial	Effect on psychiatric drug
Antimalarials	Increase phenothiazine level
Azoles	Increase alprazolam, midazolam levels Increase buspirone level
Clarithromycin, erythromycin	Increase alprazolam, midazolam levels Increase carbamazepine level Increase buspirone level Increase clozapine level
Quinolones	Increase clozapine level Increase benzodiazepine level Decrease benzodiazepine effect via GABA receptor
Isoniazid	Increase haloperidol level Increase carbamazepine level With disulfiram, causes ataxia
Linezolid	Serotonin syndrome with serotonergic drugs

Note. GABA = γ -aminobutyric acid.

sponse of influenza vaccine in subjects who are unmarried or have bereavement, loneliness, or neuroticism (Moynihan et al. 2004; Phillips et al. 2005, 2006; Pressman et al. 2005).

Mass outbreaks of psychogenic symptoms similar to those described earlier in this chapter have been reported several times following vaccinations (Clements 2003). In developed countries, the public's fears of vaccine-preventable diseases have waned, and awareness of potential adverse effects of the vaccines has increased, which is threatening vaccine acceptance (Aman and Slifka 2005). The media and Web sites have disseminated much disinformation about vaccination risks, adding to the tendency toward phobic avoidance of immunization. Rare, serious CNS adverse effects, including acute disseminated encephalomyelitis (see section "Viral Infections" earlier in this chapter; see also Huynh et al. 2008), can occur after a variety of vaccinations. However, extensive research to date does not support the widely publicized fears that measles-mumps-rubella vaccination causes encephalitis or autism (Demicheli et al. 2005; Doja and Roberts 2006). The data also do not support the hypothesis that exposure to thimerosal, a mercury-containing preservative in some vaccines, causes neuropsychological deficits (Thompson et al. 2007).

HIV/AIDS

Crystal C. Watkins, M.D., Ph.D.

Niccolo D. Della Penna, M.D.

Andrew A. Angelino, M.D.

Glenn J. Treisman, M.D., Ph.D.

SOON AFTER THE HUMAN immunodeficiency virus (HIV) epidemic began in the early 1980s, neurologists described several HIV-related central nervous system (CNS) syndromes. Psychiatrists and other mental health professionals initially focused on grief, loss, and supportive psychotherapy but soon recognized some specific psychiatric conditions, including acquired immunodeficiency syndrome (AIDS) dementia; AIDS mania; increased rates of major depression; and psychiatric consequences of CNS involvement with HIV, opportunistic infections, and neoplasms.

Decades later, it is apparent that psychiatric issues play a central role in the HIV epidemic. HIV is transmitted almost entirely by specific risk behaviors and in high-risk populations targeted for education and prevention since the mid-1980s. Because of this, HIV, at least in the developed countries, has become a condition predominantly of vulnerable people with certain risk factors. Transfusion recipients and homosexual men who were unaware of the risk of HIV were the early patients, whereas many current individuals are aware of the risks but are at increased jeopardy because of addictions, personality vulnerabilities, mood disorders, impulse-control disorders, cognitive impairment, social isolation and disenfranchisement, or other barriers to behavior change. HIV-infected patients with psychiatric illness may have great difficulty in modifying risk behaviors. Psychiatric disorders also can adversely affect the treatment of HIV infection primarily through undermining adherence because taking medications as prescribed is critical to successful treatment. Thus,

the same psychiatric disorders that prevented patients from reducing their risk prevent them from obtaining benefit from their treatment. Untreated patients with high viral loads are more infectious, leading to an increased potential for spread of the HIV epidemic.

In this chapter, we address those conditions commonly seen in HIV, including those that increase risk for HIV or are barriers to HIV treatment. The introductory part of the chapter is a medical overview of HIV disease. In the second part, we consider neuropsychiatric and medical complications associated with HIV, and we include psychiatric conditions associated with HIV in the third part. Additional details about psychiatric disorders and treatment issues can be found in the American Psychiatric Association's "Practice Guideline for the Treatment of Patients With HIV/AIDS" (Forstein et al. 2006).

Medical Overview of HIV Infection and AIDS

HIV was originally recognized through a series of cases of young homosexual men with *Pneumocystis carinii* pneumonia in the early 1980s in California. It later became clear that these patients had severe immune system compromise and were vulnerable to infections commonly seen in other immunocompromised individuals. Current global statistics suggest that 400,000 infants are born each year with HIV infection, and some estimate that 7,400 new infections occur each day, with one individual being infected

about every 10 seconds (UNAIDS Joint United Nations Programme on HIV/AIDS 2008).

In the United States, as of December 31, 2001, 807,075 adults and adolescents had been reported as having AIDS, with current estimates suggested around 1 million. Of these, 462,653 (57%) have died. The number of people estimated to be living with HIV/AIDS worldwide has declined from 42 million people in 2002 to 33 million people in 2007, with an estimated 2.7 million people acquiring the infection in 2007 (Centers for Disease Control and Prevention 2006). An estimated 20 million individuals have died from HIV worldwide. The number of new cases of HIV infection has remained steady. The prevalence and mortality rates have slowly declined since 1996, in large part because of the introduction of highly active antiretroviral therapy (HAART). There has been a subsequent reduction in viral load and an increase in CD4 cell counts in many HIV-positive patients who received HAART.

Some populations within the United States are at increased risk for infection. Homosexual men have reduced their risk substantially but as a group continue to have high seroprevalence. Blood product screening has made transfusion risk negligible. Vertical transmission risk from mother to fetus, which occurs in up to 30% of live births without intervention, is influenced by delivery type, severity of HIV disease, and the availability of preventive antiviral treatment. The frequency of vertical transmission in the developed countries has decreased dramatically in the last decade as a result of education efforts focused on avoiding breast-feeding. However, vertical transmission remains a significant problem in many other parts of the world and in some subpopulations in the United States and other developed countries. Unfortunately, psychiatric disorders continue to make many vulnerable patients unable to access or benefit from prevention efforts. For example, injection drug users and their sexual partners are currently the population with the greatest risk for infection. The introduction of crystal methamphetamines into the gay community has increased high-risk sexual behaviors that expose methamphetamine users to HIV. The Internet also has emerged as a tool for anonymous sexual activity and permits access to an expanded sexual network where people can be vulnerable to infection.

Patients who have comorbid mental illness or substance abuse are likely to have poor medical and antiretroviral adherence and therefore would fail treatment or may be excluded from treatment (Mellins et al. 2009). The primary reason for excluding them from antiretroviral drug treatment is that inconsistent adherence breeds viral resistance, rendering treatment ineffective and increasing public health risk. Additionally, resources are often scarce in HIV clinics, and patients who are less likely to remain

adherent are the least likely to receive effective treatment. These patients include injection drug users, mentally ill patients, and other patients at high risk for poor outcomes. Therefore, the ability to provide adequate psychiatric care to HIV-infected patients is critical for effective treatment of HIV. Psychiatric disorders compromise the ability to take medications, adhere to treatment, practice safer sexual behaviors, and stop using injection drugs.

HIV is a retrovirus; it contains ribonucleic acid (RNA) strands that must be transcribed into deoxyribonucleic acid (DNA) by the action of an enzyme called reverse transcriptase, an enzyme not present in uninfected cells. The mechanism of viral infection within the cell is illustrated in Figure 28-1. The viral particles contain the enzyme, two viral RNA molecules, and accessory proteins. Viral particles bind to the surface of cells expressing CD4 antigens at the CD4 protein with the help of a second cell surface protein called CCR5. After the virus is internalized, the protein coat dissolves to release the two viral strands and the viral reverse transcriptase enzyme, which then uses the deoxynucleotides present in the cell to make a DNA strand from the viral RNA. The strands are moved to the nucleus where they are spliced into the DNA by a viral enzyme called integrase. If the cell is activated, the DNA template rapidly makes a huge number of viral RNA strands, which then use the cell's own machinery to make and process viral proteins. A viral protease finally cleaves the proteins and allows mature infectious particles to leave the cell. These steps do not occur within normal human cells and are therefore optimal targets for antiviral drugs. Drugs that interfere with binding (binding inhibitors), internalization (fusion inhibitors), reverse transcription (nucleotide and nonnucleotide reverse transcriptase inhibitors, also known as NRTIs or nucs and NNRTIs or nonnucs, respectively), integrase activity (integrase inhibitors), and viral protease (protease inhibitors) are all currently on the market. Successful treatment with several drugs at once reduces virus production to undetectable levels and should extend life into the normal range for most patients.

Because reverse transcriptase is a somewhat sloppy enzyme, many viral mutations occur. All possible single point mutations probably occur in a single day of uninhibited viral infection. This means that missed medication doses can lead to the rapid development of drug-resistant virus strains. Antiviral drug resistance has become one of the major problems in the epidemic in the United States. Psychiatric disorders are known to interfere with successful medical treatment and lead to increased HIV-related mortality. Successful treatment of psychiatric disorders leads to improved outcome. Collaborative care by psychiatry in the HIV clinic facilitates successful treatment of HIV infection.

- 1 Viral binding to cell surface receptors (entry inhibitors)
- 2 Internalization of viral content (fusion inhibitors)
- 3 Reverse transcriptase makes viral DNA (nucleotide and nonnucleotide reverse transcriptase inhibitors)
- 4 Viral integration into host genome (integrase inhibitors)
- 5 Transcription of DNA to RNA
- 6 Translation of viral RNA to protein components
- 7 Protein processing, cleavage, viral assembly, and budding (protease inhibitors)

FIGURE 28-1. HIV infection and replication.

Viral particles covered with gp120, a recognition glycoprotein, bind to CD4 receptors and then to the co-receptor. A protein unfolds as a result of the bonding and facilitates fusion of the viral particle with the CD4 cell. The viral envelope dissolves and releases the viral RNA and several viral enzymes, including reverse transcriptase. The RNA is used as the template to make a viral DNA strand, which is integrated into the human DNA by the action of an enzyme called integrase. When the cell is activated, viral RNA is made from the integrated DNA and usurps the cell's machinery to make more viral RNA and viral proteins. These are further processed and then packaged as immature viral particles. Further processing by viral enzymes allows the viral particle to become a mature infectious virion.

The Internet and HIV

The Internet has become a major mechanism to disseminate information about rapidly changing areas of medicine. HIV is one of the most rapidly evolving areas of treatment, and Dr. John Bartlett was one of the first clinicians to recognize the online potential of rapid dissemination of new HIV-related information. He began a Web site at Johns Hopkins University (www.hopkins-aids.edu) that has become a reference point for HIV care. About the same time, the first commercial online HIV medical information site was launched by Dr. Jeff Drezner (a psychiatrist) as Medscape (www.medscape.com), one of the pioneering Web information sources in medicine (R. Chaisson, personal communication, September 2009). Medscape went on to become a source for general medical information and a model for other Web sites. Other later Web sites were devoted to reducing risk-related behaviors for HIV prevention, providing information about access to treatment and care, and providing information about the latest changes in treatment recommendations.

Unfortunately, the Internet is also a conduit for anonymous sexual encounters and high-risk behavior promoting erotic material. Some studies estimate that up to 16 million men and women have gone online to find love and companionship and to solicit sex (Madden and Lenhart 2006; Rebchook et al. 2006). Whether the Internet is a mediator or moderator of behavior in populations at risk for HIV is not well understood. Distinct from encounters initiated on the Internet or a traditional social scene, risk-taking individuals will still engage in high-risk sexual acts (McKirnan et al. 2007). At the same time, individuals who solicit sexual partners online have been shown to be more likely to have a sexually transmitted disease (STD) history, to participate in more unsafe sexual behaviors, and to have considerably more sexual partners compared with those who do not pursue Internet sexual partners (Liau et al. 2006; Rebchook et al. 2006; Tashima et al. 2003). A particular chat room was linked to a 1999 outbreak of syphilis among men having sex with men (Klausner et al. 2000), and cases of acute HIV infection occurred after meeting a sexual partner in another Internet chat room (Tashima et al. 2003). The anonymity of being able to connect sexually with partners from alternative social networks is also suggested to generate a hybrid of high- and low-risk persons that usually would not intermingle. This subsequent extension and interaction of sexual networks can propagate transmission of HIV and other STDs (Rebchook et al. 2006).

Creative new approaches are needed to combat STDs and HIV transmission via the Internet. The Centers for Disease Control and Prevention assembled an international panel of HIV disease experts to discuss how to use the Internet to promote HIV prevention efforts and edu-

cate others about the disease transmission risks of sexual partnering online.

Effect of Psychiatric Disorders on HIV Medication Adherence

The single most important factor affecting outcome of HIV treatment is the patient's ability to adhere to a prescribed regimen. A study of HIV-infected prisoners reported that under directly observed therapy in a prison setting, 85% of the individuals developed undetectable viral loads, with prisoners taking approximately 93% of doses (Kirkland et al. 2002). In contrast, British community studies found that only 42% of treatment-naïve patients taking antiretroviral medications attained undetectable viral loads (Lee and Monteiro 2003). Antiretroviral adherence rates between 54% and 76% have been reported in other general clinic or community samples (Liu et al. 2001; McNabb et al. 2001; Paterson et al. 2000; Wagner and Ghosh-Dastidar 2002), including groups of patients with serious mental illness (Beyer et al. 2007; Wagner et al. 2003).

Psychiatric factors associated with nonadherence include dementia, depression, psychosis, aversive life experience, personality factors, and substance use (Mellins et al. 2009). Many studies have shown decreased adherence to HAART attributable to depression (Campos et al. 2010; Koenig et al. 2008). Treatment of depression is associated with improved outcomes (Kumar and Encinosa 2009). Psychotic patients may refuse medications, deny their illness, or be too disorganized to manage adherence. Patients with dementia may forget doses and appointments. Aversive life experiences, such as sexual abuse in childhood (Meade et al. 2009), are associated with poor adherence. Personality vulnerabilities also have strong positive and negative effects on medication adherence. Substance use disorders, particularly alcohol abuse (Conen et al. 2009), contribute profoundly to poor medication adherence (Malta et al. 2008). Treatment of addictions can improve adherence and outcome (Roux et al. 2008). Constant and consistent coaching of patients at each visit is imperative, including clarifying goals of treatment (both short- and long-term) and anticipating misunderstandings. It is also useful over time to positively reinforce compliance with treatment.

Neuropsychiatric and Medical Complications of HIV Infection

Opportunistic infection rates have dramatically decreased over the last two decades and are covered in Chapter 27, "Infectious Diseases." Here we review some specifics related to HIV infection.

Toxoplasmosis

Infection with *Toxoplasma gondii* generally occurs in 30% of patients with fewer than 100 CD4 cells/mm³ (Kaplan et al. 2009). In AIDS patients, toxoplasmosis is the most common reason for intracranial masses, affecting between 2% and 4% of the AIDS population. Symptoms of CNS infection are fever, change in level of alertness, headache, confusion, focal neurological signs (approximately 80% of cases), and partial or generalized seizures (approximately 30% of cases). Computed tomography (CT) usually shows multiple bilateral, ring-enhancing lesions in the basal ganglia or at the gray-white matter junction. Magnetic resonance imaging (MRI) is more sensitive than CT and is the preferred technique for individuals without focal neurological deficits (Kupfer et al. 1990).

Treatment is usually empirical, based on clinical and imaging findings, and consists of pyrimethamine and leucovorin plus sulfadiazine or clindamycin. Clinical and radiological improvement is seen in more than 85% of the patients by day 7 (Kaplan et al. 2009). Acute treatment (6 weeks) has been followed by continuous prophylaxis to prevent relapse. Recent studies suggest that HIV-infected adult patients receiving effective HAART can safely discontinue primary and secondary prophylaxis against toxoplasmic encephalitis if their CD4⁺ T cell count has been greater than 200 cells/mm³ for more than 3 months (Miro et al. 2006).

The use of trimethoprim-sulfamethoxazole as prophylaxis has reduced the incidence of *T. gondii* infection in HIV. Patients with hypersensitivity to sulfa drugs may use pyrimethamine plus dapsone.

Cytomegalovirus

Cytomegalovirus (CMV) infection is found at autopsy in about 30%–50% of brains from HIV-infected patients (Jelinger et al. 2000). However, the development of clinically evident CMV encephalitis is fairly rare and most often occurs in patients with CD4 cell counts less than 50 cells/mm³. Short-term memory is especially impaired in CMV encephalitis in HIV-infected patients, mimicking Korsakoff's syndrome (Pirkanen-Matell et al. 2009). CMV infection of another organ, such as retina, blood, adrenal glands, or gastrointestinal tract, is often found at the time of encephalitis diagnosis. CMV encephalitis in AIDS may progress gradually as a dementia with focal deficits (Holland et al. 1994) or rapidly as a fatal delirium (Kalayjian et al. 1993). Treatment is mostly supportive. Ganciclovir and foscarnet may be prescribed but are of questionable benefit.

Cryptococcal Meningitis

Although meningitis caused by *Cryptococcus neoformans* is rare in immunocompetent persons, it is a devastating illness

that has occurred in approximately 8%–10% of AIDS patients in the United States and in up to 30% of AIDS patients in other parts of the world (Powderly 2000). More recent published incidence estimates range from 0.04% to 12% per year among persons with HIV in various regions (Park et al. 2009). Patients generally present with fever and delirium. Meningeal signs are not universally seen. Seizures and focal neurological deficits occur in about 10% of patients, and intracranial pressure is elevated in about 50% of patients. The 3-month case fatality rate is estimated to be 9% in high-income countries, 55% in low- and middle-income ones, and 70% in sub-Saharan Africa (Park et al. 2009).

Treatment of cryptococcal meningitis in HIV requires amphotericin B. Patients who survive must receive prophylaxis against recurrence. Prophylaxis can be prescribed as oral fluconazole or intermittent intravenous amphotericin B. Some authors suggest that patients who receive HAART for 6 months with a rise in CD4 cell count to greater than 100 cells/mm³ may terminate secondary prophylaxis (E. Martinez et al. 2000). Although earlier trials did not show a survival benefit from primary prophylaxis for *C. neoformans*, a prospective, multicenter trial of low-dose fluconazole showed significant survival benefit in HIV-infected patients with severe immune deficiency (Chetchotisakd et al. 2004).

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of white matter in immunocompromised patients. First described in cancer patients, the causative agent is a polyomavirus, named *JC virus* after a patient. Its transmission route is unclear but may be respiratory, and there is no clear clinical syndrome of acute infection. Prior to the implementation of HAART in 1996, the prevalence of PML in AIDS was between 1% and 10%, and AIDS patients account for almost three-quarters of PML cases reported in the United States (Engsig et al. 2009). The incidence rate of PML has been reduced by almost 50% with widespread use of HAART (Engsig et al. 2009; Sacktor 2002). The risk of PML remains significant in AIDS patients with fewer than 100 CD4 cells/mm³.

The clinical syndrome consists of multiple focal neurological deficits, such as mono- or hemiparetic limb weakness, dysarthria, gait disturbances, sensory deficits, and progressive dementia, with eventual coma and death. Occasionally, seizures or visual losses may occur. A Brazilian study found that the most common clinical manifestations were focal weakness (75%), speech disturbances (58%), visual disturbances (42%), cognitive dysfunction (42%), and impaired coordination (42%) (Vidal et al. 2008). Usually, no fever or headache occurs.

The pathology of PML consists of demyelination and death of astrocytes and oligodendroglia. MRI is more useful than CT in diagnosis; multiple areas of attenuated signal are seen on T2 images, primarily in the white matter of brain, although gray matter, brain stem, cerebellar, and spinal cord lesions are possible. Cerebrospinal fluid (CSF) studies are generally unhelpful, except for polymerase chain reaction evaluation for the presence of JC virus, which is sensitive and specific. Brain biopsy provides the definitive diagnosis but is rarely used. Trials of the antiviral agents cytarabine, cidofovir, and topotecan for the treatment of PML in HIV-infected patients have been largely unsuccessful, probably because the acute infection with JC virus occurs many years before PML develops.

Central Nervous System Neoplasms

Lymphoma is the most common neoplasm seen in AIDS patients, affecting between 0.6% and 3%. AIDS is the most common condition associated with primary CNS lymphoma. The patient is generally afebrile; may develop a single lesion with focal neurological signs or small, multifocal lesions; and most commonly presents with mental status change. Seizures occur in about 15% of these patients. CNS lymphoma manifests late in the course of HIV infection and is associated with a very poor prognosis.

CNS lymphoma is at times misdiagnosed as toxoplasmosis, HIV dementia, or other encephalopathy. CT scan of the brain may be normal or show one or multiple hypodense or patchy, nodular enhancing lesions. MRI generally shows enhanced lesions that may be difficult to differentiate from CNS toxoplasmosis, but thallium single photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning may help differentiate the two disorders. CSF studies may be normal or show a moderate monocytosis; cytology studies report lymphoma cells in fewer than 5% of patients. Brain biopsy is required for confirmation of the diagnosis of CNS lymphoma. Because this procedure carries some morbidity, clinicians should strongly consider the possibility of lymphoma in afebrile patients with a negative toxoplasma immunoglobulin G (IgG) screening test result, patients with a single lesion, and patients whose symptoms do not respond to empirical therapy for toxoplasmosis as indicated by clinical examination and repeat MRI. The differential diagnosis of CNS neoplasm also includes metastatic Kaposi's sarcoma and primary glial tumors.

Lymphoma may respond in part to radiation therapy, thus alleviating high intracranial pressure and its associated symptoms. Chemotherapy is generally adjunctive for lymphoma. CNS lymphoma had a grim prognosis with an average survival of 3–5 months prior to the advent of HAART. In the post-HAART era, there appears to be a dis-

inction between the onset and prognosis of systemic lymphoma and that of CNS non-Hodgkin's lymphoma, with an overall marked improvement in survival. HIV-related lymphomas arising in the periphery are in a less advanced stage and manifest earlier in the disease, whereas CNS lymphomas still carry a poor prognosis and manifest late in the disease course (Robotin et al. 2004).

Fatigue

Fatigue is a very common symptom in HIV-infected patients, which is often overlooked, improperly assessed, or inadequately investigated. It is associated with poor quality of life and impaired physical functioning (Marcellin et al. 2007; Pence et al. 2008). Estimates of prevalence of fatigue in patients infected with HIV range from 10% to 38% in early infection to 40% to 60% in AIDS cases (Sullivan and Dworkin 2003) and even higher in some samples (Pence et al. 2008). Fatigue may be mild and annoying, or it may be severe enough to impair function. A scale specific to HIV-related fatigue has been published (Pence et al. 2008). Fatigue is a nonspecific symptom and may have a single or multifactorial etiology. In a sample of ambulatory AIDS patients, fatigue significantly correlated with anemia and pain (Breitbart et al. 1998). In addition to disease causes, fatigue may be a side effect of medications, including HAART. Fatigue is one of the most common side effects of protease inhibitors and may be a reason for non-adherence (Duran et al. 2001).

Fatigue also may be the result of substance abuse, depression, or other psychiatric disorders. HIV-infected patients with major depression are much more likely to complain of fatigue than are patients without depression (Sullivan and Dworkin 2003; Voss et al. 2007). HIV wasting syndrome, chronic diarrhea, and testosterone deficiency are all associated with fatigue. Low serum testosterone level has been found among symptomatic AIDS patients, especially those with HIV wasting syndrome (Knapp et al. 2008). HIV-infected men with wasting syndrome treated with testosterone experienced significant improvements in fatigue, energy, mood, and quality of life compared with HIV-infected individuals who received placebo (Knapp et al. 2008). Another study showed that the testosterone-treated group had a profound amelioration of fatigue symptoms, even greater than in the fluoxetine-treated group (Rabkin et al. 2004). Hypotestosteronism is most likely in advanced AIDS (Kopicko et al. 1999; Rabkin et al. 2004) but also may be caused by medications (e.g., fluconazole, ketoconazole, or ganciclovir) (Wagner et al. 1995).

In many HIV-positive patients, the fatigue has no clear etiology, and empirical treatment is reasonable. Testosterone may be a successful treatment for fatigue in HIV-infected men, even when depressive symptoms are present

(Kong and Edmonds 2003). HIV-infected women taking testosterone for 18 months appear to have significant improvement in quality of life as well as an increase in skeletal muscle mass and bone mineral density without a change in body weight (Dolan Looby et al. 2009).

More activating antidepressants may be better tolerated by fatigued depressed patients. Some authors have reported that stimulants may be useful in treating fatigue and depression in HIV, as discussed later in this chapter. Care must be exercised in using stimulants in patients with histories of substance abuse, although risk of abuse loses relevance in terminal AIDS.

Psychiatric Conditions Associated With HIV

Delirium

Prevalence and Clinical Presentation

Delirium occurs frequently in patients with advanced HIV infection (Angelino and Treisman 2008; Bialer et al. 1991). One study found that 46% of the AIDS patients at a skilled nursing facility had at least one episode of delirium (Uldall and Berghuis 1997). More subtle delirium is common in compromised patients, although assessment can be difficult. In addition, delirium has been shown to be a marker for decreased survival in patients with AIDS (Uldall et al. 2000b). Hospitalized patients with AIDS also were found to have increased mortality if delirium complicated their hospital course (Uldall et al. 2000a). Delirium also occurs in children with AIDS (Hatherill and Flisher 2009).

The clinical presentation of delirium in HIV-infected patients is the same as in non-HIV-infected individuals and is characterized by inattention, disorganized thinking or confusion, and fluctuations in level of consciousness. Emotional changes are common and often unpredictable, and hallucinations and delusions are frequently seen. The syndrome has an acute or a subacute onset and remits fairly rapidly once the underlying etiology is treated. If untreated, patients have a marked increased risk of mortality, with estimates of about 20% in hospitalized patients.

Differential Diagnosis

Aside from general risk factors such as older age, multiple medical problems, multiple medications, impaired visual acuity, and previous episodes of delirium, patients with HIV-associated dementia are at increased risk to develop delirium. The differential diagnosis of delirium includes HIV-associated dementia (especially with AIDS mania), minor cognitive-motor disorder, major depression, bipolar disorder, panic disorder, and schizophrenia. Delirium usually

can be differentiated on the basis of its rapid onset, fluctuating level of consciousness, and link to medical etiology.

Etiology

The cause of delirium should be aggressively sought. The approach to determining cause is similar to that for delirium in general (see Chapter 5, "Delirium"). Particular considerations in HIV-positive patients include hypoxia with *P. carinii* pneumonia, malnutrition, CNS infections and neoplasms, systemic infections (e.g., mycobacteria, CMV, bacterial sepsis), HIV nephropathy, substance intoxication and withdrawal, medication toxicity, and polypharmacy. Variations in hydration or electrolyte status also may profoundly affect patients with HIV who already have cerebral compromise. HIV infection itself also may produce an acute encephalopathy similar to that reported with CMV (Vlassova et al. 2009).

Treatment

Management of delirium in HIV is very similar to that for delirium in general (see Chapter 5, "Delirium"), including identification and removal of the underlying cause (when possible), nonpharmacological reorientation and environmental interventions, and pharmacotherapy. Low doses of high-potency antipsychotic agents, such as haloperidol, usually are effective. Newer atypical antipsychotics are currently being used with some success, but those with more anticholinergic activity may worsen the condition. Benzodiazepines should be used with caution because they may contribute to delirium in some patients but are of particular use in alcohol or benzodiazepine withdrawal delirium. Physical restraint may be necessary if the patient becomes violent but should be used only when alternatives are inadequate because restraint may worsen delirium.

Treatment with antipsychotic medication requires awareness of the higher susceptibility of patients with HIV to neuroleptic-induced extrapyramidal symptoms (EPS), even with exposure to drugs with low potential for inducing EPS (D.V. Kelly et al. 2002; Meyer et al. 1998). Increased susceptibility to EPS has been particularly notable with use of conventional antipsychotic medications and has limited the dosage that can be used to treat patients (Sewell et al. 1994). Patients with AIDS-related psychosis are more sensitive to EPS and respond to lower than standard doses of antipsychotics (Dolder et al. 2004; Sewell et al. 1994). Extreme sensitivity to EPS is encountered in patients with HIV dementia (Dolder et al. 2004). Marked neuronal degeneration in the basal ganglia of patients with HIV (Ferrando and Wapenyi 2002; Itoh et al. 2000), with accompanying dopaminergic neuron destruction or alteration, may explain these findings. Dyslipidemia and hyperglycemia are also potential side effects when using

antipsychotics in the setting of antiretroviral therapy (Oh and Hegele 2007).

To date, only one randomized controlled trial in delirious patients with AIDS has documented efficacy of low-dose haloperidol and chlorpromazine. Lorazepam was ineffective and was associated with significant adverse effects (Breitbart et al. 1996). Lorazepam was reported to be useful in cases of AIDS-associated psychosis with catatonia, however (Scamvougeras and Rosebush 1992). Case reports indicate that molindone and ziprasidone are of benefit for HIV-associated psychosis and have minimal EPS (Fernandez and Levy 1993; Leso and Schwartz 2002).

If indicated, typical neuroleptic medications should be used at the lowest dosage and for the briefest duration possible. Atypical antipsychotics are generally preferred because of lower risk for EPS. Terminal delirium in HIV, as in other terminal diseases, is more refractory to treatment.

Dementia

Prevalence

Early in the AIDS epidemic, some patients presented with rapidly progressive neurocognitive disturbances, which led to an intensive search for etiology. Several CNS opportunistic conditions were identified, including CMV encephalitis, PML, cerebral toxoplasmosis, cryptococcal meningitis, and CNS lymphoma. However, a subset of patients remained for which no identifiable pathogen could be found, and it was deduced that HIV itself was the causative factor behind the dementia. Autopsy studies of AIDS patients with dementia found characteristic white matter changes and demyelination, microglial nodules, multinucleated giant cells, and perivascular infiltrates but a marked absence of HIV within neurons. This has led to the current theories of neuronal loss through the action of macrophages and microglial cells and/or through activation of cytokines and chemokines that trigger abnormal neuronal pruning. It appears that basal ganglia and nigrostriatal structures are affected early in the dementia process, with diffuse neuronal losses following. Typical late findings show an approximate 40% reduction in frontal and temporal neurons. Analyses of CSF (Gallo et al. 1989; Laverda et al. 1994) and autopsy material (Tyor et al. 1992; Wesselingh et al. 1994) also have shown aberrant production of specific cytokines in patients with HIV-associated dementia.

In 1986, HIV-associated dementia was reported in up to two-thirds of AIDS patients (Navia et al. 1986), but it is less frequent now in patients receiving HAART. It became one of the leading causes of dementia in persons younger than 60 years (McArthur et al. 1993). However, its frequency among patients with otherwise asymptomatic HIV infection or CD4 cell count greater than 500 cells/mm³ is prob-

ably less than 5% in a community sample (Handelsman et al. 1992; Krikorian et al. 1990; Maj et al. 1994; McKegney et al. 1990; Wilkie et al. 1990). In the Multicenter AIDS Cohort Study (Sacktor et al. 2001), the incidence of HIV-associated dementia declined 50% from 1990–1992 to 1996–1998, a period during which effective antiretroviral therapy was used (Sacktor 2002; Sacktor et al. 2001).

With the widespread use of HAART in developing countries in the mid 1990s, there was a dramatic decrease in the rates of AIDS dementia (Bhaskaran et al. 2008), with cases usually associated with specific risk factors, including higher HIV RNA viral load, lower educational level, older age, anemia, illicit drug use, and female gender. In the post-HAART era, minor cognitive-motor disorder and depression are more predictive of severity of HIV-associated dementia (Dunlop et al. 2002; Sevigny et al. 2004; Stern et al. 2001). HIV-associated dementia generally occurs in patients who have had a CD4 cell count nadir of less than 200/mm³. With patients living longer with HAART, there is some concern that AIDS dementia prevalence will increase in association with the length of infection, or with residual virus confined to the CNS (Letendre et al. 2008). However, the overall incidence and prevalence rates of HIV dementia in the post-HAART era vary greatly by geography, treatment, and risk factors studied, as well as by whether patients are sampled in the community, a clinic, or a hospital. Studies from 1996 to 2002 in Italy estimated rates of cognitive impairment and dementia as 55% and 10%, respectively (Tozzi et al. 2005). In the country of Georgia, an estimated 25% of HIV/AIDS patients have developed dementia from the disease (Bolokadze et al. 2008). Of the women in Puerto Rico who were identified as “at risk” for development of dementia because of their HIV status, 49% had cognitive impairment, and 29% had dementia (Wojna et al. 2006). This is in contrast to what is observed in hospitalized HIV/AIDS patients in Kenya, where dementia is rarely detected (Jowi et al. 2007). The factors that contribute to the variance of prevalence and incidence rates, whether related to the disease, environment, or diagnostic tools used, require further investigation.

Pathophysiology

Although mechanisms of neuronal death in HIV-associated dementia have been unclear (McArthur et al. 1989; Wiley et al. 1991), the prevailing theories involve infection of the virus in brain macrophages and activated microglia in the CNS (Gonzalez-Scarano and Martin-Garcia 2005; Kaul 2009). Neurons, astrocytes, and oligodendrocytes do not appear to be directly infected by the virus. A cascade of chemokines and cytokines mediated by activated microglial cells leads to cell death through decreased arborization of neurons.

Assessment

Clinically, HIV dementia presents with the typical triad of symptoms seen in other subcortical dementias—memory and psychomotor speed impairments, depressive symptoms, and movement disorders. Initially, patients may notice slight problems with reading, comprehension, memory, and mathematical skills, but these symptoms are subtle, so they may be overlooked or discounted as being caused by fatigue and illness. Patients with early dementia usually will show impairments in timed trials, such as a timed oral Trail-Making Test or grooved pegboard. Cognitive screening tools have been recently reviewed (Skinner et al. 2009). A useful bedside screening tool, the Modified HIV Dementia Scale, has been shown to be the most specific and valid assessment tool and can be administered serially to document disease progression (Davis et al. 2002). Later, patients develop more global dementia, with marked impairments in naming, language, and praxis.

Motor symptoms are also often subtle in the early stages and include occasional stumbling while walking or running; slowing of fine repetitive movements, such as playing the piano or typing; and slight tremor. On examination, patients will have impaired saccadic eye movements, dysdiadochokinesia, hyperreflexia, and, especially in later stages, frontal release signs. In late stages, motor symptoms may be quite severe, with marked difficulty in smooth limb movements, especially in the lower extremities. Impairments on tests of psychomotor speed in patients at the time of AIDS diagnosis with no memory complaints have been shown to predict development of HIV-associated dementia up to 2 years later (Dunlop et al. 2002; Sevigny et al. 2004). Rate of progression is variable and may cause mild dysfunction over a long period or rapid progression with severe impairment (Price and Brew 1988). Parkinsonian features are common in HIV-associated dementia, and clinical correlates between HIV and parkinsonism have been identified (Koutsilieris et al. 2002; Mirsattari et al. 1998). Parkinsonian features may be provoked by dopamine antagonists (Hriso et al. 1991), opportunistic infections including toxoplasmosis (P. Maggi et al. 2000), or CNS infection with HIV itself (Mirsattari et al. 1998).

Apathy is a common early symptom of HIV-associated dementia, often causing noticeable withdrawal by the patient from social activity. A frank depressive syndrome also commonly develops, typically with irritable mood and anhedonia instead of sadness and crying spells. Sleep disturbances and weight loss are common. Restlessness and anxiety may occur. Psychosis develops in a significant number of patients, typically with paranoid thoughts and hallucinations. In about 5%–8% of patients, a syndrome known as AIDS mania develops (see subsection “Bipolar Disorder” later in this chapter). Overall, HIV-associated dementia is

rapidly progressive, usually ending in death within 2 years. Because of impulsive behavior and emotional lability, HIV-associated dementia has been suggested as a strong risk factor for suicide (Alfonso and Cohen 1994).

Diagnosis

Typical findings on MRI of patients with advanced HIV-associated dementia include significant white matter lesions, as well as cortical and subcortical atrophy (Descamps et al. 2008; Roc et al. 2007). These abnormalities may appear as discrete foci, as patchy regions of confluent involvement, or as diffuse parenchymal involvement (Descamps et al. 2008; Roc et al. 2007). Partial improvement of MRI signal abnormalities (Olsen et al. 1988) and worsening of atrophy and white matter lesions (Post et al. 1992) have been reported in small reviews of patients taking zidovudine. MRI also has been suggested to be of utility in monitoring HIV-associated dementia treatment with HAART (Thurnher et al. 2000).

Various functional neuroimaging techniques, including PET (Rottenberg et al. 1996), SPECT (Harris et al. 1994; Rosci et al. 1996), and magnetic resonance spectroscopy (MRS) (Barker et al. 1995; Chang et al. 1999; Lopez-Villegas et al. 1997), have shown alterations in cerebral blood flow and metabolic patterns in the brains of individuals infected with HIV. Most of these studies were done in patients with dementia or other cognitive impairment, but other MRS investigations showed abnormalities in patients with no cognitive deficit (Chang et al. 1999; Meyerhoff et al. 1999; Suwanwela et al. 2000). Increased brain activation on functional MRI during working memory was found in patients with early HIV cognitive disturbance (Chang et al. 2001). Further studies showed increased activation on functional MRI in HIV-positive patients that predated clinical signs or deficits on cognitive tests (Ernst et al. 2002).

HIV-associated dementia also may develop in the presence of milder immunosuppression (Dore et al. 1999). The rates of HIV-associated dementia have declined but not to the same extent that other AIDS-defining illnesses have declined, suggesting that CNS eradication of HIV is becoming more challenging with current antiretroviral regimens. It has been proposed that increasing resistance to HAART regimens may be linked to this possible evolution. In the Multicenter AIDS Cohort Study (1990–1998; Sacktor et al. 2001), the proportion of cases of HIV-associated dementia in patients with CD4 cell counts between 201 and 350 cells/mm³ was higher in 1996–1998 compared with the early 1990s. This suggests that screening for HIV-associated dementia should be extended to patients with CD4 cell counts less than 350 cells/mm³ (McArthur 2004). The extended survival that antiretroviral regimens have offered patients also may increase their vulnerability to

developing dementia rather than dying secondary to other fulminant complications (McArthur 2004).

Treatment

Controlled trials for HIV-associated dementia through 2008 have been reviewed elsewhere (Clifford 2000; Uthman and Abdulmalik 2008). Intensification of antiretroviral therapy and associated control of viral load are associated with significantly lower risk for progression to HIV-associated dementia (Letendre et al. 2007). Furthermore, HAART improves cognitive impairment in patients with HIV-associated dementia (Letendre et al. 2007; Robinson-Papp et al. 2009).

Controversy exists regarding the duration of treatment and outcome of dementia. The long-term effect of HAART on the course of HIV-associated dementia remains undetermined, with some evidence of ongoing HIV-related cognitive damage despite more than 3 years of potent antiretroviral treatment (Joska et al. 2010; Tozzi et al. 2001). The only other controlled trial of antiretroviral drugs compared effective antiviral therapy with and without added high-dose abacavir (Brew et al. 2007), but the study did not detect further cognitive improvement.

At first, it was believed that only antiretroviral agents with good penetration into the CNS would be useful in treating HIV-associated dementia with associated reduction of CSF HIV RNA levels (Halman and Rourke 2000), but later efforts indicated that HAART in many different combinations, including those with poor CNS levels, could provide some relief. Drugs that cross well into CSF include nucleoside reverse transcriptase inhibitors (zidovudine, stavudine, and abacavir) and the nonnucleoside nevirapine. Despite these theoretical considerations, little evidence suggests an improved outcome for any particular antiretroviral regimen (Clifford 2000). However, the observation of increased proportions of patients with HIV-associated dementia compared with other AIDS-defining illnesses (Dore et al. 1999; Masliah et al. 2000) suggests that HAART may not be as effective for treating HIV-associated dementia.

Various clinical trials have evaluated neuroprotective medications for HIV-associated dementia, including nimodipine (Navia et al. 1998), antioxidants (The Dana Consortium on the Therapy of HIV Dementia and Related Cognitive Disorders 1997, 1998), a platelet-activating factor antagonist (Schifitto et al. 1999), peptide T (Heseltine et al. 1998), and memantine (Schifitto et al. 2007), but none were shown to be efficacious.

Use of dopamine receptor agonists in pediatric patients with HIV and parkinsonian features has led to improvement in motor function (Mintz et al. 1996), yet results of

similar medications in adults have been less fruitful (Kiebert et al. 1991). Psychostimulants have been shown to improve cognitive performance in patients with HIV (Brown 1995; Hinkin et al. 2001), but others have noted apparent acceleration of HIV-associated dementia following psychostimulant use (Czub et al. 2001; Nath et al. 2001). There have not been more recent reported clinical trials with dopamine agonists or stimulants.

Risperidone and clozapine have been described in case reports of HIV-associated dementia with psychosis, with significant improvement in psychotic symptoms and few EPS (Dettling et al. 1998; Zilakis et al. 1998).

Quality care for patients with HIV-associated dementia is to ensure an optimal HAART regimen and to treat associated symptoms aggressively. Depression can be treated with standard antidepressants, and, in some cases, methylphenidate or other stimulants may be useful in treatment of apathy.

Minor Cognitive–Motor Disorder

Clinical Presentation and Prevalence

HIV-associated dementia is a late-stage disorder, whereas minor cognitive–motor disorder (or mild neurocognitive disorder) is a less severe syndrome seen in earlier HIV infection. The symptoms of minor cognitive–motor disorder are often overlooked because they may be very subtle, but they are essentially mild manifestations of the same symptoms seen in HIV-associated dementia (cognitive and motor slowing). Patients with this disorder may present with a singular minor complaint, such as taking longer to read a novel, dysfunction when performing fine-motor tasks such as playing the piano, an increased tendency to stumble or trip, or making more mistakes when balancing the checkbook. Minor cognitive–motor disorder is now regarded as part of the spectrum of HIV-associated dementia, and its description in the literature has fallen out of use.

Prevalence data for minor cognitive–motor disorder are variable, often suggesting up to 60% prevalence by late-stage AIDS (Seigny et al. 2004). Prevalence in earlier stages is not well defined. Whether minor cognitive–motor disorder inevitably leads to HIV-associated dementia is uncertain. It appears that some patients may continue to have minor problems, whereas others will progress to frank dementia. This question is now confounded by the effects of HAART; data from earlier in the epidemic cannot be reasonably compared with current data.

Treatment

No controlled treatment data are available specifically for minor cognitive–motor disorder.

Major Depression

Prevalence

Depression is a significant problem among persons with HIV and AIDS. The estimated prevalence of major depressive disorder (MDD) in HIV-infected patients has been reported as 19%–43% (Cysique et al. 2007; Gibbie et al. 2007). The question of whether the incidence or prevalence of major depression is increasing in HIV-infected patients has been a controversial topic (Ciesla and Roberts 2001). Several factors complicate this issue. First, identification of MDD rather than depressive symptoms is a methodological barrier to cross-sample comparison. Additionally, populations at risk for HIV infection, including homosexual men and patients with substance use disorders, have elevated rates of major depression. A meta-analysis of 10 studies comparing HIV-positive and at-risk HIV-negative patients found a twofold increase in the prevalence of major depression in patients infected with HIV (Ciesla and Roberts 2001). Studies have shown that depression has a negative effect on patient adherence to treatment (Dimatteo et al. 2000; Mello et al. 2010), quality of life (Lenz and Demal 2000; Meltzer-Brody and Davidson 2000), and treatment outcome (J. Holmes and House 2000).

Lyketsos et al. (1993b) reported an association between depression and HIV infection as early as 1993 and speculated that major depression was a risk factor for developing HIV. Studies have shown prevalence rates of major depression among individuals with HIV of 15%–40%, depending on the setting and risk group studied (American Psychiatric Association 2000b; Rabkin et al. 2004). However, the prevalence exceeds 50% in individuals with HIV seeking psychiatric treatment (American Psychiatric Association 2000b). Major depression is a risk factor for HIV infection (McDermott et al. 1994) by virtue of its effect on behavior, intensification of substance abuse, exacerbation of self-destructive behaviors, and promotion of poor partner choice in relationships. HIV-negative persons with higher scores on screening instruments for general psychological distress were found to have increased risk behaviors for HIV acquisition (Hartgers et al. 1992). Distress symptoms in AIDS patients have been found to correlate with poor performance, decreased global quality of life, and presence of HIV-related medical conditions but not with CD4 cell count (Vogl et al. 1999). A sevenfold increase was found in the lifetime prevalence of mood disorders among patients without substance use disorders presenting for HIV screening (Perry et al. 1990).

Risk Factors

Major depression also is a risk factor for various behavioral disturbances that may increase exposure to HIV infection

(W.D. Johnson et al. 2008). In this way, depression can be seen as a vector of HIV transmission (Angelino and Treisman 2001). Depression not only serves as a risk for perpetuation of the HIV epidemic (Himelhoch and Medoff 2005) but also is a complication preventing effective treatment. It has been clearly shown to hinder effective treatment of HIV infection (Sledjeski et al. 2005; van Servellen et al. 2002). Patients with major depression are at increased risk for disease progression and mortality (Alciati et al. 2007; Ickovics et al. 2001).

HIV increases the risk of developing major depression through a variety of mechanisms, including direct injury to subcortical areas of brain, chronic stress, worsening social isolation, and intense demoralization.

Direct evidence for a relation between worsening HIV disease and the development of major depression is supported by several studies, particularly the Multicenter AIDS Cohort Study. This study showed that rates of depression increased 2.5-fold as CD4 cells declined to fewer than 200/mm³ just before patients developed AIDS (Lyketsos et al. 1996a), suggesting that lower CD4 cell counts predict increased rates of depression. Major depression is associated with decreased killer T cell activity (Alciati et al. 2007) and lower CD4 cell counts in people living with HIV (Sledjeski et al. 2005).

Patients with AIDS have been recognized as a group with a high risk for psychological distress (Himelhoch et al. 2007a; Lyketsos et al. 1996b). High prevalence rates of suicide have been reported among HIV-infected patients (Carrico et al. 2007; Sherr et al. 2008). Factors associated with HIV and suicide include depression, hopelessness, alcohol abuse, poor social support, low self-esteem, and history of psychiatric disorder (Carrico et al. 2007; Sherr et al. 2008). Recent diagnosis of HIV or presence of pain also is associated with increased suicidal thoughts (Andraghetti et al. 2001; Louhivuori and Hakama 1979). The course of HIV has been purported to affect the prevalence of suicidal thoughts and behavior (Rabkin et al. 1993), and stage of HIV infection also may alter the potential for suicidal behavior and other psychiatric symptoms (Lyketsos et al. 1994) (see also Chapter 9, "Suicidality").

Taken together, these lines of evidence indicate that HIV is a risk factor for depression and that depression is a risk factor for HIV and its morbidity, underlining the importance of recognition and treatment of depression in HIV-infected patients.

Differential Diagnosis

The diagnosis of major depression in the HIV clinic is complicated by the high frequency of depressive symptoms that are associated with these other problems. Despite this, studies of HIV-positive patients with major depres-

sion have shown that its response to treatment is similar to that expected in other populations.

The differential diagnosis of depression in HIV includes nonpathological states of grief and mourning (sometimes made quite severe by the vulnerabilities of the person) and a variety of psychological and physiological disturbances. Patients with complaints of depressive syndromes can have dysthymia, dementia, delirium, demoralization, intoxication, withdrawal, CNS injury or infection, malnutrition, wasting syndromes, medication side effects, and a variety of other conditions. HIV-associated dementia and other HIV-related CNS conditions can produce a flat, apathetic state that is often misdiagnosed as depression. Cocaine withdrawal produces a depressive syndrome, and hypoactive delirium can be mistaken for depression. CNS syphilis, a condition that had become quite rare prior to the HIV epidemic, has been reappearing and remains “the great imitator,” as it was originally described.

HIV-infected patients with major depression frequently present to internists and family practitioners with multiple somatic symptoms. These include (but are not limited to) headache, gastrointestinal disturbances, inexplicable musculoskeletal or visceral pain, cardiac symptoms, dizziness, tinnitus, weakness, and anesthesia. Neurovegetative symptoms are especially common. Patients report slowed thought processes, with impairments in concentration and short-term memory and occasionally generalized confusion. Given the burdens of HIV, the medical problems associated with the disease, and the side effects of medications, depression may be very low on the list of considered causes of the patient's complaints. Even patients complaining of depressive symptoms may have their depression overlooked or discounted because of the presence of a plethora of other diagnoses. Nonspecific somatic symptoms are often the result of depression rather than HIV infection in patients whose infection is early and asymptomatic. Depression is most likely to be missed when symptoms are attributed to HIV-associated dementia, fatigue, demoralization and disenfranchisement, wasting syndrome, or substance abuse. Care should be taken in distinguishing between major depression and demoralization (i.e., adjustment disorder) in patients with HIV. Approximately one-half of the patients presenting to an urban HIV clinic with depressive complaints were found to have demoralization alone (Lyketsos et al. 1994). The ability to report feeling fairly normal when distracted from thinking about the precipitating event or circumstance causing distress is a hallmark of demoralization.

As an example, fatigue has been found to be more associated with depression than with HIV disease progression. Worsening of fatigue and insomnia at 6-month follow-up was highly correlated with worsening depression

but not with CD4 cell count, change in CD4 cell count, or disease progression by Centers for Disease Control and Prevention category (Leserman et al. 2008). These findings support the notion that somatic symptoms generally suggestive of depression should trigger a full psychiatric evaluation. In later-stage HIV infection, various illnesses are common, often moving depression down on the differential diagnosis list. Somatic symptoms always should be evaluated carefully and considered in context (i.e., either with other indicators of progression of HIV disease or with other indicators of depression).

Certain HIV-related medical conditions and medications can cause depressive symptoms. These include CNS infections, such as toxoplasmosis, cryptococcal meningitis, lymphoma, and syphilis. Some investigators have found significant rates of depressive symptoms, including low mood, poor appetite with loss of weight, decreased libido, and fatigue, among male HIV-positive patients with low testosterone levels (Rabkin et al. 2006). Several drugs used in patients with HIV, including efavirenz, interferon, metoclopramide, sulfonamides, anabolic steroids, and corticosteroids, have been reported to produce depression. These depressive symptoms often respond to withdrawal of the offending drug; when they do not respond to withdrawal of the drug or when the drug must be continued, the symptoms should be treated as major depression with appropriate antidepressant medication.

Routine screening for depression in people with HIV can effectively identify cases. Both the nine-item depression scale of the Patient Health Questionnaire (PHQ-9) and the PHQ-2 (see Chapter 1, “Psychiatric Assessment and Consultation,” and Chapter 8, “Depression”) have been valid and reliable (Hirshfield et al. 2008; Mao et al. 2009).

Treatment

Pharmacotherapy. Treatment with HAART was associated with significant improvement in symptoms of depression but did not necessarily have a causal relation (Ferrando and Freyberg 2008; Himelhoch and Medoff 2005). Several studies reported efficacy of various antidepressants in HIV-infected patients, but no single antidepressant has been found superior in treating HIV-infected patients as a group. As with all depressed patients, nonadherence is the most common reason for ineffective drug treatment, and adverse effects are the most common reason for nonadherence. Because HIV-infected patients are likely to be more sensitive to side effects, antidepressants should be started at subtherapeutic dose and raised slowly.

For a detailed review of the pharmacological treatment of major depression in HIV, see the article by Ferrando and Freyberg (2008). There are methodological limitations in interpreting clinical trial outcomes, including variable

stage of infection, wide-ranging durations of treatment, overrepresentation of gay and bisexual males, and underrepresentation of injection drug users and women. Inclusion and outcome criteria also have been variable, and high placebo response rates have been seen (up to 50%).

One early double-blind study reported a favorable response to imipramine; 74% of the patients responded, compared with 30% taking placebo (Rabkin et al. 1994a). Another study found a favorable response to imipramine but showed a slightly higher placebo response (Manning et al. 1990). Attrition from the imipramine group was significant; 30% discontinued it by 6 months, most often because of side effects. Clomipramine and imipramine might have anti-inflammatory and neuroprotective effects by modulating glial cell activation in the CNS (Hwang et al. 2008). However, anticholinergic and other adverse effects of the tricyclic antidepressants (TCAs) make them difficult to use in patients with AIDS. Open-label trials of fluoxetine, sertraline, and paroxetine in various stages of HIV illness reported response rates (including affective and somatic depressive symptoms) between 70% and 90%, and all the medications were well tolerated (Ferrando and Freyberg 2008; Rabkin et al. 1994b). One double-blind, placebo-controlled study of fluoxetine found significant response (Rabkin et al. 1999a). Another similarly designed trial in HIV-infected users of intravenous cocaine and opioids showed significant reduction in depressive symptoms with fluoxetine compared with placebo (Barki et al. 1993).

Supportive group psychotherapy and fluoxetine were found to be superior to placebo plus group therapy for a population of homosexual or bisexual men with HIV, and patients with more severe symptoms tended to achieve greater benefits from medication (Himelhoch et al. 2007b; Zisook et al. 1998). In a comparison of paroxetine and imipramine, both drugs were superior to placebo in patients with HIV and major depression (Elliott et al. 1998). Small open-label trials of venlafaxine, mirtazapine, and nefazodone in patients with major depression and HIV found that response rates were higher than 70%, and few side effects occurred (Elliott and Roy-Byrne 2000; Elliott et al. 1999; Fernandez and Levy 1997).

Fewer specific studies of the treatment of major depression have been conducted in HIV-positive women. In a comparison between fluoxetine and desipramine in women with AIDS, rates of response were 53% and 75%, respectively (Schwartz and McDaniel 1999). A separate trial comparing women taking fluoxetine and sertraline showed response rates of 78% and 75%, respectively (Ferrando et al. 1999).

Major depression in HIV-positive men with testosterone deficiency has been effectively treated with intramuscular testosterone in clinical trials (with 79% response in mood symptoms) (Rabkin et al. 1999b, 2004, 2006) and

was replicated in a double-blind, controlled trial (Rabkin et al. 2000b). Dehydroepiandrosterone, a precursor to testosterone, improved mood symptoms during an open-label phase but not during a placebo-controlled discontinuation phase (Rabkin et al. 2000a).

Psychostimulants also have been evaluated for treatment of fatigue, cognitive impairment, and depression in patients with HIV. Open-label trials report an 85% mood response rate in patients with HIV-associated dementia taking methylphenidate (V.F. Holmes et al. 1989) and a 95% mood response rate in men with AIDS taking dextroamphetamine (Wagner et al. 1997). A double-blind trial showed that patients with AIDS and major depression, subthreshold major depression, or dysthymia had a significant response to dextroamphetamine compared with placebo (Wagner and Rabkin 2000). Double-blind comparison of methylphenidate, pemoline, and placebo in patients with HIV (most with AIDS) found improvement in both depressive symptoms and fatigue (Breitbart et al. 2001). No known reports document abuse of prescription stimulants in patients with HIV (Ferrando and Wapenyi 2002).

St. John's wort is often used by patients as alternative antidepressant treatment, but it may lower serum levels of protease inhibitors (Di et al. 2008; "St. John's Wort and HAART" 2000) (see also Chapter 38, "Psychopharmacology"), and patients receiving any HIV treatment should be advised not to take it. S-Adenosylmethionine also has been studied in patients with HIV and major depression, with preliminary suggestion of antidepressant efficacy (Shippy et al. 2004).

The side effects of certain antidepressants can render them advantageous or disadvantageous in particular patients with HIV. For example, selective serotonin reuptake inhibitors are best avoided in patients with chronic diarrhea. Sedating antidepressants should be avoided in patients with weakness, lethargy, orthostasis, or other risk for falls. TCAs should be avoided with oral candidiasis because of the aggravating effect of dry mouth on thrush. In cases of anorexia or cachexia, antidepressants with appetite-stimulating effects are best selected.

An important issue is the interaction of antidepressants and HAART medications. Potential interactions are designated in Table 38-2 in Chapter 38, "Psychopharmacology." Two points deserve emphasis. First, particularly because depression is associated with reductions in adherence to HAART, the risks of untreated depression must be measured against those of potential medication interactions. Second, the clinical significance of some of these drug-drug interactions has not yet been clearly established (i.e., dose adjustments are probably not required). This is likely because both antidepressants and HAART, unlike drugs such as warfarin or digoxin, have wide therapeutic

indices. Finally, no evidence indicates that antidepressants cause fluctuations in CD4 cell counts (Kumar and Encinosa 2009; Schroecksnadel et al. 2008).

Psychotherapy. The literature on the use of psychotherapy for treatment of depression in HIV-infected patients is extensive, but clinical trial data are sparse. One study showed that interpersonal psychotherapy and supportive psychotherapy with adjunctive use of imipramine were superior to cognitive-behavioral therapy (CBT) or supportive psychotherapy without antidepressants in treating symptoms of depression and improving Karnofsky performance scores (Himelhoch et al. 2007b; Markowitz et al. 1998). Group CBT used alone or in combination with medication also has shown efficacy for HIV-infected patients. Improvements have been reported as well for HIV-positive patients receiving group CBT either as a single treatment modality or combined with medication (Antoni et al. 1991; J. Kelly 1998; Lutgendorf et al. 1997; Safren et al. 2009). Quality of life in women with AIDS also improved after group-based cognitive-behavioral interventions (Berg et al. 2008; Lechner et al. 2003).

A wide range of intrapsychic or interpersonal issues may be the focus of psychotherapy. Supportive psychotherapy can help patients with major depression who interpret their suffering to be a sign of weakness in the face of adversity. These patients often believe that they should pull themselves out of depression and get frustrated when they fail. Education about the disease and nature of their depression, encouragement, and therapeutic optimism all may be helpful. Other issues that arise in psychotherapy include guilt over acquiring HIV; guilt over infecting others; and anger at the source of disease, at oneself, or at God. The diagnosis of HIV infection may lead to precipitous revelation of hidden sexual or drug abuse behavior, eliciting shame and self-loathing. The stigma of HIV may lead to rejection or abandonment by loved ones, and shunning by wider society, making patients feel like lepers. Despite the development of HAART, some patients become hopeless and nihilistic and forgo HIV treatment.

Bipolar Disorder

Prevalence and Clinical Presentation

Patients with preexisting bipolar disorder may experience exacerbations because of the stresses of HIV illness. Perhaps the additional presence of CNS inflammation or degeneration secondary to HIV may also worsen underlying bipolar disorder, and new-onset mania could be a result of the organic insult itself. The first report of mania associated with HIV was in 1984 (Hoffman 1984). Numerous case reports and case series since then have described ma-

nia in HIV-infected patients (Lyketsos et al. 1997; Nakimuli-Mpungu et al. 2008).

The prevalence of mania has been found to be increased in patients with AIDS compared with the general population (Atkinson et al. 2009). One report indicated a 17-month prevalence of 1.4% in those with HIV and 8.0% in patients with AIDS, which was 10 times the expected 6-month prevalence in the general population (Lyketsos et al. 1993a). In this group, late-onset patients were less likely to have a personal or family history of mood disorder. Another study among inpatients reported a 29-month prevalence of secondary mania of 1.2% in patients with HIV and 4.3% in those with AIDS (Ellen et al. 1999).

Some have suggested that mania should be subdivided into primary and secondary types, with patients who have the secondary type showing close temporal proximity to an organic insult, no history of illness, essentially negative family history, and late age at onset (Ellen et al. 1999; Nakimuli-Mpungu et al. 2006). Secondary mania includes those cases caused by HIV brain disease itself (Nakimuli-Mpungu et al. 2006, 2008; Robinson 2006), those due to antiretroviral drugs (O'Dowd and McKegney, 1988), and those due to other HIV-related conditions (e.g., cryptococcal meningitis) or medications. Concurrent or subsequent cognitive impairment has been reported among cases of HIV-related mania (Lyketsos et al. 1997; Nakimuli-Mpungu et al. 2008). However, cases without such deficits also have been reported. An increased risk of HIV-associated dementia and cognitive slowing was found in one group of patients with secondary HIV mania, with cognitive decline prior to onset of mania (Lyketsos et al. 1997). In addition, the secondary mania associated with HIV is associated with low CD4 cell count (Nakimuli-Mpungu et al. 2006, 2008), often lower than 100 cells/mm³. The incidence of secondary mania, like that of HIV-associated dementia, appears to have declined since the widespread use of HAART (Ferrando and Freyberg 2008).

AIDS mania seems to have a clinical profile somewhat different from that of primary mania (Ellen et al. 1999; Lyketsos et al. 1993a, 1997). Irritable mood is often a prominent feature, but elevated mood can be observed. Sometimes prominent psychomotor slowing accompanying the cognitive slowing of AIDS dementia will replace the expected hyperactivity of mania, which complicates the differential diagnosis. AIDS mania is usually quite severe in its presentation and malignant in its course. In one series, patients with late-onset mania (presumed to have AIDS mania) had a greater total number of manic symptoms than did early-onset patients. Late-onset patients also were more commonly irritable and less commonly hyperverbal. AIDS mania seems to be more chronic than episodic, with infrequent spontaneous remissions, and usually relapses with cessation of treatment. Because of their cognitive deficits,

patients have little functional reserve to begin with and are less able to pursue treatment independently or consistently.

One presentation of mania, either early or late, is the delusional belief that one has discovered a cure for HIV or has been cured. Although this belief may serve to cheer otherwise demoralized patients, it also may result in the resumption of high-risk behavior and lead to the spread of HIV and exposure to other infections. When euphoria is a prominent symptom in otherwise debilitated late-stage patients, caregivers may question whether to deprive patients of the illusion of happiness. It is the often-devastating effects of the other symptoms of mania that tip the balance toward treatment.

Neuroradiological correlates of secondary HIV mania have been attempted, but the results have been conflicting. Some studies indicate that findings on neuroimaging are not of any clinical significance (Ellen et al. 1999). Abnormal MRI scans have been reported, however (Kiebert et al. 1991).

Treatment

Treatment of secondary HIV or AIDS mania has not been systematically studied to date, and the optimal treatment remains unclear. Reports often have indicated a particular resistance of manic symptoms to treatment. Others have noted few differences in response in the treatment of secondary HIV mania compared with bipolar disorder (Ellen et al. 1999). The treatment of mania in early-stage HIV infection is not substantially different from the standard treatment of bipolar disorder with mood stabilizers and antipsychotics. As HIV infection advances, with lower CD4 cell counts, more medical complications, more CNS involvement, and greater overall physiological vulnerability, changes in treatment may be required. Treatment with traditional antimanic agents can be very difficult in patients with advanced disease. AIDS mania patients may respond to monotherapy with antipsychotic agents such as risperidone (A. Singh et al. 1997) or mood stabilizers such as carbamazepine (Ellen et al. 1999). Late-stage patients are sensitive to side effects of antipsychotics, especially EPS, as noted earlier in this chapter (see "Treatment" subsection of "Delirium" section). Thus, the dose of antipsychotic required may be much lower than that customarily used for mania. The more advanced these patients' HIV and/or dementia, the more sensitive they are to small dosage increases. These patients are also very sensitive to anticholinergic side effects, including delirium.

There has been considerable experience with traditional mood-stabilizing agents in selected AIDS mania patients, but with relatively little published literature. One case report of lithium use in secondary HIV mania showed control of symptoms at a dose of 1,200 mg/day (Tanquary

1993). Lithium use has been problematic for several reasons, including side effects of cognitive slowing, nausea, diarrhea, and polyuria resulting in dehydration, all of which may already plague HIV-infected patients. The major problem with lithium in AIDS patients has been rapid fluctuations in blood level, especially in the hospital, despite previously stable doses. Anecdotal reports describe problems with administering lithium and valproic acid because of subsequent delirium (Angelino and Treisman 2001).

Valproic acid has been used with success, titrated to the usual therapeutic serum levels of 50–100 µg/L. Enteric-coated valproic acid is better tolerated in many patients. A study of valproic acid in the treatment of HIV-associated mania reported that it was well tolerated and led to significant improvement in manic symptoms, with doses up to 1,750 mg/day and serum levels greater than 50 µg/L (Halman et al. 1993). Another report documented reduction in symptoms with levels of 93 and 110 µg/L (RachBeisel and Weintraub 1997). Concern has been raised over hepatotoxicity in patients with HIV taking valproic acid (Cozza et al. 2000) and potential interactions with antiretroviral therapy (Sheehan et al. 2006). In cases of severe hepatic insufficiency (e.g., *Mycobacterium avium* complex [MAC] infiltration with portal hypertension), valproic acid probably should be avoided, but this has not been studied. Valproic acid also can affect hematopoietic function, so white blood cell and platelet counts must be monitored.

Carbamazepine also was reported to be effective in the treatment of HIV mania in a placebo-controlled trial (Vlasova et al. 2009). However, concerns exist regarding the potential for synergistic bone marrow suppression in combination with antiviral medications and HIV itself. It also may lower serum levels of protease inhibitors (Ferrando and Freyberg 2008). Lamotrigine may be ideal as monotherapy because it is well tolerated in the elderly and is efficacious in treating bipolar disorder (Angelino and Treisman 2008). Potential drug interactions between anticonvulsant mood stabilizers and HAART are shown in Chapter 38, "Psychopharmacology."

The treatment of psychosis in HIV-related mania with risperidone has shown significant improvement (A. Singh et al. 1997). Two case reports note potential drug interactions when combined with the cytochrome P450 2D6 inhibitor ritonavir, including EPS (D.V. Kelly et al. 2002) and a reversible coma from risperidone toxicity (Jover et al. 2002). Olanzapine has been anecdotally reported to be effective in HIV-associated mania (Ferrando and Wapenyi 2002). Remoxipride was found to be effective in HIV-related mania but was subsequently withdrawn because of reports of aplastic anemia (Scurlock et al. 1995). Atypical antipsychotics have the advantage of lower risk of tardive dyskinesia, but this is not an important issue for patients with end-stage AIDS.

Reduction of the risk of EPS is a noteworthy consideration in selecting an antipsychotic, in addition to other factors including affordability. The common side effect of significant weight gain with some atypical antipsychotics is less problematic for patients with HIV who are cachectic.

One case report showed rapid clinical improvement of HIV-associated manic symptoms with clonazepam, allowing reduction of antipsychotic dosage (Budman and Vandersall 1990). No unacceptable side effects were reported, but treatment with benzodiazepines is less useful in maintenance treatment because of tolerance, abuse liability, and cognitive impairment.

Schizophrenia

Prevalence and Clinical Presentation

The literature on patients with severe and chronic mental illnesses, primarily schizophrenia and bipolar disorder, reports HIV prevalence rates of between 2% and 20% in both inpatient and outpatient samples (De Hert et al. 2009; Senn and Carey 2008). Investigators have noted that clinicians working with patients with schizophrenia were often unaware of their increased risk for acquiring HIV and made little effort to screen for seropositivity (Cournos et al. 1991, 2005). Perhaps this is because schizophrenic patients traditionally have been seen as markedly hyposexual because of the illness itself and antipsychotic drugs. However, many schizophrenic patients are sexually active (Cournos et al. 1994), often with higher-risk partners (Kalichman et al. 1994); seldom use condoms (Cournos et al. 1994); and do not otherwise practice safe sex. Substance abuse is very common in schizophrenic patients, including during sexual activity (Cournos et al. 1994; Forney et al. 2007). Patients with schizophrenia have significantly less knowledge about HIV infection and transmission than do persons without schizophrenia (Kalichman et al. 1994; J.A. Kelly et al. 1992). Even increased knowledge about HIV in schizophrenic patients may not lead to decreased risk behaviors (McKinnon et al. 1996). Cumulatively, these factors help explain the increased risk of HIV infection in schizophrenic patients (Cournos et al. 1991, 2005). Suicidality is increased in patients with both schizophrenia and HIV infection. For all these reasons, clinicians should evaluate schizophrenic patients for risk behaviors and for their knowledge about HIV. A validated screening tool—the “Risk Behaviors Questionnaire”—is available (Volavka et al. 1992).

Treatment

Treatment of schizophrenia in HIV-infected patients follows the same basic principles as for other patients with schizophrenia—namely, control of symptoms with medications and psychosocial support and rehabilitation. Close

collaboration with HIV providers is strongly suggested, so that HIV treatment can be coordinated. Schizophrenic patients are very likely to have difficulties accessing care, affording medication, and adhering to complex HAART regimens. Educational interventions have promoted safer sexual practices (Jacobs and Bobek 1991; Leucht et al. 2007) and may decrease risk behaviors (Carmen and Brady 1990; Kalichman et al. 1995).

Haloperidol is effective in treating psychotic symptoms of schizophrenia in patients with HIV (Mauri et al. 1997). Patients with HIV may be highly sensitive to the EPS of antipsychotic medications, as already noted. Molindone was reported to be of benefit for psychosis and agitation with few EPS in patients with HIV (Fernandez and Levy 1993). Clozapine also has shown efficacy in treating HIV-associated psychosis in patients with drug-induced parkinsonism (Lera and Zirulnik 1999). Risperidone also has been reported to be effective (A. Singh et al. 1997). However, in one study, two-thirds of patients with schizophrenia and AIDS who received antipsychotic medication did not continue taking antipsychotics (Bagchi et al. 2004). Drug interactions between antipsychotics and HAART are discussed in Chapter 38, “Psychopharmacology.”

Substance Abuse and Addiction

Substance abuse is a primary vector for the spread of HIV for those who use injection drugs and their sexual partners and those who are disinhibited by intoxication or driven by addiction to unsafe sexual practices. Patients with substance use disorders may not seek health care or may be excluded from or discriminated against in health care settings. In addition, intoxication and the behaviors necessary to obtain drugs interfere with access to, and effectiveness of, health care.

Triple diagnosis refers to a patient with a dual diagnosis (substance abuse and psychiatric disorder) who also has HIV, and such patients are overrepresented in HIV-infected populations. One study found that as many as 44% of the new entrants to the HIV medical clinic at the Johns Hopkins Hospital had an active substance use disorder. Of these patients, 24% had both a current substance use disorder and another nonsubstance-related Axis I diagnosis (Lyketsos et al. 1994). The Criminal Justice Drug Abuse and Treatment studies show the strongest correlation between comorbid substance abuse and mental illness for risk of contracting HIV (Pearson et al. 2008; Treisman et al. 2001).

In the United States at the end of 2008, the proportion of injection drug users with AIDS had declined to 19% from 24% in 2001 (Centers for Disease Control and Prevention 2008). Even among noninjection drug users, substance abuse plays a major, albeit more subtle, role in HIV transmission. Addiction and high-risk sexual behavior

have been linked across a wide range of settings. Addiction has been shown to promote unsafe sexual practices by disinhibition, prostitution, needle sharing, and concentrating patients at high risk into networks of HIV dissemination. Specific drugs have been implicated in different routes of transmission. The advent of drugs that can be rapidly absorbed without injection did not decrease HIV transmission as many had hoped, although it did diminish needle sharing in some groups. This was because the advent of smokable cocaine (crack) and later smokable amphetamine (crystal methamphetamine, crystal meth) led to increased use of these substances. The dramatic increase in the use of crystal methamphetamine is partly a result of the ease of manufacture, the length of time the drug produces intoxication, and the low cost of the drug.

Crack cocaine abusers are more likely to engage in prostitution to obtain money for drugs (Edwards et al. 2006). Men who use crack cocaine are more likely to engage in unprotected anal sex with casual male contacts (Schönnesson et al. 2008). Additionally, methamphetamine has been linked to an upsurge in sexually transmitted HIV in homosexual men who use the drug in conjunction with sildenafil, particularly in group settings (Semple et al. 2009). Methamphetamine increases sexual drive, decreases caution, and increases the desire for intense sexual experiences. Both cocaine and amphetamines are thought to work through the release of dopamine, and dopamine has been shown to increase the uptake of HIV viral particles by macrophages (Gaskill et al. 2009). Alcohol intoxication also can lead to risky sexual behaviors by way of cognitive impairment and disinhibition (Pearson et al. 2008). All of these drugs have been shown to affect medication adherence, the crucial factor in both successful treatment and successful prevention. Poorer medication adherence leads to higher viral loads, making viral transmission more likely, and to the development of resistant virus, increasing the risk of treatment failure. The transmission of resistant virus is also likely to be increased by substance abuse and has become a major problem in HIV treatment.

Neuropsychological testing of drug abusers with and without HIV indicates that substance use can contribute to the cognitive decline of HIV-associated dementia (Pakesch et al. 1992). Substance use may augment HIV replication in the CNS and increase HIV encephalopathy in early AIDS (Kenedi et al. 2008; Kibayashi et al. 1996). For example, cocaine abuse augments HIV replication in vitro (Kenedi et al. 2008) and also increases permeability of the blood-brain barrier to HIV (Zhang et al. 1998).

Treatment

Substance abuse can be successfully treated in those at risk for HIV. One of the most extensively studied interventions

in risk reduction is methadone maintenance, which resulted in sustained reductions in HIV risk and lower incidence of HIV infection (Davstad et al. 2009). Linked programs providing model care for HIV-infected patients with triple (i.e., HIV, substance abuse, and psychiatric) diagnoses have shown promising results. Methadone can be linked to directly observed therapy for HIV, which has been shown to improve outcome. Model programs of fully integrated care providing HIV treatment, substance abuse treatment, and psychiatric treatment have been shown to improve outcome as well (Himelhoch et al. 2007a).

Substance Use Disorders and Interaction With HIV Treatment

The medical sequelae of chronic substance abuse accelerate the process of immunocompromise and amplify the burdens of HIV infection. Injection drug users are at higher risk for developing bacterial infections such as pneumonia, sepsis, and endocarditis. Tuberculosis, STDs, viral hepatitis, coinfection with human CD4 cell lymphotropic virus, and lymphomas also occur more commonly in injection drug users with HIV than in other patients with HIV. HIV-infected injection drug users are at higher risk for fungal or bacterial infections of the CNS. Alcohol abuse is immunosuppressive and increases risk for bacterial infections, tuberculosis, and dementia. Heroin may worsen HIV-associated nephropathy.

Important drug interactions occur between abused substances and antiretroviral and antibiotic drugs. Rifampin increases the elimination of methadone and may result in withdrawal symptoms. Decreased plasma levels of methadone also occur with concurrent administration of ritonavir, nelfinavir, efavirenz, and nevirapine (Kharasch et al. 2008a, 2008b). Patients in a methadone program will be unlikely to take medications that have caused withdrawal.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) and its symptoms occur at greatly increased rates in HIV-infected patients (A. Martinez et al. 2002). Of the HIV-infected women attending county medical clinics, 42% met diagnostic criteria for PTSD (Cottler et al. 2001) with a lifetime prevalence of 40% (Martin and Kagee 2008). Minority women (Hien et al. 2010) and women prisoners (Hutton et al. 2001; Lewis 2005) are particularly at risk for both PTSD and HIV. Male veterans with a diagnosis of PTSD are at increased risk for HIV infection, especially if they are substance abusers (Fuller et al. 2009; Hoff et al. 1997). PTSD symptoms are associated with high-risk behaviors, including prostitution, choosing other high-risk sexual partners, injection drug use, and unsafe sexual practices (Martin and Kagee 2008). Among the HIV-infected female partners of male

drug users, those who had a history of rape or being assaulted were more likely to engage in high-risk HIV behaviors (Hien et al. 2010). These studies are cross-sectional and cannot determine causality. PTSD from early-life trauma may predispose an individual to engage in high-risk sexual or drug behavior. On the other hand, risk behaviors such as prostitution and drug abuse increase exposure to trauma and thus the likelihood of developing PTSD. Finally, HIV infection itself may be the cause of PTSD (Boarts et al. 2009). Rates of PTSD in response to HIV infection are higher than those in response to other debilitating illnesses (Fauerbach et al. 1997), including cancer (Alter et al. 1996). In one study, about 30% of persons recently diagnosed with HIV subsequently developed PTSD, with half of the cases appearing within 1 month of HIV diagnosis (B. Kelly et al. 1998). Prior PTSD increased the risk for PTSD in response to HIV diagnosis. Even asymptomatic HIV-infected individuals have high levels of PTSD symptoms (Botha 1996), and occupational exposure to HIV also has resulted in PTSD (Worthington et al. 2006).

PTSD in at-risk or HIV-infected individuals is significant for several reasons. PTSD has high rates of psychiatric comorbidity (up to 80%), most often depression (Leserman et al. 2008), and cocaine and opioid abuse (Kessler et al. 1995), which are also risks for HIV (Lyketsos and Federman 1995). HIV-infected persons with PTSD have higher levels of pain (Tsao et al. 2004). PTSD symptoms in HIV-positive patients predicted lower CD4 cell counts (Fincham et al. 2008; Leserman et al. 2008) and lower CD4-to-CD8 T cell ratios (Kimerling et al. 1999). This may represent faster HIV disease progression, generally associated with stressful life events (Leserman et al. 2008).

Persons at risk for HIV and HIV-infected individuals should be routinely screened for PTSD and psychiatric comorbidities, with treatment targeted accordingly. Failure to do so in this very high-risk population has serious consequences, both for this population's welfare and for public health.

Issues of Personality in Patients Infected With HIV

A disturbing trend in the HIV epidemic has been the persistence of modifiable risk factors among persons who are HIV infected. Such individuals, who report high rates of sexual and/or drug risk behaviors, include HIV-infected drug users (Latkin et al. 2009), patients presenting at HIV primary care clinics for medical treatment (Beyer et al. 2007), and HIV-infected men who have sex with other men (Fox et al. 2009). The fact that knowledge of HIV and its transmission is insufficient to deter these individuals

from engaging in HIV risk behaviors suggests that certain personality characteristics may enhance a person's tendency to engage in such behaviors.

Traditional approaches in risk reduction counseling emphasize the avoidance of negative consequences in the future, such as condom use during sexual intercourse to prevent STDs. Such educational approaches have proved ineffective for individuals with certain personality characteristics (Vlassova et al. 2009). Effective prevention and treatment programs for HIV-infected individuals must consider specific personality factors. In this section, we outline the role of personality characteristics and personality disorders in the risk of acquiring HIV and highlight specific interventions to reduce the risk of HIV that are formulated for individuals whose personality characteristics place them at increased risk.

Implications of Personality for HIV Risk Behavior

Our clinical experience suggests that unstable extroverts are the most prone to engage in practices that place them at risk for HIV. We estimate that in the psychiatry service of the Johns Hopkins AIDS clinic (a referral-biased sample), about 60% of our patients present with this blend of extroversion and emotional instability. These individuals are preoccupied by, and act on, their feelings, which are labile, leading to unpredictable and inconsistent behavior. Most striking is the inconsistency between thought and action. Regardless of intellectual ability or knowledge of HIV, unstable extroverts can engage in extremely risky behavior. Past experience and future consequences have little importance in decision making for the individual who is ruled by feeling; the present is paramount. Their primary goal is to achieve immediate pleasure or removal of pain, regardless of circumstances. As part of their emotional instability, they experience intense fluctuations in mood. It is difficult for them to tolerate painful affects; they want to escape or avoid feelings as quickly as possible. They are motivated to pursue pleasurable experiences, however risky, to eliminate negative moods.

Unstable extroverts are more likely to engage in behavior that places them at risk for HIV infection and are more likely to pursue sex promiscuously. They are less likely to plan and carry condoms and more likely to have unprotected vaginal or anal sex. They are more fixed on the reward of sex and remarkably inattentive to the STD they may acquire if they do not use a condom. Unstable extroverts are also less likely to accept the diminution of pleasure associated with the use of condoms or, once aroused, to interrupt the "heat of the moment" to use condoms. Similarly, unstable extroverts are more vulnerable to alcohol and drug abuse. They are drawn to alcohol and drugs as a quick route to pleasure. They are more likely to exper-

iment with different kinds of drugs and to use greater quantities. Unstable extroverts are also more likely to become injection drug users.

The second most common personality type that we have observed, which may represent about 25% of our patients, is that of the stable extrovert. Stable extroverts are also present oriented and pleasure seeking; however, their emotions are not as intense, as easily provoked, or as mercurial. Hence they are not as strongly driven to achieve pleasure. Stable extroverts may be at risk because they are too optimistic or sanguine to believe that they will become infected with HIV.

Introverted personalities appear to be less common among our psychiatric patients. Their focus on the future, avoidance of negative consequences, and preference for cognition over feeling render them more likely to engage in protective and preventive behaviors. HIV risk for introverts is determined by the dimension of emotional instability–stability. About 14% of our patients present with a blend of introversion and instability. Unstable introverts are anxious, moody, and pessimistic. Typically, these patients seek drugs and/or sex not for pleasure, but for relief or distraction from pain. They are concerned about the future and adverse outcomes but believe that they have little control over their fates. Stable introverts constitute the remaining 1% of patients. These patients, with their controlled, even-tempered personalities, are least likely to engage in risky or hedonistic behaviors. Typically, these individuals are HIV positive as a result of a blood transfusion or an occupational needle stick. These percentages of personality styles are illustrative of one center's experience and may not be generalizable.

Personality Disorders in HIV

Prevalence rates of personality disorders among HIV-infected patients (19%–36%) and individuals at risk for HIV (15%–20%) (Hansen et al. 2009) are high and significantly exceed rates found in the general population (10%) (J.G. Johnson et al. 1995). The most common personality disorders among HIV-infected patients are antisocial and borderline types (Bennett et al. 2009). Antisocial personality disorder is the most common (Perkins et al. 1993) and is a risk factor for HIV infection (Weissman 1993). Individuals with personality disorder, particularly antisocial personality disorder, have high rates of substance abuse and are more likely to inject drugs and share needles compared with those without an Axis II diagnosis (Hansen et al. 2009). Approximately half of drug abusers may meet criteria for a diagnosis of antisocial personality disorder. Individuals with antisocial personality disorder are also more likely to have higher numbers of lifetime sexual partners,

engage in unprotected anal sex, and contract STDs compared with individuals without antisocial personality disorder (Ladd and Petry 2003).

In our AIDS clinic, patients are characterized along the dimensions of extraversion–introversion and emotional stability–instability rather than in the discrete categories provided by DSM's Axis II for several reasons. First, it is easier for staff to determine where a patient falls along two dimensions than to evaluate the many criteria for personality disorders. Second, it is simpler to design intervention strategies for two dimensions. Third, a diagnosis of antisocial or borderline personality disorder can be stigmatizing, particularly in a general medical clinic. Finally, a classification system based on a continuum approach may be a better predictor of HIV risk behavior than are DSM-IV-TR Axis II categories (American Psychiatric Association 2000a; Tourian et al. 1997).

Effect of Personality on Medication Adherence

Identifying factors that influence adherence in HIV disease is important in improving overall health outcomes (Koenig et al. 2008; Murri et al. 2009). Adherence is especially challenging in HIV, which carries all of the components of low adherence, long duration of treatment, preventive rather than curative treatment, asymptomatic periods, and frequent and complex medication dosing (Koenig et al. 2008; Murri et al. 2009).

Our clinical experience suggests that nonadherence is more common among our extraverted or unstable patients. The same personality characteristics that place them at risk for HIV also reduce their ability to adhere to demanding drug regimens. Specifically, their present-time orientation, combined with reward-seeking behavior, makes it more difficult to tolerate side effects from drugs whose benefits may not be immediately apparent. It is also difficult for feeling-driven individuals to maintain consistent, well-ordered routines, so following frequent, rigid dosing schedules is problematic. Our unstable extroverted patients usually intend to follow the schedule, but their chaotic and mercurial emotions interfere and disrupt daily routines. For example, a patient may report that he felt very upset and nihilistic after a fight with a family member and missed several doses of his antiretroviral medicines. Missing doses of HAART can increase the chance of HIV resistance developing.

Treatment Implications

We have found that a cognitive-behavioral approach is most effective in treating patients who present with extroverted and/or emotionally unstable personalities. Five principles guide our care:

1. *Focus on thoughts, not feelings.* Individuals with unstable extroverted personalities often do not recognize the extent to which their actions are driven by feelings of the moment.
2. *Use a behavioral contract for all patients to build consistency.* The contract outlines goals for treatment and responsibilities and expectations of both the patient and the providers.
3. *Emphasize constructive rewards.* Positive outcomes, not adverse consequences, are salient to extroverts. Most of the patients have already experienced negative consequences from their behavior. Exhortations to use condoms to avoid STDs are unpersuasive. More success has been achieved with extroverts by eroticizing the use of condoms (Tanner and Pollack 1988) or by incorporating novel techniques into sexual repertoires (Abramson and Pinkerton 1995). Similarly, the rewards of abstaining from drugs or alcohol are emphasized, such as having money to buy clothing, having a stable home, or maintaining positive relationships with children. In building adherence to antiretroviral therapies, the focus is on the rewards of an increased CD4 cell count and reduced viral load rather than on the avoidance of illness. Use of the viral load as a strategy to build adherence can increase acceptance in all patients but is especially effective in reward-driven extroverts.
4. *Use relapse prevention techniques.* The relapse prevention model, originally developed for treatment of substance abuse behavior, is an effective method for changing habitual ways of behaving.
5. *Develop a coordinated treatment plan.* The mental health professional coordinates with the medical care provider, supplying information about a patient's personality and how it influences behavior. Both professionals work in tandem to develop behavioral contracts to reduce HIV risk behaviors and build medication adherence.

Psychosocial Interventions to Prevent HIV Transmission

In intervention studies of men who have sex with other men (still the largest subgroup in terms of new HIV infections in the United States), many psychosocial interventions have shown a decrease in either risk behaviors or infection (Dilley et al. 2002; Fox et al. 2009; W.D. Johnson et al. 2002, 2008). A meta-analysis examining the effect of HIV prevention strategies found that psychosocial interventions can lead to sexual risk reduction among drug users (Semaan et al. 2002), as did a separate large study of cocaine-dependent patients (Woody et al. 2003). Studied

interventions have included stress management and relaxation techniques, group counseling, education, cognitive training, negotiation skills training, psychotherapy directed at emotional distress reduction, relapse prevention models of high-risk behavior reduction, education directed at eroticizing safer sex, assertiveness training, and peer education in bars. All of these interventions showed a modest effect on either risk behavior or HIV infection. Although most studies focused on men who have sex with other men, the results have been similar in heterosexually transmitted HIV, women, injection drug users, and adolescents (Di-Clemente et al. 2008). It is unclear from the data what the best intervention is and how to stratify the interventions. The HIV notification rates for men having sex with men, which declined in the second half of the 1990s, have shown a slight increase beginning in 2000 (Sullivan et al. 2009). This is an indication that effective preventive interventions need to be studied further and implemented worldwide.

Mental Health Care for Patients With HIV Infection

Patients with HIV infection are underserved with regard to mental health. This is critical because psychiatric disorders increase the risk for HIV and have a negative effect on HIV treatment. Although model clinics exist, in which treatment for HIV, substance abuse, and psychiatric illness is integrated, these clinics are exceptional. Psychiatric disorders are underrecognized and undertreated in patients with many chronic medical conditions, but HIV-infected patients are especially likely to be impoverished, disenfranchised, vulnerable, and members of underserved minorities, all of which further decrease the likelihood that they will receive adequate treatment. Integrated expert care by psychiatrists and other mental health professionals should be a high priority both to promote effective treatment of HIV infection and to stem the tide of an epidemic that spreads through modifiable behaviors.

Conclusion

The interrelations between HIV/AIDS and psychiatry are myriad and complex. In a sense, psychiatric disorders can be seen as vectors of HIV transmission, through associated high-risk behaviors. They also complicate the treatment of HIV infection. HIV causes several psychiatric conditions and exacerbates many others. Comorbid psychopathology, including major depression, schizophrenia, addictions, personality vulnerabilities such as unstable extroversion, and the effects of traumatic life experiences, is highly prevalent in patients with HIV/AIDS. Each of these problems

has the potential to sabotage treatment for HIV infection and its many complications. Yet there is a profound shortage of funding and availability of psychiatric care in HIV clinics. Our experience in caring for HIV patients is that by developing a comprehensive diagnostic formulation on which to base treatment, even many of the most difficult patients can be successfully treated.

With the advent of HAART, we have seen terminal patients who have undergone nearly miraculous recoveries only to find themselves unprepared to meet the challenges of facing life again—of pressing on in the face of the daily burdens of ongoing treatment, side effects, stigma, and continuing injury. To assist them with this monumental task is a great challenge, but we have the lessons from the field of psychiatry that have helped patients shoulder similar burdens from chronic mental illness. At the heart of our work, we try to impart hope for the future, therapeutic optimism, advocacy, sanctuary, and rehabilitation.

Dermatology

Madhulika A. Gupta, M.D., F.R.C.P.C.

James L. Levenson, M.D.

DERMATOLOGICAL DISORDERS are associated with psychiatric and psychosocial comorbidity in 25%–30% of cases (Gupta and Gupta 1996). The skin is the largest organ of the body and functions as a social, psychological, and metabolically active biological interface between the individual and the environment. Beginning at birth, the skin functions as a powerful organ of communication—at the social, psychological, and biological levels. The skin and its appendages are well innervated with a dense network of afferent sensory nerves and efferent autonomic nerves. The afferent sensory nerves convey sensations for touch, pain, itch, temperature, and other physical stimuli. The efferent autonomic—mainly sympathetic—nerves play a role in maintaining cutaneous homeostasis by regulating vasomotor and pilomotor functions and the activity of the apocrine and eccrine sweat glands. Stimulation of the skin, which is richly innervated and has bilateral communication with the central nervous system (CNS), serves as a means of regulating affect and coping with intense emotional states.

As an organ of communication, the skin plays a vital role in attachment, starting in infancy. Freud observed that during early development, the ego was rooted in the body, especially the skin. Bodily sensations and experiences, both internal and from the surface of the body, form the core around which the ego develops. The skin reacts to emotional states such as extreme fear, anxiety, and embarrassment with blanching, increased perspiration, flushing, and blushing. In addition, even minimal flaws in the overall appearance of the skin can have a profound effect on

the body image of the individual, especially in adolescents, and can result in body image pathology.

The impact of psychological stress on the skin is not necessarily primarily mediated by the CNS but instead appears to be mediated by a local stress response system in the skin that further interacts with the CNS. The skin (Arck et al. 2006) is both a target and a source of key stress mediators, such as corticotropin-releasing hormone (CRH) and the pro-opiomelanocortin (POMC)-derived peptides, cortisol, catecholamines, prolactin, substance P, and nerve growth factor. An equivalent of the central hypothalamic-pituitary-adrenal (HPA) axis is activated in the skin in response to stress (Slo-minski et al. 2000). The skin's responses to acute stress include an enhanced skin immune function with increased intracutaneous migration of immunocompetent cells, while chronic stress may suppress cutaneous immunity. Acute psychological stress, which is associated with increased glucocorticoid levels, adversely affects recovery of skin barrier function after tape stripping and may exacerbate barrier-mediated dermatoses such as psoriasis and atopic dermatitis (Choi et al. 2005; Garg et al. 2001). Acute stress is associated with increased mast cell activation and degranulation with release of histamine. The mast cell is an important regulator of neurogenic inflammation during the stress response and plays an important role in various stress-mediated dermatoses. Chronic stress can reduce the immune response to vaccines, slow wound healing, and reactivate latent viral infections such as herpesviruses. Dermatology and psychiatry interface at both basic and clinical levels; this chapter reviews the clinical aspects of psychocutaneous disorders.

Classification

Psychodermatological disorders have been generally divided into two major categories (Gupta and Gupta 1996; Koblenzer 1987; Medansky and Handler 1981):

1. *Dermatological manifestations of psychiatric disorders* (Table 29-1)—This category also includes the self-induced dermatoses. A subgroup of disorders (i.e., the mucocutaneous dysesthesias, idiopathic pruritus, prurigo nodularis, and lichen simplex chronicus) can be loosely classified as “functional dermatological disorders,” as their primary cause remains unclear; however, these disorders are strongly influenced by psychosomatic factors.
2. *Psychological factors in dermatological disorders*—This category includes a wide range of skin conditions and has been further separated into three subcategories:
 - a. Disorders that have a primary dermatopathological basis but may be influenced in part by psychological factors—for example, psoriasis, atopic dermatitis, urticaria and angioedema, alopecia areata, and acne. Most of the disorders in this group are exacerbated by psychological stress and are associated with psychiatric comorbidity. A wide range of other dermatological disorders, such as viral infections of the skin (e.g., viral warts) and other immunologically mediated skin disorders such as vitiligo, may be exacerbated by psychological stress.
 - b. Disorders and states that represent an accentuated physiological response, such as hyperhidrosis and blushing.
 - c. Disorders that result in an emotional reaction primarily as a result of cosmetic disfigurement and/or the social stigma associated with the disease.

These three subcategories are not mutually exclusive, and some dermatological disorders may fall into more than one subgroup.

General Guidelines for Management of the Psychocutaneous Patient

Standard psychiatric therapies are used to treat psychiatric comorbidity in the dermatology patient. Psychiatric drugs are generally used for one of three purposes: 1) management of dermatological manifestations of primary psychiatric disorders, 2) management of psychiatric disorders that are comorbid with primary dermatological disorders, and 3) provision of certain desired pharmacological properties of psychotropic agents (e.g., the antihistaminic effect

TABLE 29-1. Dermatological manifestations of psychiatric disorders

Delusions

- Delusions of parasitosis
- Delusions of bromhidrosis (delusional belief that a foul odor is being emitted)
- Delusions of disfigurement

Hallucinations

- Tactile or haptic hallucinations

Distorted perceptions

- Amplified or dysesthetic cutaneous pain
- Intractable pruritus

Conversion and dissociation

- Unexplained sensory syndromes (e.g., involving cutaneous pain or numbness)
- Unexplained pruritic states
- Idiopathic urticaria and angioedema
- Self-induced dermatoses (e.g., dermatitis artefacta, trichotillomania)
- “Psychogenic purpura”

Obsessions and compulsions

- Compulsive hand washing
- Compulsive rubbing or picking of the skin
- Self-excoriation
- Hair plucking or trichotillomania
- Onychophagia and onychotillomania

Anxiety and panic

- Unexplained profuse perspiration, night sweats
- Flushing reactions
- Urticarial reactions

Body image misperceptions related to the skin

- Dermatological complaints about imagined or slight “flaws” of the skin
- Concern about skin lesion out of proportion to its clinical severity

of doxepin), even in the absence of a comorbid psychiatric disorder. Currently, no orally administered psychotropic agents are approved by the U.S. Food and Drug Administration (FDA) for the treatment of a primary dermatological disorder; 5% topical doxepin cream is FDA approved for short-term (up to 8 days) management of moderate pruritus in adults with conditions such as atopic dermatitis.

In diagnosis and management of comorbid psychopathology, there are some special considerations in patients

with skin diseases. Certain dermatological disorders, such as atopic dermatitis, acne, and psoriasis, have been associated with a high prevalence of suicidal ideation, which may not always be commensurate with the clinical severity of the skin disorder. Suicidal ideation has been reported among patients with a wide range of dermatological conditions (at rates of 6.2%–8.6%) (Picardi et al. 2006) and is especially prevalent in patients with severe pruritus and cosmetically disfiguring skin conditions (Gupta et al. 2005). Body dysmorphic disorder (BDD) may be overtly or covertly comorbid with skin diseases and can impair functional outcomes, contribute to treatment resistance, and increase suicide risk. Disease-related stress and daily hassles from the impact of the skin condition on the patient's quality of life, as well as other psychosocial stressors such as major life events, have been associated with exacerbation of the dermatological disorder in up to 70% of cases of psoriasis, atopic dermatitis, chronic idiopathic urticaria, and acne. Even minor lesions in easily visible body regions or the genital area can lead to significant disease-related stress and should be treated aggressively. Pediatric and adolescent patients should be asked about appearance-related teasing and bullying (Magin et al. 2008), as this can significantly contribute to psychological morbidity. Pruritus (itching), the most common symptom of skin disorders, interferes with sleep and is associated with increased psychiatric comorbidity (Weisshaar et al. 2008), making it an important target of treatment. Some patients with post-traumatic stress and dissociative symptoms (especially those secondary to childhood neglect and emotional and sexual abuse) may excessively manipulate or excoriate their skin in an effort to regulate emotions (see "Self-Induced Dermatoses" later in this chapter) (Gupta 2006), and the cutaneous self-injury can in turn exacerbate comorbid dermatological conditions such as psoriasis.

Dermatological Manifestations of Psychiatric Disorders

Delusional Parasitosis

Delusional parasitosis (delusions of infestation) is classified as a *delusional disorder, somatic type*, and is characterized by a fixed false belief that one is infested by parasites or insects that is maintained despite negative clinical and laboratory findings (Bishop 1983). Delusional parasitosis is rarely seen by general psychiatrists but is common in dermatological practice. The mean age at onset is the mid-50s to 60s, with an equal sex distribution in patients younger than 50 years and a female-to-male ratio of 3:1 in patients ages 50 years and older (Lyell 1983). Patients with delusional parasitosis typically present the doctor with alleged

parasite specimens in a pill bottle, matchbox, adhesive tape, or plastic bag (Lepping and Freudenmann 2008). Such patients tend to treat their skin by scratching and may use disinfectants, repellants, pesticides, and antimicrobials. They may consult exterminators or entomologists, repeatedly launder clothing and linens, and discard possessions and even pets (fearing them as the source). Tactile and olfactory hallucinations related to the delusional theme may be present. Patients with delusional parasitosis often complain of *formication*—cutaneous sensations of crawling, stinging, and/or biting. Belief of infestation may extend to any body orifice—for example, the nares (Walling and Swick 2008), oral cavity (Maeda et al. 1998), or orbit (Sherman et al. 1998). In contrast to schizophrenia, apart from the impact of the delusion, the patient's thought processes, behavior, and functioning are not obviously odd or bizarre. Delusional parasitosis has been reported to lead to *folie à deux* (shared psychotic disorder), in which the belief in the patient's infestation comes to be shared by a significant other (Trabert 1999). This has been reported to occur in 5%–15% of cases of delusional parasitosis (Lepping and Freudenmann 2008). Although most cases of delusional parasitosis appear to represent a primary delusional disorder, some have been considered secondary to other psychiatric disorders—for example, schizophrenia, obsessive-compulsive disorder (OCD), or psychotic depression—or medical disorders—for example, structural brain disease, delirium, dementia, endocrinopathy (e.g., hypothyroidism), vitamin deficiency (B₁₂ deficiency and pellagra), neuropathies, uremia, hepatic encephalopathy, and other toxic states, especially abuse of amphetamines or cocaine (Lepping and Freudenmann 2008). Of course, it is important not to make the diagnosis of delusional parasitosis prematurely; some patients really do have infestations (e.g., scabies, lice).

Management

Appropriate dermatological and medical examinations and investigations are required to rule out dermatological disease and secondary causes of delusional parasitosis. Because patients with delusional parasitosis do not view themselves as having a psychiatric disorder, they are usually unwilling to be referred to a psychiatrist. Consequently, treatment is best carried out with a psychiatrist providing consultation and liaison to a dermatologist (Harth et al. 2009). Patients present with firmly held beliefs that they have an infestation or infection or "Morgellons disease" (Harth et al. 2010a). The biggest challenge in the pharmacotherapy of delusional parasitosis is convincing the patient to take a psychiatric drug. Delusional parasitosis is often difficult to manage even in a dermatological setting because of limited response to antipsychotic medications

and problems with adherence to treatment recommendations (Ahmad and Ramsay 2009). Psychotherapy is of little help, and the clinician should focus on developing a therapeutic relationship (which is likely to enhance adherence to psychopharmacology) rather than emphasizing the delusional nature of the complaint. The dermatologist should be advised to listen to the patient's stories, ask about how the condition has affected the patient's life, and attempt to prevent harm (e.g., determine whether the patient is using pesticides). Socially isolated (often elderly) patients with relative sensory deprivation can misinterpret cutaneous sensations; such patients may benefit from increased social support and sensory stimulation.

Both typical and atypical antipsychotics have been effective in delusional parasitosis (Freudenmann and Lepping 2008; Kenchaiah et al. 2010), although there are no randomized controlled trials (RCTs). An antipsychotic with antihistaminic and sedative properties may be helpful in ameliorating anxiety and pruritus. A recent review of antipsychotic treatment in primary and secondary delusional parasitosis noted that risperidone and olanzapine have been the most widely used atypical antipsychotics and have resulted in full or partial remission in 69% and 72% of cases, respectively (Freudenmann and Lepping 2008). There is an extensive dermatological literature on the use of pimozide, but no evidence demonstrates the superiority of pimozide over other antipsychotics for delusional parasitosis. Pimozide is generally started at 1 mg/day and increased by 1 mg every 5–7 days to a maximum of 4 mg/day (C. S. Lee 2008). Sudden deaths have been reported with pimozide and are thought to be due to ventricular arrhythmias caused by QTc prolongation. Additive effects on QTc prolongation should be anticipated if pimozide is administered concomitantly with tricyclic antidepressants (TCAs) or cytochrome P450 (CYP) 3A4 inhibitors (e.g., fluoxetine, azole antifungals, macrolide antibiotics, grapefruit juice). Secondary delusional parasitosis is more likely than primary delusional parasitosis to respond to antipsychotics (78% vs. 59% trend) (Freudenmann and Lepping 2008). Selective serotonin reuptake inhibitors (SSRIs) have sometimes been helpful in patients whose parasite sensations have been more obsessional than delusional (Fellner and Majeed 2009).

Cutaneous Body Image Disorders

Cutaneous body image (Gupta et al. 2004), defined as an individual's mental perception of the appearance of his or her integument (skin, hair, and nails), is an important core dermatological construct. This is relevant both in cosmetically disfiguring skin disorders, where cutaneous body image dissatisfaction can have a profound impact on quality of life, and in situations where the cutaneous body image

is distorted, as in BDD. Cutaneous body image dissatisfaction has been associated with increased risk for suicide (Cotterill and Cunliffe 1997). Patients with BDD, which usually begins during adolescence, present to dermatologists with complaints about imagined or slight "flaws" of the face or head (e.g., hair thinning, wrinkles, very minimal acne, scars, vascular markings, paleness or redness of the complexion, swelling or facial asymmetry, excessive facial hair) or concerns about the shape, size, or some other aspect of the nose, eyes, eyelids, eyebrows, ears, mouth, lips, teeth, jaw, chin, or cheeks. BDD patients may also excessively pick their skin (Phillips and Taub 1995). Reported rates of BDD in cosmetic surgery and dermatology settings range from 6% to 15% of patients (American Psychiatric Association 2000); a Polish survey of 118 dermatologists reported that almost 18% were currently treating a BDD patient (Szepietowski et al. 2008), and a Turkish study (Kaymak et al. 2009) of university students reported higher BDD-related symptom scores among students with a wide range of skin diseases, including acne (which was present in the majority of cases). The diagnosis *delusional disorder, somatic type*, should be considered if the preoccupation with an imagined defect in appearance reaches delusional proportions. If obsessional preoccupation about the appearance is associated with compulsive behaviors (e.g., compulsive mirror checking), a diagnosis of OCD may be appropriate (American Psychiatric Association 2000).

Patient dissatisfaction with cutaneous body image is often the primary consideration in deciding whether to institute treatment in skin disorders such as acne, where BDD may be comorbid in more than one-third of cases in some centers (Bowe et al. 2007). In a study of 200 BDD patients (Phillips et al. 2006), 25% reported BDD-related tanning (i.e., tanning motivated by a desire to improve a perceived defect in one's appearance). In 84% of the tanners with BDD, the skin was the body area of chief concern; 26% of the tanners with BDD had attempted suicide, and 52% had received dermatological treatment, which was usually ineffective for their symptoms. Tanners were more likely than nontanners to compulsively pick their skin (Phillips et al. 2006).

Anorexia nervosa and *bulimia nervosa* can initially present as dermatological complaints (Gupta et al. 1987a) resulting from malnutrition (e.g., lanugo-like body hair, carotenoderma, pernio) and bingeing and purging (hand calluses, gingivitis, flare-ups of acne), as well as increased cutaneous body image concerns. In a cross-sectional study (Gupta and Gupta 2001a) examining concerns about various aspects of skin appearance among young adult (<30 years) eating disorder patients ($n = 32$) and nonclinical control subjects ($n = 34$), it was observed that 81% of the eating disorder patients, versus 56% of control subjects, reported dissatisfaction with the appearance of their skin ($P = 0.03$).

The cutaneous attributes of greatest concern among the eating disorder patients were those that are also associated with aging and photodamage (e.g., “darkness” under the eyes, freckles, fine wrinkles, and patchy hyperpigmentation) in addition to dryness and roughness of the skin, which are often secondary to the eating disorder. Starvation in eating disorders has been associated with pruritus (Gupta et al. 1992), and rapid refeeding can lead to a flare-up of acne, mostly likely because of rising androgen levels (Gupta and Gupta 2001b). It has been advised that anorexia nervosa should be considered in all patients with low body weight and pruritus (J.F. Morgan and Lacey 1999). As patients with eating disorders often tend to minimize or deny their symptoms, the dermatological signs may be the first clinical clue that the patient has an eating disorder.

Management

BDD may occur on its own or be comorbid with other dermatological disorders. If the BDD is not addressed, the patient is likely to remain dissatisfied with dermatological treatment outcomes. Treatments for BDD include SSRI antidepressants and cognitive-behavior therapy (CBT) (Phillips et al. 2002).

Self-Induced Dermatoses

Dermatitis Artefacta

Dermatitis artefacta describes cutaneous lesions that are wholly self-inflicted; however, the patient typically denies the self-inflicted nature of the lesions (Fabisch 1980; Gupta et al. 1987b; Nielsen et al. 2005). The median age has been reported as 39 years (range 18–60 years), with about three-fourths of adult cases in women (Nielsen et al. 2005; Verraes-Derancourt et al. 2006) and a similar female preponderance in children (Saez-de-Ocariz et al. 2004). The lesions in dermatitis artefacta have a wide range of features and may present as purpura, blisters, ulcers, erythema, sinuses, edema, or nodules, depending on the means employed to create them; thus, they can mimic a wide range of cutaneous disorders. Cutaneous ulcers and excoriations are the most common types of lesions, and 35%–90% of patients have multiple lesions (Nielsen et al. 2005; Saez-de-Ocariz et al. 2004; Verraes-Derancourt et al. 2006). The lesions typically occur in regions that are accessible by hand; they may occur at the site of an old scar or surgical wound or appear suddenly in previously normal skin. Facial and periocular skin and the upper limbs are the most common sites (Saez-de-Ocariz et al. 2004; Ugurlu et al. 1999). Self-inflicted lesions are often bizarre, with sharp geometric borders surrounded by normal-looking skin. Full-thickness skin loss or severe scarring from self-inflicted lesions may necessitate extensive plastic surgery or amputation

(Gupta et al. 1987b). Like patients with other factitious disorders, patients with dermatitis artefacta typically consult numerous physicians and are treated unsuccessfully with multiple medications before the correct diagnosis is made (Ugurlu et al. 1999).

Psychiatric comorbidity. A personality disorder characterized by very immature coping mechanisms is often observed in which the self-induced lesions serve as “an appeal for help.” In the pediatric population, many cases may be associated with mental retardation (Saez-de-Ocariz et al. 2004), and Munchausen’s syndrome by proxy should be ruled out (Harth et al. 2010b). Dissociative disorders, which are often underrecognized, should also be considered—especially when a patient denies any memory of self-inducing the lesions—as well as posttraumatic stress disorder (PTSD) with prominent dissociative symptoms (Gupta 2006). Dermatitis artefacta may co-occur in mood, anxiety, and psychotic disorders, as well as in malingering (Cohen and Vardy 2006). The clinician should always rule out an underlying dermatological disorder in the patient suspected of having dermatitis artefacta, as a patient may self-excoriate a primary dermatological lesion and create secondary artifactual lesions (Ahmad and Ramsay 2008).

Management. Early diagnosis is important, as this may prevent unnecessary surgery and chronic morbidity (Gupta and Gupta 1996). Patients with dermatitis artefacta typically are not able to describe how their lesions evolved, and the lesions heal if occlusive dressing or a plaster dressing is used. Most authors recommend a supportive and empathic approach to the patient, avoiding direct discussion or confrontation regarding the self-inflicted nature of the lesions. Patients typically refuse to see a psychiatrist; however, nursing staff can play an important role in the psychosocial assessment and management of the patient (Nielsen et al. 2005). Once a satisfactory therapeutic alliance has been established, a more insight-oriented psychotherapeutic approach may be used (Fabisch 1980). A major psychosocial stressor such as illness, accident, or bereavement may precede dermatitis artefacta in about 20%–30% of cases, and recovery may occur through mobilization of social support for the patient. Other helpful adjunctive therapies that have been used include relaxation exercises and a course of antianxiety or antidepressant medications if indicated (Fabisch 1980; Nielsen et al. 2005).

Neurotic or Psychogenic Excoriation, Acne Excoriée, Onychophagia, and Onychotillomania

In neurotic or psychogenic excoriation, lesions are produced as a result of repetitive self-excoriation that may be initiated by an itch or other cutaneous dysesthesia or

through the urge to excoriate an acne pimple or other irregularity on the skin. Unlike patients with dermatitis artefacta, patients with neurotic excoriation typically acknowledge the self-inflicted nature of their lesions (Freunsgaard 1984). Self-excoriation can initiate and perpetuate the “itch-scratch cycle,” and in some cases the self-excoriative behavior can become a true compulsive ritual (Hatch et al. 1992). The lesions in neurotic excoriation are usually a few centimeters in diameter, may range in number from a few to several hundred, and are weeping, crusted, or scarred with postinflammatory hypo- or hyperpigmentation. Unlike lesions in dermatitis artefacta, the lesions in neurotic excoriation do not mimic those of other cutaneous disorders. The repetitive self-excoriation may exacerbate a pre-existing dermatosis (e.g., in acne excoriée). Onychophagia involves repetitive nail biting; onychotillomania refers to compulsive peeling of the nail and surrounding skin.

Psychiatric comorbidity. The psychiatric disorders most commonly associated with neurotic or psychogenic excoriation or “pathological skin picking” (Arnold et al. 2001; Calikusu et al. 2003; Freunsgaard 1984; Grant and Odlaug 2009; Gupta et al. 1987b; Hatch et al. 1992; Mutasim and Adams 2009) include OCD, personality disorders, major depressive disorder, and bipolar disorder, as well as BDD, PTSD, and dissociative disorders where the self-excoriation and/or nail biting or picking often serve as a means of self-regulating intense emotional states. Psychosocial stressors precede neurotic excoriation in 33%–98% of cases (Freunsgaard 1984; Gupta et al. 1987b). Neurotic excoriation may follow physical disability from illness or aging in persons with strongly compulsive personality traits (Gupta et al. 1986).

Management. The patient should be fully investigated for other systemic and local causes of pruritus. An empathic and supportive approach in psychotherapy (Freunsgaard 1984) has been reported to be more effective than insight-oriented psychotherapy, which can exacerbate symptoms. Several small trials suggest the efficacy of SSRIs in cutaneous excoriation (skin picking), including clomipramine 50–100 mg/day (Gupta et al. 1986), fluoxetine (up to 80 mg/day) (Simeon et al. 1997), sertraline (up to 200 mg) (Kalivas et al. 1996), and fluvoxamine (Arnold et al. 1999), with little correlation with presence of, or improvement in, psychiatric comorbidity. There have also been case reports of the efficacy of doxepin (30–75 mg/day) (Harris et al. 1987), olanzapine (2.5–5.0 mg/day) (Blanch et al. 2004; Gupta and Gupta 2000), aripiprazole augmentation of fluoxetine (Curtis and Richards 2007), and naltrexone (50 mg at bedtime) (Smith and Pittelkow 1989).

Trichotillomania

Trichotillomania refers to nonscarring alopecia as a result of self-plucking of hair. The hair of the scalp (especially the crown and parietal regions), eyebrows, eyelashes, beard, or pubic area can be affected (Gupta and Gupta 1996; Koo and Lee 2008). Trichotillomania occurring solely during sleep has been reported (Murphy et al. 2007). Patients deny that their alopecia is self-induced in 43% of cases (Christenson et al. 1991a). In one-third of cases, the extracted hair may be chewed or swallowed (Grant and Odlaug 2008), and the trichophagia can lead to trichobezoars, which may cause gastrointestinal complications such as obstruction and acute pancreatitis. An affected area in trichotillomania is rarely completely devoid of hair, and hairs of various lengths are usually partially distributed over the area of alopecia. Histopathological examination may be necessary to confirm the diagnosis. Trichotillomania should be distinguished from benign hair pulling, which can be associated with thumb sucking and nail biting in children.

Psychiatric comorbidity. Trichotillomania is a heterogeneous disorder (Duke et al. 2010; Lochner et al. 2010). It is classified as an impulse-control disorder in both DSM-IV-TR (American Psychiatric Association 2000) and ICD-10 (World Health Organization 1992). In trichotillomania, the hair pulling helps to regulate emotions by decreasing negative ones such as boredom, sadness, anger, and tension and increasing positive ones such as relief and calm (Diefenbach et al. 2008). Although an extensive literature classifies trichotillomania as an obsessive-compulsive spectrum disorder, brain imaging studies of trichotillomania (Rauch et al. 2007) do not support this. Trichotillomania has been associated with a history of psychological trauma (e.g., bereavement) and PTSD (Gershuny et al. 2006), high dissociation scores (Gupta et al. 2000; Lochner et al. 2004), and depression. Trichotillomania may be a feature of mental retardation, eating disorders, and personality disorders in which patients tend to be highly dissociated.

Management. The three major treatments studied in trichotillomania are habit-reversal therapy, SSRIs, and clomipramine (Bloch et al. 2007). A systematic review of these interventions in seven blinded, randomized clinical trials in which the primary outcome measure was mean change in trichotillomania severity revealed that habit-reversal therapy was superior to both SSRIs and clomipramine. Clomipramine, but not SSRIs, was more effective than placebo (Bloch et al. 2007). A 10-week controlled trial found clomipramine (100–250 mg/day) to be more effective than desipramine (150–200 mg/day) in trichotillomania (Swedo et al. 1989). A 12-week RCT involving 25 trichotillomania pa-

tients reported that olanzapine, at an average dose of about 10 mg daily, was significantly more effective than placebo in decreasing ratings of psychological morbidity except for hair pulling (Van Ameringen et al. 2010). Some open-label and case studies report the efficacy of mood stabilizers such as lithium (Christenson et al. 1991b), topiramate (Lochner et al. 2006), and oxcarbazepine (Leombruni and Gastaldi 2010). Group therapy in clinical trials has not been effective (Diefenbach et al. 2006). It is possible that treatments will be more effective when the underlying issues of trauma and dissociation in trichotillomania are addressed.

Functional Dermatological Disorders

Mucocutaneous Dysesthesias

The mucocutaneous dysesthesias represent a heterogeneous group of disorders that involve unexplained cutaneous pain and other sensory syndromes. One form is “scalp dysesthesia” (Hoss and Segal 1998), in which patients (women are most often affected) present with complaints of pruritus, pain, trichodynia, and burning and/or stinging sensations of the scalp without objective physical findings. Other such localized dysesthesias without objective physical findings include vulvodynia, scrotodynia, atypical facial pain, and “burning mouth syndrome” or glossodynia (Abetz and Savage 2009; Eli et al. 1994; Hampf et al. 1987; Lamey and Lamb 1988; McKay 1994). Commonly associated psychiatric disorders include depressive and somatoform disorders, PTSD, and dissociative states (Gupta and Gupta 2006).

Management

Various psychotherapeutic interventions including hypnosis and eye movement desensitization and reprocessing (EMDR) (Gupta and Gupta 2002) may be helpful when the cutaneous symptom represents a conversion disorder, a dissociative state, or a sensory flashback in PTSD. The mucocutaneous dysesthesias are usually treated with the same agents used for the treatment of neuropathic pain, such as TCAs, serotonin–norepinephrine reuptake inhibitors (SNRIs), or anticonvulsants, but controlled clinical trials are lacking (Haefner et al. 2005; Zakrzewska et al. 2005; see also Chapter 36, “Pain”). Scalp dysesthesia and other idiopathic pruritic conditions may respond to antihistaminic TCAs such as amitriptyline and doxepin (Hoss and Segal 1998).

Idiopathic Pruritus

Psychosomatic Aspects of Pruritus

Pruritus, or itching, is an unpleasant sensation that elicits a desire to scratch, which leads to inflammation and stim-

ulation of cutaneous nerve fibers, which in turn leads to more itching and scratching and perpetuation of the itch-scratch cycle. Scratching leads to problems with skin barrier function, lichenification, and prurigo formation. Pruritus, the most common symptom of skin disorders (Weishaar et al. 2008), may occur with or without visible skin lesions. Pruritus may be a feature of a systemic disease in 10%–50% of cases (e.g., hepatic or renal failure, HIV), especially in advanced age, or may occur as a drug side effect (e.g., opioids). The pathophysiology of pruritus is not well understood, and it is unclear why it is worse at night. Itch is mediated by both peripheral (e.g., histamine, proteinases, substance P, opioid peptides, neurotrophins such as nerve growth factor) and CNS factors (Yosipovitch and Ishiuchi 2009). Perception of pruritus, irrespective of etiology, can be modulated by psychological factors. Recent stressful life events and anxiety and/or depressive symptoms have been correlated with an increased ability to experience itching. Persons with mental distress were found to be twice as likely to experience itching as those without (Dalgard et al. 2007).

Chronic Idiopathic Pruritus

Whereas pruritus is a common symptom of many dermatological and systemic diseases, the cause in chronic pruritus is often not identifiable. Such idiopathic pruritus is typically experienced on a daily basis, especially at night and in the evening, resulting in most having difficulty falling asleep. Generalized idiopathic pruritus mainly involves the legs, arms, and back. The most common focal presentations of idiopathic pruritus are pruritus ani, vulvae, and scroti. Idiopathic pruritus may be described as crawling, tickling, stinging, or burning (T-J Goon et al. 2007; Yosipovitch et al. 2002). In one study, patients with idiopathic pruritus described the itching as unbearable (73%), bothersome (72%), annoying (67%), and/or worrisome (45%) (T-J Goon et al. 2007). Psychiatric symptoms are common in idiopathic pruritus, and idiopathic pruritus is common in psychiatric patients: two Israeli studies in psychiatric inpatients reported a prevalence of 32% (Mazeh et al. 2008) and 42% (Kretzmer et al. 2008), respectively. In the latter study, patients without adequate social support and those without regular employment showed higher rates of idiopathic pruritus (Kretzmer et al. 2008). It is not surprising that depression is common among patients with idiopathic pruritus, especially given the condition's chronicity and associated sleep disturbance (Sheehan-Dare et al. 1990). Idiopathic pruritus was more frequent in patients with high trait anger (Kretzmer et al. 2008) and dissociation (Gupta and Gupta 2006; Gupta et al. 2000). However, not all patients with idiopathic pruritus have psychopathology or high life stress, and idio-

pathic pruritus should be considered as a functional disorder rather than a psychogenic one.

Management. New onset of unexplained pruritus should lead to evaluation for occult medical disease before considering it to be idiopathic pruritus. Idiopathic pruritus represents a heterogeneous condition and may be a symptom of psychophysiological arousal in the psychiatric patient. Treatment of the underlying psychiatric disorder should therefore help the pruritus. For focal idiopathic pruritus (e.g., pruritus ani, vulvae, scroti), topical treatments are used. For both generalized and focal idiopathic pruritus, the most commonly prescribed oral medications are antihistamines, which usually provide some short-term relief. TCAs, especially doxepin, can relieve chronic idiopathic pruritus. Paroxetine has also been reported to be helpful (Zylicz et al. 2003). Opiate receptor antagonists and anti-convulsants (e.g., gabapentin, pregabalin, carbamazepine) have been suggested as possible remedies (Lynde et al. 2008). Behavioral treatment such as habit reversal training and CBT may also be helpful in interrupting the itch-scratch cycle, and there are reports of the benefits of hypnosis.

Prurigo Nodularis

Prurigo nodularis (Koo and Lee 2008) is a chronic skin condition characterized by intensely pruritic hard dome-shaped papules or nodules with central scale-crust. Patients may present with a few hundred lesions, usually in a symmetric distribution, with predominance on the extensor surfaces of the limbs. It is thought that the lesions of prurigo are caused by chronic and severe scratching and rubbing; however, the morphology of the lesions is not easily explained (Koo and Lee 2008), and the etiology of prurigo nodularis remains unknown (M.R. Lee and Shumack 2005). Histologically, there is hypertrophy and proliferation of dermal nerves and marked increase in calcitonin gene-related peptide and substance P immunoreactivity. These neuropeptides may mediate the cutaneous neurogenic inflammation and pruritus in prurigo nodularis (M.R. Lee and Shumack 2005).

Psychiatric Comorbidity

Psychosocial factors such as anxiety and depression may be a primary factor or secondary to the itch in prurigo nodularis (M.R. Lee and Shumack 2005), and psychosocial stress is a factor among 33% of patients (Harth et al. 2009). When compared with psoriasis patients, prurigo nodularis patients had the same degree of alexithymia, somatization symptoms, hypochondriasis, anxiety, and depression, with 18% cases of anxiety and 22% cases of depression (Schneider et al. 2006).

Management

Treatment involves interruption of the itch-scratch cycle, which is typically difficult (M.R. Lee and Shumack 2005). Among psychiatric therapies, relaxation techniques such as autogenic training and progressive muscle relaxation may be helpful (Harth et al. 2009). Strongly antihistaminic psychotropic agents such as doxepin (10–75 mg at night) may reduce pruritus (M.R. Lee and Shumack 2005). It should be noted that the first-line treatments for prurigo nodularis involve standard dermatological therapies such as corticosteroids.

Lichen Simplex Chronicus

Lichen simplex chronicus (LSC) is characterized by hyperpigmented, lichenified, leathery plaques that result from habitual scratching and rubbing of the skin (Koo and Lee 2008). LSC is most frequently observed in older adults. The plaques of LSC have a predilection for the nuchal and occipital area in women and for the scrotum and perineal area in men. The scratching can begin unconsciously and evolves into a compulsive ritual, which may lead to lichenification of the skin (Konuk et al. 2007). Peripheral neuropathy may play a role in some patients (Solak et al. 2009).

Psychiatric Comorbidity

Psychosocial stressors, OCD, depression, and high levels of dissociation have all been associated with LSC (Konuk et al. 2007; Koo and Lee 2008). LSC is associated with arousals from Stage II non-rapid eye movement (REM) sleep due to scratching and a lower percentage of time spent in Stages III and IV sleep (Koca et al. 2006). This in turn can lead to nonrestorative sleep and daytime fatigue.

Management

Treatment involves interruption of the itch-scratch cycle. Counseling and support for underlying psychosocial stressors, SSRI antidepressants, and doxepin (Koo and Lee 2008) may be useful adjunctive therapies.

Psychogenic Purpura

Psychogenic purpura, also referred to as “autoerythrocyte sensitization syndrome” and Gardner-Diamond syndrome, is a poorly understood condition that presents as spontaneous, painful ecchymotic bruising. The condition mainly affects adult women, with a few cases affecting men and children. In addition to dermatological symptoms, menorrhagia, epistaxis, and gingival and gastrointestinal bleeding (Ivanov et al. 2009; Puetz and Fete 2005) have been described in two-thirds of patients (Ratnoff 1989). Severe emotional stress and other psychological factors (Ivanov et al. 2009; Ratnoff 1980, 1989) have been observed in the ma-

jority of cases; however, there is a marked heterogeneity of psychological findings, and the exact role of psychological factors in psychogenic purpura remains unclear. Some of the reported psychological associations (Ivanov et al. 2009; Ratnoff 1980) include conversion reaction, hysterical or masochistic personality, depression, anxiety, difficulty in dealing with hostile feelings, and religious stigmata.

Gardner and Diamond (1955), who described four cases, postulated that patients become sensitized to their own red blood cells. Subcutaneous injection of autologous red blood cells and hemolysate has been shown to reproduce the lesions, suggesting an underlying autoimmune process. Overall, fewer than 200 cases have been described in the literature (Ivanov et al. 2009). In their review of the literature, Puetz and Fete (2005) observed that most case studies of Gardner-Diamond syndrome have not reported detailed results of screening for von Willebrand's disease or platelet dysfunction and that patients in whom platelet aggregation studies have been reported have been found to have a platelet function disorder.

Psychiatric Aspects of Selected Dermatological Disorders

Atopic Dermatitis

Atopic dermatitis, which is a form of eczema (Kang et al. 2008), is a chronic relapsing dermatitis associated with intense pruritus, which is a hallmark of atopic dermatitis. Most prevalence data are derived from school-age children, with a 10%–20% estimated prevalence in the United States, which has been on the rise over the past decades. Pruritus in atopic dermatitis is often worse in the evening and can interfere with nighttime sleep. The rubbing and scratching in response to the pruritus, which typically further exacerbates the atopic dermatitis, can result in excoriations with or without hemorrhagic crusts, and produces lichenified plaques and prurigo nodularis. As a result of repeated rubbing and scratching, lichen simplex chronicus (thickened and leathery skin with exaggerated skin markings) may develop. Atopic dermatitis can occur at any age; however, up to 90% of cases have their onset before the age of 5 years, and usually not before the age of 2 months. Atopic dermatitis has a partially genetic basis with variable expression that is influenced by environmental factors. Atopic dermatitis is often associated with a personal or family history of atopy (i.e., xerosis), asthma, and/or allergic rhinitis. Typically, there are three stages—infantile, childhood, and adulthood—and periods of disease quiescence can occur between these stages. With increasing age, atopic dermatitis typically presents as chronic inflammation and lichenification and tends to localize in the flexural regions; atopic derma-

titis skin is characterized by severe dryness with an impaired barrier function of the stratum corneum. Psychoneuroimmunological factors play an important role in the pathogenesis of atopic dermatitis (Steinhoff and Steinhoff 2009).

Stress

The onset or exacerbation of atopic dermatitis often follows stressful life events (Picardi and Abeni 2001). Divorce or separation of parents and severe disease of a family member have been identified as events that particularly increase risk (Bockelbrink et al. 2006). In children, stress as a risk factor for atopic dermatitis interacts with environmental variables such as sweating (Langan et al. 2006; Williams et al. 2004). Two small studies, one in adults (Buske-Kirschbaum et al. 2002) and one in children (Buske-Kirschbaum et al. 1997), have demonstrated a hyporesponsive HPA axis, as evidenced by a blunted cortisol response to a stressor, in patients with atopic dermatitis compared with healthy control subjects.

Psychosocial and Psychiatric Factors

Atopic individuals with emotional problems may develop a vicious cycle between anxiety/depression and dermatological symptoms. Pruritus severity has been directly correlated with the severity of depression in atopic dermatitis (Gupta et al. 1994). Suicidal ideation has been reported among 2.1% of mild to moderately affected adult atopic dermatitis patients in one U.S. sample (Gupta and Gupta 1998); however, a Japanese study of patients ages 15–49 years reported a suicidal ideation prevalence of 0.21%, 6%, and 19.6%, respectively, for patients with mild, moderate, and severe atopic dermatitis (Kimata 2006). Atopic dermatitis patients have also been found to have higher state and trait anxiety and greater psychophysiological reactivity that cannot be attributed solely to increased disease activity (Seiffert et al. 2005). Data from a German population-based administrative database showed a significant association between atopic eczema and attention-deficit/hyperactivity disorder (ADHD) (odds ratio [OR] = 1.54; 95% confidence interval [CI] = 1.06–2.22; $P=0.02$) among the 6- to 17-year age group (Schmitt et al. 2009). The authors noted that because of the cross-sectional study design, it remains unclear whether the observed association is due to shared etiological factors or whether the symptoms of atopic dermatitis (e.g., itching, sleep impairment) and disease-related psychosocial factors might exacerbate ADHD symptoms in a subgroup of patients (Schmitt et al. 2009).

In one direction of causality, anxiety and depression are frequently a consequence of the disorder. The misery of living with atopic dermatitis may have a profoundly negative effect on health-related quality of life of children and their families. Intractable itching causes significant insomnia,

and sleep deprivation then leads to fatigue, mood lability, and impaired functioning. Teasing and bullying related to contagion, and use of teasing as an instrument of social exclusion, can lead to significant psychological sequelae in the child and adolescent with atopic dermatitis (Magin et al. 2008). Similar embarrassment in adults promotes social isolation. The social stigma of a visible skin disease, frequent visits to doctors, and the need to constantly apply messy topical remedies all add to the burden of disease. Lifestyle restrictions in more severe cases can be significant and include limitations on clothing, staying with friends, owning pets, and engaging in swimming or sports. The impairment of quality of life caused by childhood atopic dermatitis has been shown to be greater than or equal to that caused by asthma or diabetes (Lewis-Jones 2006).

In the other direction of causality, anxiety and depression also aggravate atopic dermatitis. This may occur via several possible mechanisms, including modulation of pruritus perception (Gupta et al. 1994), perturbation of epidermal permeability barrier homeostasis (Garg et al. 2001), or acceleration of immune responses (Hashizume et al. 2005).

There is an extensive literature on emotional dysfunction and disturbed child-family relationships in childhood atopic dermatitis (Howlett 1999). Early theories hypothesized inadequate holding and caressing of the infant and maternal rejection and neglect, but later literature focused on increased symptoms in the child, such as dependency, clinginess, and sleep difficulties, with mothers who were stressed and lacking in social support (Howlett 1999). Parents are often reluctant to discipline their child for fear that this could provoke distress and precipitate scratching. Furthermore, parents and sometimes medical professionals may focus more on the care of the skin disorder than on the emotional and developmental needs of the child with atopic dermatitis (Howlett 1999).

Management

Psychotherapy. At least 47 different medical, psychological, and environmental interventions for atopic dermatitis have been studied in clinical trials (Hoare et al. 2000). A wide variety of psychotherapeutic treatments have been advocated to interrupt the vicious cycle of itching and scratching in atopic dermatitis, including psychological, behavioral, and psychoeducational therapies. There have been several RCTs of psychological and educational interventions (including relaxation training, habit reversal training, cognitive-behavioral techniques, and stress management training) as an adjunct to conventional therapy for children with atopic eczema to enhance the effectiveness of topical therapy, but the evidence base remains limited regarding their efficacy (Ersser et al. 2007). RCTs have

also shown that interventions directed toward the parents of the child with atopic dermatitis can decrease the severity of the skin disease (Ersser et al. 2007).

Psychopharmacology. Pharmacotherapy of atopic dermatitis should aim to interrupt the itch-scratch cycle and optimize nighttime sleep. Topical doxepin (5% cream) is effective in the treatment of pruritus in atopic dermatitis (Drake and Millikan 1995) and is FDA approved for short-term treatment in adults but not children. Low-dose oral doxepin (e.g., starting at 10 mg at bedtime) is helpful in adults because of its antihistaminic and sedative properties (Kelsay 2006), with dose increases based on response and side effects. There have also been reports suggesting some benefit from bupropion (Modell et al. 2002), mirtazapine (Hundley and Yosipovitch 2004; Mahtani et al. 2005), and trimipramine (Savin et al. 1979). Sedating antidepressants may be beneficial in part through promoting sleep. The strongly antihistaminic antidepressants doxepin, trimipramine, and amitriptyline may also be effective because of their strong anticholinergic properties, as the eccrine sweat glands in atopic dermatitis have been found to be hypersensitive to acetylcholine. There are no established guidelines for the treatment of sleep disturbance in atopic dermatitis (Kelsay 2006). A small short-term RCT of the benzodiazepine nitrazepam did not significantly reduce nocturnal scratching (Ebata et al. 1998), and benzodiazepine withdrawal may further exacerbate pruritus.

Psoriasis

Psoriasis (Van de Kerkhof and Schalkwijk 2008) is a chronic and recurrent inflammatory disorder characterized by circumscribed erythematous, dry, scaling plaques that are usually covered by silvery white adherent scales. The lesions are typically symmetrical; have a predilection for the scalp, nails, extensor surfaces of the limbs, hands and feet, and sacral and genital regions; and are associated with pruritus. Psoriasis is influenced by both genetic and environmental factors, with about 70% concordance rate in monozygotic twins. In addition to psychosocial stress, other risk factors and comorbidities in psoriasis include cigarette smoking, alcohol consumption, obesity, diabetes, hypertension, and hyperlipidemia (Gottlieb et al. 2008). The worldwide prevalence of psoriasis is 2%. Psoriasis can occur at any age; in approximately 75% of patients, the onset is before age 40 years. In contrast to atopic dermatitis, psoriasis is uncommon (about 1%) in individuals younger than 16 years. More than one-third of patients have severe disease, and 5%–30% have psoriatic arthritis. Visibility of lesions, presence of lesions in the genital area, degree of scaling, and pruritus severity have the greatest impact on patient quality of life (Gupta et al. 1989).

Lithium-induced psoriasis can appear within a few months but usually occurs within the first few years of treatment. The absolute increased risk is quite small (Brauchli et al. 2009). Psoriasis precipitated or exacerbated by lithium is typically resistant to conventional antipsoriatic treatments. When the psoriasis becomes intractable, lithium must be discontinued, and the psoriasis usually remits within a few months. A small RCT showed that inositol supplements have a significant beneficial effect on psoriasis patients taking lithium (Allan et al. 2004). Beta-blockers such as propranolol (often used to treat lithium-induced tremors) have also been associated with psoriasis, but a recent population-based study does not support this (Brauchli et al. 2009).

Stress

Stress has long been reported to trigger psoriasis. Uncontrolled studies have reported very high rates of stressful life events preceding the onset of the illness; for example, in one study, antecedent stressful life events were reported by 50% of children and 43% of adults (Raychaudhuri and Gross 2000). However, perception and recall biases influence such rates. In a case-control study comparing 560 psoriasis patients and 690 patients with new diagnoses of other skin conditions, psoriasis patients were more than twice as likely as the control patients to have experienced stressful life events within 1 year prior to onset of their psoriasis (Naldi et al. 2005). A prospective study of psoriasis patients found that at times of higher daily stress, patients experienced more severe psoriasis and significantly more itching (Verhoeven et al. 2009a). However, not all studies have supported the belief that stressful life events precipitate psoriasis (Picardi et al. 2003a). Ultimately, however, most patients who report episodes of psoriasis precipitated by stress describe disease-related stress resulting from the cosmetic disfigurement and social stigma of psoriasis, rather than stressful major life events or nonspecific distress.

Psychosocial and Psychiatric Factors

There is an extensive literature on psychosocial and psychiatric comorbidity in psoriasis (Fortune et al. 2005; Gupta and Gupta 2003). In general, psychological factors, including perceived health, perceptions of stigmatization, and depression, are stronger determinants of disability in patients with psoriasis than are disease severity, location, and duration (Fortune et al. 2005; Kirby et al. 2001). The impact of psoriasis on both physical and mental health-related quality of life has been found to be comparable to the impact of conditions such as cancer, diabetes, arthritis, hypertension, depression, and heart disease (Rapp et al. 1999). Many studies have reported the presence of symptoms of depressive and anxiety disorders, which occur largely in reaction to the

cosmetic disfigurement and social stigma associated with psoriasis and anticipatory anxiety about the reaction of others. Patients' cognitive and behavioral patterns of worrying and scratching have been shown to influence their vulnerability to the impact of stress on psoriasis in a prospective study (Verhoeven et al. 2009b). Some of the psychological reactions associated with feelings of stigmatization include shame, decreased self-esteem and increased self-consciousness, social anxiety, and social phobia. A study of 2,490 Vietnam war veterans reported an odds ratio of 4.7 (95% CI=1.9–11.7) for comorbidity of psoriasis and chronic PTSD (Boscarino 2004).

A review of the literature indicates a 10%–58% prevalence of depression in psoriasis (Fortune et al. 2005). Suicidal ideation has been reported among 2.5%–10% of psoriasis patients (Gupta and Gupta 1998; Picardi et al. 2006). Several but not all studies have reported a direct correlation between severity of psoriasis and severity of depressive symptoms (Fortune et al. 2005; Gupta et al. 1994). However, even clinically mild psoriasis may lead to stigmatization and depression in some patients. Improvement in depression has been shown to be associated with improvement in psoriasis (Gupta et al. 1988; Sampogna et al. 2007). Several recent studies (Bassukas et al. 2008; Tyring et al. 2006) have reported significant improvement in psychological comorbidity in psoriasis patients treated with biological response modifiers.

Management

Psychotherapy. Psychotherapy should be considered in patients whose psoriasis is stress-reactive (Harth et al. 2009), because stress associated with daily hassles can in turn result in flare-ups of the psoriasis (Gupta et al. 1989), and psychological distress can undermine the effectiveness of medical therapies. For example, psoriasis patients with high levels of pathological worrying were almost half as likely as low-worrying patients to achieve improvement with psoralen plus ultraviolet A (PUVA) photochemotherapy, after other dermatological, psychological, and demographic factors were controlled for (Fortune et al. 2003). Obesity, moderately heavy alcohol use, and tobacco smoking have been associated with poor response to dermatological therapies (Gottlieb et al. 2008) and need to be managed. There are a number of specific targets for psychological interventions, including interpersonal dependency or an inordinate need to gain the approval of others, and difficulty with the expression of anger, which have been associated with greater stress reactivity of the psoriasis (Gupta et al. 1989). Psychological consequences of psoriasis such as social isolation, sedentary lifestyle, and comorbid depressive illness promote other psoriasis risk factors such as substance abuse and obesity (Skolnick and Alex-

ander 2006). Regular support groups aimed at addressing feelings regarding the impact of psoriasis on quality of life, reducing feelings of isolation, and enhancing coping skills and self-efficiency can be a helpful adjunct to standard therapies (Abel et al. 1990). Various interventions have been reported to be effective; these include group psychotherapy for psychoeducation, mindfulness meditation-based stress reduction (Kabat-Zinn et al. 1998), CBT that provides support and targets negative patterns of thinking (Fortune et al. 2005), cognitive-behavioral stress management, relaxation training and symptom control imagery training (Zachariae et al. 1996), hypnosis (Tausk and Whitmore 1999), and EMDR (Gupta and Gupta 2002).

Psychopharmacology. The association between psoriasis and metabolic syndrome (Gottlieb et al. 2008) has important implications for the choice of psychotherapeutic agents. Treatment of depressive symptoms may reduce pruritus and insomnia in psoriasis. In a placebo-controlled trial, the reversible monoamine oxidase inhibitor (MAOI) moclobemide (currently not available in the United States) reduced psoriasis severity and anxiety (Alpsoy et al. 1998). In a small open-label trial, bupropion induced improvement in psoriasis, with return to baseline levels after its discontinuation (Modell et al. 2002), and paroxetine was reported to be effective in two cases with both depression and psoriasis (Luis Blay 2006).

Urticaria and Angioedema

Urticaria (Grattan and Black 2008), or hives, is characterized by transient (usually lasting less than 24 hours) mucosal or skin swellings due to plasma leakage. The superficial swellings are *wheals*; the deep swellings in the dermis and subcutaneous or submucosal tissue are termed *angioedema* and typically last for 2–3 days. Angioedema can also be a feature of anaphylaxis if the throat is involved. The wheals of urticaria are characteristically pruritic, and the angioedema is often painful. Urticaria has a spectrum of clinical presentations, ranging from occasional localized wheals to widespread recurrent whealing and angioedema affecting the skin, mouth, and/or genitalia. Urticaria is found worldwide, is more common in women, and can occur at any age, with an estimated prevalence of 1%–5% (Grattan and Black 2008). All urticarias are acute initially and termed chronic when they occur over a period of 6 weeks or longer. Chronic urticaria may be a manifestation of an underlying autoimmune disorder. Mast cell degranulation with release of histamine is central to the development of urticaria. The underlying etiology is not identifiable in about 70% of cases of chronic urticaria. Psychogenic factors are reported to be important in around 50% of cases of chronic urticaria (Gupta 2009). “Adrenergic

urticaria,” which presents as “halo-hives” or papules surrounded by blanched vasoconstricted skin, is an entity that is largely stress induced (Haustein 1990); the symptoms can be provoked by injection of epinephrine or norepinephrine and treated with propranolol (Haustein 1990).

Stress

Severe emotional stress may exacerbate urticarial reactions, regardless of the primary cause. There is an extensive body of literature on stress and urticaria that is more than 30 years old (Gupta 2009). Stress so often seemed a precipitant to angioedema that for many years clinicians referred to the disorder as *angioneurotic edema*. However, the evidence base for this belief about stress inducing urticaria is somewhat limited. In one study of 48 patients (Czubalski and Rudzki 1977), exacerbation by emotional factors occurred in 77% of patients with cholinergic urticaria and 82% of patients with dermatographism, but did not occur in cold urticaria. Urticaria had been referred to as an “emotional allergy” in the earlier literature, and two forms of psychogenic urticaria were described (Panconesi and Hautmann 1996, p. 418): 1) an “acute emotional form” that follows specific events with a clear cause–effect relationship; and 2) a “chronic recurrent form” that “seems to be structured deeply on a psychodynamic basis as a psychosomatic disease.” Panconesi and Hautmann (1996) further noted that in specific immunological tests, immunoglobulin E (IgE)–dependent induction is evident in only a minority (<20%) of cases. A review of the literature indicates that stressful major life events have been reported to precede the onset of urticaria in 30%–81% of patients (Gupta 2009). Stressors have ranged from catastrophic and traumatic major life events such as earthquakes, bereavement, or accidents to chronic and prolonged stressors such as family and marital problems or problems at work (Gupta 2009). One possible mediator in the relationship between stress and urticaria is dehydroepiandrosterone sulfate (DHEAS), which plays an important role in modulating the vulnerability of the organism to the negative effects of stress (J.F. Morgan et al. 2004). Some patients with chronic urticaria have been shown to have lower serum levels of DHEAS during the active period of the disease (Kasperska-Zajac et al. 2008), and low DHEAS levels were associated with greater psychological distress, as exemplified by higher anxiety and depression scores (Brzoza et al. 2008).

Psychosocial and Psychiatric Factors

Recent studies in Turkey and Germany have shown 48%–60% prevalence of Axis I diagnoses in chronic urticaria patients, with depressive disorders and OCD most common (Ozkan et al. 2007; Staubach et al. 2006; Uguz et al. 2008). A Turkish study using the Minnesota Multiphasic Per-

sonality Inventory found a diverse range of psychopathological traits (including high scores for hypochondriasis, depression, hysteria, psychopathic deviance, paranoia, psychasthenia, schizophrenia, and social introversion) which did not correlate with the duration of chronic urticaria (Pasaoglu et al. 2006). Pruritus in chronic urticaria has a significant adverse effect on quality of life and has been directly correlated with the severity of comorbid depression (Gupta et al. 1994). Sixty-two percent of chronic urticaria patients reported that pruritus interfered with sleep, and itch scores were significantly higher in chronic urticaria patients who were also depressed (Yosipovitch et al. 2002). Insomnia has been reported to be the most important symptom associated with onset of chronic urticaria and a mediator of the relationship with stress (Yang et al. 2005). The role of PTSD, often chronic, tends to be underrecognized as a contributing factor in some cases of chronic urticaria (Gupta 2009); a study of 100 chronic urticaria patients and controls with allergies reported an odds ratio of 1.89 for PTSD among the chronic urticaria patients versus the controls (Chung et al. 2010).

Management

Psychotherapy. There is an extensive literature on the effect of hypnotic suggestion on urticaria. Hypnosis is known to be able to influence cutaneous blood flow and other autonomic functions that are not under conscious control (Shenefelt 2000). For example, hypnotized volunteers have been shown to have a significantly decreased flare reaction to the histamine prick test (Shenefelt 2000). In one small pre-post controlled study of hypnosis for chronic idiopathic urticaria, hypnosis in combination with relaxation techniques reduced pruritus but not the number of wheals, although at follow-up 5–14 months after therapy, 40% were free of hives and most of the rest reported improvement (Shertzer and Lookingbill 1987). The impact of chronic urticaria on patient quality of life (Poon et al. 1999) should be addressed. Individual and group psychotherapy and stress management may be useful adjunctive therapies.

Psychopharmacology. In interpreting the chronic urticaria treatment literature, one must first recognize the very high rate of response to placebo (Rudzki et al. 1970). The less-sedating second-generation antihistamines (loratadine, fexofenadine, and cetirizine) are the first-line antihistaminic agents, and diphenhydramine is useful if itching is causing sleep disturbance. A low dose of a sedating antihistaminic antidepressant such as doxepin is helpful for pruritus in chronic urticaria, especially because pruritus interferes with sleep (Yosipovitch et al. 2002). Two small randomized trials of doxepin have demonstrated its efficacy at dosages of 10 mg three times daily (Greene et al. 1985) and

25 mg three times daily (Goldsobel et al. 1986). Doxepin may provide more than symptomatic relief, by reducing the urticarial reaction itself (Rao et al. 1988). Combined H₁ plus H₂ antihistamine therapy may be more effective than H₁ antihistamines alone for urticaria, as dermal blood vessels possess both H₁ and H₂ histamine receptors, and the TCAs doxepin, trimipramine, and amitriptyline are potent histamine H₁ and H₂ receptor antagonists. There are also case reports of the benefits of mirtazapine (Bigatà et al. 2005) and SSRIs (Gupta and Gupta 1995, 2001c) in chronic urticaria.

Alopecia Areata

Alopecia areata (Sperling 2008) is a nonscarring alopecia that typically presents as round or oval patches of nonscarring hair loss involving the scalp; other presentations include alopecia totalis (loss of all scalp hair) and alopecia universalis (loss of all scalp and body hair). Alopecia areata is postulated to be an autoimmune disease, with the average lifetime risk of developing alopecia areata estimated to be 1.5%. A concordance rate of 55% was found among monozygotic twins, suggesting the role of both genetic and environmental factors in its pathogenesis. Alopecia areata tends to have an unpredictable course and may improve spontaneously without any active treatment. The hair follicle is richly innervated and is both a source and a target of numerous cytokines, neuropeptides, and other neuroimmune factors. Like the skin, the hair follicle has a functionally organized HPA axis equivalent, and increased expression of corticotropin-releasing factor (CRF), adrenocorticotrophic hormone (ACTH), and alpha-melanocyte-stimulating hormone (α -MSH) has been reported in hair follicles from alopecia areata patients (Tobin and Peters 2009). Substance P, a central stress-associated neuropeptide in the skin, regulates hair growth and perifollicular inflammation and plays an important role in alopecia areata (Tobin and Peters 2009).

Stress

There are conflicting conclusions regarding the role of stress in alopecia areata (Picardi and Abeni 2001; Picardi et al. 2003b). In one study, only 6.7% of alopecia areata patients reported a severely disturbing event 6 months before the onset of symptoms, but no patient reported a coincidence of alopecia areata with a stressful event (Van der Steen et al. 1992). In contrast, in a recent case-control study, significantly more alopecia areata patients than control patients experienced total lifetime (OR = 2.46; 95% CI = 1.15–5.28) and early childhood emotionally and physically traumatic events (OR = 2.16; 95% CI = 1.15–4.06) (Willemsen et al. 2009). Yet another study (Manolache and Benea 2007) reported that 68.9% of alopecia areata patients identified a

stressful life event during the prior year, compared with 22.2% of dermatological control subjects with non-stress-related skin conditions ($P=0.005$). Almost half of the stressful events were family related (e.g., death of a family member, family disputes). Alopecia areata patients who consider their disease to be stress reactive have higher depression scores (Gupta et al. 1997).

Psychosocial and Psychiatric Factors

Alopecia areata patients often have a high prevalence of psychiatric comorbidity, which often does not necessarily have a direct temporal association with the onset, exacerbation, or severity of dermatological symptoms (Gupta and Gupta 1996). High rates of psychiatric comorbidity are also found in pediatric alopecia areata patients (Ghanizadeh 2008). However, the extent of alopecia areata is an important predictor of psychological distress, with 40% of women with alopecia areata attributing marriage breakup to alopecia areata and 63% reporting career-related problems as a result of alopecia areata (Hunt and McHale 2005). Loss of eyebrows and eyelashes has been associated with core identity issues in alopecia areata patients (Hunt and McHale 2005). Overall prevalence of psychiatric comorbidity has been reported to range from 23% to 93% (Gupta and Gupta 1996), and the prevalence of suicidal ideation in alopecia areata as 0% to 2%. Koo et al. (1994) reported an overall 23.3% prevalence of at least one psychiatric disorder, with 8.8% major depression, 18.2% generalized anxiety disorder, and 4.4% paranoid disorder. In a small study, 66% of alopecia areata patients presented with psychiatric comorbidity, mainly adjustment disorders, generalized anxiety disorder, and depressive episodes (Ruiz-Doblado et al. 2003). Picardi et al. (2003b) compared 21 patients with recent onset of alopecia areata and 102 dermatology control subjects and found that alopecia areata was associated with high avoidance in attachment relationships and poor social support.

Management

Psychotherapy. Objective evaluation of the efficacy of psychosocial therapies in alopecia areata is difficult because alopecia areata patients can experience remission of symptoms without active therapies (Delamere et al. 2008). A small open trial in patients with treatment-refractory alopecia areata used a hypnotherapeutic approach combining symptom-oriented suggestions with suggestions to improve self-esteem. Significant scalp hair growth occurred in 12 of 21 patients, and all patients had a significant decrease in scores for anxiety and depression (Willemssen and Vanderlinden 2008). Psychotherapy may help the patient's mental state but may not affect the alopecia areata, and

self-help and support groups can help the patient cope with the psychosocial impact of alopecia areata (Beard 1986).

Psychopharmacology. The literature on the use of psychotropic agents in alopecia areata is inconclusive. A 2008 Cochrane review of treatment for alopecia areata concluded that very few treatments of any kind have been well evaluated in randomized trials (Delamere et al. 2008). In a double-blind, placebo-controlled study of 13 patients with alopecia areata, 5 of 7 patients taking imipramine, but none receiving placebo, had significant hair regrowth after 6 months (Perini et al. 1994), and reduction of alopecia did not correlate with alleviation of depressive symptoms. In a case series of 7 women with alopecia areata, a 3-month course of citalopram led to objective clinical improvement in alopecia in 6 of the 7 women, in addition to improvement in the anxiety and depression scores (Ruiz-Doblado et al. 1999). A 3-month randomized, double-blind, placebo-controlled study of paroxetine in 13 alopecia areata patients reported "complete regrowth of hair" in 2 patients and "partial regrowth" in 4, while 1 patient from the placebo group had "an almost complete regrowth of hair" (Cipriani et al. 2001, p. 601).

Acne

Acne vulgaris (Zaenglein and Thiboutot 2008) is a multifactorial disorder of the pilosebaceous unit characterized by comedones (whiteheads and blackheads), papules, pustules, nodules, cysts, and scars; it affects the face, neck, upper trunk, and upper arms. Acne vulgaris has a peak incidence during adolescence, affects 85% of individuals 12–24 years of age, and continues on into later life in 12% of women and 3% of men. Androgens from the gonads and adrenal glands affect sebum secretion and play a key role in the pathogenesis of acne. Endocrine disorders associated with high androgen levels are associated with increased risk for acne. Acne excoriée and acne excoriée des jeunes filles, which often have significant psychiatric comorbidity, develop when acne comedones and papules are excoriated by the patient, often young women, leaving crusted erosions that may scar.

Stress

Psychosocial stress can lead to exacerbations of acne in more than 60% of cases (Chiu et al. 2003; Harth et al. 2009). On the other hand, having to cope with the cosmetic disfigurement associated with acne can be a significant source of stress for some patients. The impact of acne on quality of life and acne-related stress often does not correlate directly with the clinical severity of the condition (Gupta and Gupta 2001b).

Psychosocial and Psychiatric Factors

Psychiatric and psychosocial comorbidity is one of the most disabling features of acne and is sometimes the most important factor in deciding whether to institute dermatological therapies. The extent of psychiatric morbidity in acne, including the prevalence of suicidal ideation, is not consistently related to the clinical severity of the skin condition. Bullying and teasing related to the cosmetic effects of acne can be a problem for a significant minority of adolescent acne patients (Magin et al. 2008), which in turn can lead to anxiety, poor self-esteem, acting out, or aggression. In a study of 18-year-old Norwegian high school students, those adolescents who had acne reported "significantly more depressive symptoms, lower self-attitude, more feelings of uselessness, fewer feelings of pride, lower self-worth, and lower body satisfaction" (Dalgard et al. 2008, p. 750). A cross-sectional survey of 9,567 12- to 18-year-olds in New Zealand revealed that self-reported "problem acne" was associated with approximately twice the frequency of depressive symptoms, anxiety, and suicide attempts. The association of acne with suicide attempts remained after controlling for depressive symptoms and anxiety (OR = 1.50, 95% CI = 1.21–1.86) (Purvis et al. 2006). The prevalence of suicidal ideation among acne patients has been reported to be 5%–7% (Gupta and Gupta 1998; Piccardi et al. 2006).

Acne and eating disorders often coexist; patients with both are very sensitive about and preoccupied with their appearance. Acne is also one of the dermatological manifestations of eating disorders (Strumia 2005). Binge eating is often associated with acne flare-ups, and starvation, which can result in lower androgen levels, may improve acne. Acne is a major concern among patients with BDD, and dermatological treatments are the most frequently sought after and received nonpsychiatric treatments in BDD, the most common being topical acne agents (Crenand et al. 2005). In a study of acne patients ages 16–35 years, 36.7% of patients with clinically "minimal to non-existent acne" and 32.9% of patients with clinically mild acne met criteria for BDD (Bowe et al. 2007). Those requiring systemic isotretinoin therapy were twice as likely to have BDD as those who never used it (Bowe et al. 2007).

The peak incidence of acne is during the mid-teens, a life stage when the individual is dealing with the social challenges of adolescence and is normally sensitive about his or her appearance and body image. This is also the age when mood and anxiety disorders, BDD, eating disorders, and schizophrenia often become symptomatic. The association of acne with depressive symptoms and BDD, and the higher prevalence of suicidal behavior in this age group, therefore does not necessarily imply a direct causal relationship with acne. Social isolation, difficulties in

interpersonal relationships, and body image concerns, which may be a consequence of a psychiatric disorder, are often instead attributed to acne, both by the adolescent patients and sometimes by their parents, who may not be ready to acknowledge the possibility that their child has a mental disorder.

Isotretinoin and Psychiatric Side Effects

Isotretinoin, which is generally used to treat severe acne, has been associated with depression, psychosis, suicide, and aggressive behaviors (Physicians' Desk Reference 2008), an association first reported by the FDA in 1998 (Nightingale 1998) and followed in 2002 by an additional warning regarding aggressive and/or violent behaviors. In 2005, the FDA reported that it continues to assess reports of suicide and suicide attempts associated with the use of isotretinoin. However, the general consensus at present is that the relationship between psychiatric side effects and isotretinoin is unclear, with little support from controlled trial data (Marqueling and Zane 2005; Strahan and Raimer 2006). However, individual cases have been reported in which the relationship between depression and isotretinoin use was confirmed by rechallenge with isotretinoin (Scheinman et al. 1990). A recent Canadian case–crossover study reported a doubling of risk for depression in those exposed to isotretinoin (Azoulay et al. 2008). Overall, improvement in acne with isotretinoin is associated with an improvement in depression scores. Patients who develop depression with isotretinoin may have previously used the drug with no adverse psychiatric effects (Scheinman et al. 1990). The current guidelines for prescribing isotretinoin (Accutane is one of the trade names) in the United States state that "prior to initiation of Accutane therapy, patients and family members should be asked about any history of psychiatric disorder, and at each visit during therapy, patients should be assessed for symptoms of depression, mood disturbance, psychosis, or aggression to determine if further evaluation may be necessary" (Physicians' Desk Reference 2008, p. 2608). Discontinuation of isotretinoin is not necessarily associated with a remission of the psychiatric symptoms. The decision to continue isotretinoin in a patient who has experienced a psychiatric reaction should be based on the risk–benefit ratio for the particular patient.

Management

Psychotherapy. Acne can lead to problems with socialization, self-esteem, anger, and body image that can be addressed in psychotherapy (Fried and Wechsler 2006). When adolescent acne is untreated, some of these problems may persist into later life, when acne is no longer a problem. BDD patients, who typically express concern about clinically mild acne, tend to resist any psychological

explanation for their skin concerns. Some patients pick their skin and self-excoriate their acne to regulate emotions (e.g., in PTSD); underlying trauma issues should be addressed in therapy after the patient is adequately stabilized. Cognitive-behavioral therapies and hypnosis have been used in *acne excoriée* (Shenefelt 2003). Because a significant number of adolescents with eating disorders also develop acne, it is important for the clinician to be aware of this association and to evaluate the potential impact of acne on the patient's body image and eating behavior.

Psychopharmacology. Psychotropic medications in acne patients are directed at underlying psychiatric pathology. Some patients on isotretinoin who develop depression may require standard antidepressant agents. There are some case studies of failure of hormonal contraceptives in patients using isotretinoin who self-medicate depression with St. John's wort, which is a CYP 3A4 inducer and thus increases the metabolism of some hormonal contraceptives. Case reports attest to the benefits of a wide variety of psychotropic agents for acne, including paroxetine (Mousavian 2001) and olanzapine for *acne excoriée* (Gupta and Gupta 2000), but there are no controlled clinical trials.

Cutaneous Reactions to Psychopharmacological Agents

Adverse cutaneous drug reactions (ACDRs) can be divided into common (usually relatively benign) ACDRs (Table 29-2), rare life-threatening ACDRs (Table 29-3), and precipitation or aggravation of a primary dermatological disorder (Litt 2004; Warnock and Morris 2002a, 2002b, 2003).

Common Adverse Cutaneous Drug Reactions

Common ACDRs include pruritus, exanthematous rashes, urticaria with or without angioedema, fixed drug eruptions, photosensitivity reactions, drug-induced pigmentation, and alopecia.

TABLE 29-2. Most common cutaneous drug reactions to psychotherapeutic agents

Pruritus and exanthematous rashes
Urticaria with or without angioedema
Fixed drug eruptions
Photosensitivity reactions
Drug-induced pigmentation
Alopecia

Pruritus is the most common ACDR, encountered with all antipsychotics, antidepressants, and mood stabilizers, and is usually secondary to other ACDRs.

Exanthematous rashes (morbilliform or maculopapular eruptions) can occur with all antipsychotics, antidepressants, and mood stabilizers. The rash usually occurs within the first 3–14 days of starting the drug and may subside without discontinuation of the causative agent. A rash accompanied by painful skin lesions, mucosal lesions, or sore throat may represent the early stages of one of the more severe and life-threatening ACDRs, such as Stevens-Johnson syndrome.

Urticaria with or without *angioedema* is the second most common ACDR after pruritus; it occurs within minutes to hours—but sometimes as late as several days—after starting the drug and can lead to laryngeal angioedema and anaphylaxis. Urticaria can occur with all antipsychotics, antidepressants, and anticonvulsants.

Fixed drug eruptions, which can theoretically occur with any drug, characteristically present as sharply demarcated, solitary or occasionally multiple lesions. Eruptions occur within a few to 24 hours after ingestion of the drug and resolve within several weeks of drug discontinuation.

Drug-induced photosensitivity can present either as phototoxicity (an exaggerated sunburn restricted to sun-exposed skin) or as photoallergy (a more generalized eruption triggered by sun exposure when a person is on certain drugs). Drug-induced photosensitivity tends to involve only sun-exposed skin, although there may be exceptions. Photosensitivity reactions can be caused by any of the antipsychotics but are much more frequently associated with chlorpromazine (3% incidence). Photosensitivity also occurs with many antidepressants, anticonvulsants, and sedative-hypnotics. Patients should be advised regarding the use of sunscreen and minimization of sun exposure in those instances where the medication has to be continued. Photosensitivity caused by psychotropic drugs may interfere with PUVA and ultraviolet B (UVB) phototherapy for psoriasis and other pruritic dermatoses.

TABLE 29-3. Severe and life-threatening cutaneous drug reactions to psychotherapeutic agents

Erythema multiforme
Stevens-Johnson syndrome
Toxic epidermal necrolysis
Drug hypersensitivity syndrome (also drug eruption with eosinophilia and systemic symptoms [DRESS])
Exfoliative dermatitis
Drug hypersensitivity vasculitis

Drug-induced pigmentation, which may involve the skin and eyes (retina, lens, and cornea), has been reported after long-term (>6 months) high-dose (>500 mg/day) use of low-potency typical antipsychotics, especially chlorpromazine and thioridazine. Pigmentary changes have been associated with some antidepressants, including various TCAs, all SSRIs, venlafaxine (hypopigmentation), and several anticonvulsants (also changes in hair color and texture).

Alopecia has been frequently reported with lithium (>5%) and valproic acid (>5%) and less frequently with the other mood stabilizers. Alopecia has also been associated with most antidepressants and several antipsychotics. Hair loss may occur rapidly or a few months after the drug is started, with recovery generally 2–18 months after drug discontinuation.

Severe and Life-Threatening Adverse Cutaneous Drug Reactions

Severe and life-threatening skin reactions (see Table 29–3) are most often associated with anticonvulsants and include erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), drug hypersensitivity syndrome or drug eruption with eosinophilia and systemic symptoms (DRESS), exfoliative dermatitis, and vasculitis (Litt 2004; Warnock and Morris 2002a, 2002b, 2003). Erythema multiforme, Stevens-Johnson syndrome, and TEN lie on a continuum of increasing severity. About 16% of Stevens-Johnson syndrome/TEN cases have been associated with short-term use of anticonvulsant drugs, with greatest risk for development of TEN within the first 8 weeks of initiating therapy. Use of multiple anticonvulsants and higher dosages increases the risk. Treatment of severe reactions should include immediate discontinuation of the drug and emergency dermatology consult. Patients typically require fluid and nutritional support as well as infection and pain control, which may involve management in an intensive care or burn unit.

Erythema multiforme occurs within days of starting the drug and may present as a polymorphous eruption, with pathognomonic “target lesions” typically involving the extremities and palmoplantar surfaces. The potential for evolution to more serious Stevens-Johnson syndrome and TEN should always be considered. Although rarely associated with antipsychotics and antidepressants, it is most commonly associated with carbamazepine, valproic acid, lamotrigine, gabapentin, and oxcarbazepine.

Stevens-Johnson syndrome usually occurs within the first few weeks after drug exposure and presents as flu-like symptoms followed by mucocutaneous lesions; it has a mortality rate as high as 5% due to loss of the cutaneous barrier and sepsis. Bullous lesions can involve mucosal surfaces, including the eyes, mouth, and genital tract. Stevens-

Johnson syndrome is most frequently associated with the same anticonvulsants as erythema multiforme.

Toxic epidermal necrolysis is considered to be an extreme variant of Stevens-Johnson syndrome, resulting in epidermal detachment in excess of 30% of patients, occurring within the first 2 months of treatment, with a mortality rate as high as 45% due to sepsis. In 80% of TEN cases, a strong association is made with specific medications (versus a 50% association with specific medications in Stevens-Johnson syndrome), most often anticonvulsants.

Drug hypersensitivity syndrome (drug eruption with eosinophilia and systemic symptoms, or DRESS) characteristically occurs 1–8 weeks after starting drug treatment, presenting as a drug eruption with fever, eosinophilia, lymphadenopathy, and multiple organ involvement. Treatment involves immediate discontinuation of the suspected drug, systemic steroids, and antihistamines. The mortality rate is 10% if symptoms are unrecognized or untreated. The rash can range from a simple exanthem to TEN and is almost exclusively associated with anticonvulsants.

Exfoliative dermatitis presents as a widespread rash characterized by desquamation, pruritic erythema, fever, and lymphadenopathy within the first few weeks of drug therapy, with a good prognosis if the causative agent is withdrawn immediately. It has been reported with antipsychotics, most TCAs and other antidepressants, mood stabilizers, lithium, sedatives, and hypnotics.

Drug hypersensitivity vasculitis, characterized by inflammation and necrosis of the walls of blood vessels, occurs within a few weeks of starting a drug. Lesions (e.g., palpable purpura) are primarily localized on the lower third of the legs and ankles. It has been associated rarely with clozapine, maprotiline, trazodone, carbamazepine, lithium, phenobarbital, pentobarbital, diazepam, and chlorthalidone.

Drug-Induced Precipitation or Aggravation of a Primary Dermatological Disorder

A number of primary dermatological disorders (Litt 2004; Warnock and Morris 2002a, 2002b, 2003) may be precipitated or exacerbated by a psychotropic drug, including acne, psoriasis, seborrheic dermatitis, hyperhidrosis, and porphyria. Acne has been associated with most antidepressants, lithium, anticonvulsants, and antipsychotics. It is well recognized that lithium can precipitate or exacerbate psoriasis. Lithium-induced psoriasis can occur within a few months but usually occurs within the first few years of treatment. Psoriasis precipitated or exacerbated by lithium is typically resistant to conventional antipsoriatic treatments and usually there is no family history of psoriasis. When psoriasis becomes intractable, lithium must be discontinued, and remission usually follows within a

few months. Anticonvulsants, atypical antipsychotics, and SSRIs have been less commonly reported to precipitate or aggravate psoriasis. Seborrheic dermatitis is very common in patients on long-term phenothiazines and also has been reported with other antipsychotics, lithium, and anticonvulsants. Hyperhidrosis, often manifested as night sweats, is common with SSRIs, SNRIs, bupropion, and MAOIs. Sweating is mediated by the sympathetic cholinergic innervation of the eccrine sweat glands; however, the more anticholinergic TCAs have also caused hyperhidrosis, and therefore switching to a more anticholinergic antidepressant is not necessarily helpful. Hyperhidrosis has also been reported with antipsychotics and anticonvulsants. Porphyrria may be exacerbated by certain drugs (e.g., carbamazepine, valproic acid, and many sedative-hypnotics (especially barbiturates), resulting in acute dermatological, neuropsychiatric, and abdominal pain symptoms. Chlorpromazine, although photosensitizing, is considered to be “safe” and actually was approved by the FDA for use in acute intermittent porphyria.

Interactions Between Dermatology Drugs and Psychopharmacological Agents

Most pharmacokinetic interactions (Litt 2004) between dermatological and psychotropic drugs result from inhibition of CYP-mediated drug metabolism, mainly involving the CYP 2D6 and 3A4 isoenzymes. Selected interactions are listed in Table 29-4.

Conclusion

Psychodermatological disorders are usually classified either as dermatological manifestations of a primary psychiatric disorder—for example, delusional or body image pathology presenting as a dermatological complaint—or as psychological factors in a primary dermatological disorder (e.g., psoriasis, atopic dermatitis) that is exacerbated by psychosocial stress and that often is comorbid with psychiatric morbidity (e.g., depression, anxiety). Psychological trauma and dissociative symptoms are often factors in the self-induced dermatoses. Factors that increase psychiatric morbidity (including suicide risk) in the dermatology patient include pruritus and sleep difficulties, disease-related stress (largely due to the cosmetic disfigurement), social stigma associated with the skin disorder, and (in the pediatric age group) appearance-related bullying. The a high prevalence of suicidal ideation among dermatology patients is not consistently related to the clinical severity of the skin condition. Covert body dysmorphic disorder can also increase suicide risk and treatment resistance. Standard psychopharmacological agents, with adequate clinical monitoring, may be used to treat psychiatric comorbidity in dermatological disorders. Severe and life-threatening dermatological reactions to psychotropic agents (e.g., Stevens-Johnson syndrome, toxic epidermal necrolysis) are most frequently associated with the mood-stabilizing anticonvulsants, with the greatest risk of development during the first 2 months of therapy. Assessment and treatment of the dermatology patient should follow a biopsychosocial model. The psychiatrist should thoroughly address and

TABLE 29-4. Selected dermatological drug–psychotherapeutic drug pharmacokinetic interactions

Medication used in dermatology	Effects on CYP isoenzymes	Effects on psychotropic drug levels
Azole antifungals (oral formulations only) Itraconazole Ketaconazole	Inhibition of CYP 3A4	Benzodiazepine serum levels for agents that undergo hepatic oxidative metabolism (e.g., alprazolam, triazolam) may increase.
Macrolide antibiotics Clarithromycin Erythromycin		Buspirone levels are increased.
Cyclosporine (both substrate and inhibitor of CYP 3A4)		Carbamazepine levels are increased.
		Pimozide levels are increased.
Terbinafine	Inhibition of CYP 2D6	Antidepressant serum levels may increase for CYP 2D6 substrates (e.g., tricyclic antidepressants, paroxetine, venlafaxine, atomoxetine).
		Antipsychotic serum levels may increase for CYP 2D6 substrates (e.g., phenothiazines, haloperidol, risperidone, olanzapine, clozapine, aripiprazole).

Note. CYP = cytochrome P450.

manage any pruritus and sleep difficulties the patient may be experiencing and should recommend aggressive dermatological treatment of even clinically mild skin disease that is cosmetically disfiguring or stigmatizing.

Surgery

Pauline S. Powers, M.D.

Carlos A. Santana, M.D.

SURGICAL PATIENTS OFTEN have preexisting psychiatric disorders, and a range of psychosocial problems may become evident after surgery. The prevalence of psychiatric problems in surgical patients has been estimated to be as high as 50% (Strain 1982) and is known to be particularly high in certain specialized surgical units, such as burn and trauma centers. Although surgeons are less likely to refer patients to psychiatrists than are other physicians, there is evidence that rates of referrals for both consultation and liaison services are increasing across medical specialties and that during the last 20 years, the most frequent reasons for referral have begun to change from suicide attempts and a history of psychosis to depression and other current psychiatric symptoms (Devasagayam and Clarke 2008; Sloan and Kirsh 2008). Another important trend has been a global increase in reports of consultation-liaison service use. For example, a review of 3,608 consecutive referrals to hospital consultation-liaison psychiatry units conducted by the European Study on Quality Assurance in Consultation-Liaison Psychiatry and Psychosomatics in Spain reported that the main sources of referrals were internal medicine (17.5%), traumatology (7.5), and general surgery (7.3%) (Valdés et al. 2000).

In the hospital, psychiatrists provide consultations for patients on general surgical floors, but they are more likely to provide liaison services to specialized surgical units such as burn units or organ transplant programs. Consultations for general surgical patients often involve preoperative issues such as consent for surgery, fear of anesthesia or surgery, or management of preexisting psychiatric disorders during hospitalization. Postoperative hospital consultations are often initiated for assessment and treatment of delirium or behavior problems. On specialized surgical

units, the psychiatrist is more likely to provide classic liaison services, including teaching members of an interdisciplinary team to recognize and manage various psychiatric and psychological problems unique to the unit.

General Issues

Open, Closed, and Random Systems

The general surgical unit and specialized units often have significant differences in operational style. Systems theory can be helpful in understanding these differences (Luhmann and Knodt 1995). An *open system* has regular members who belong to the system and flexible rules about entering and leaving the system. In a *closed system*, only certain individuals can come into and go out of the system, and “outsiders” are excluded from the system. In *random systems*, individuals move into and out of the system at random, with few rules about how entry and exit occur.

Most general surgical units are open systems, and some poorly functioning ones are random systems. Specialized units, such as burn units, are often closed systems with very rigid rules about entering or leaving the system. Because hospital consultations usually involve one to three sessions, it is important that the consultant be able to move easily into and out of the system. This is possible in the open systems typically present on general surgical floors. However, communication with the consultee may require significant effort on the part of the consultant, who may have to track down the consulting surgeon (who may be in the operating room all day); this problem is accentuated on a ward that tends toward randomness. In contrast, the psychiatrist who provides liaison to a closed

specialized unit will need to be well known to the team and be a regular attendee at team meetings. Communication within the closed system may be easier because all members are likely to accept recommendations from another member of the team.

Outpatient Consultation-Liaison Services

In the outpatient department, the psychiatrist may be an integral part of a specialized team. For example, bariatric surgery teams typically rely on a presurgical psychiatric assessment of patients to determine whether the patient is an appropriate candidate for surgery; the psychiatrist also may participate in the long-term follow-up of the patient after bariatric surgery. This type of psychiatric consultation requires detailed knowledge of the unique risks and benefits of the proposed surgery.

The dramatic rise in outpatient surgery, in which the patient may arrive only a few hours before the operation and leave a few hours later, has complicated identification of perisurgical psychiatric problems. This relatively new development in surgery has occurred at the same time that it has been recognized that patients so often present with multiple physical and psychiatric disorders, whether in the inpatient, outpatient, or ambulatory surgery setting. A recent proposal is to envision consultation-liaison psychiatry as one means of providing integrated care for the multiple and complex needs of patients (G.C. Smith 2009). This would entail integrating quantitative methods (e.g., utilizing results of randomized clinical trials) and qualitative methods (e.g., assessment and treatment of psychodynamic conflicts) and devising effective methods of communication between all health care personnel. Such a systematic approach might resolve the issues related to identification of psychiatric problems among ambulatory surgery patients because the patient would be part of a well-informed system in which key problems are known and incorporated into an integrated treatment plan.

Transference and Countertransference

Transference and countertransference issues are important, irrespective of the site of the surgical intervention. *Transference* is defined as the set of emotional reactions that a patient has toward the surgeon: these reactions are shaped by previous relationships with important people in the life of the patient and may facilitate or inhibit the relationship with the surgeon. Relationships with parents and others in authority typically influence current reactions to the surgeon. For example, a surgical candidate who has had a trusting relationship with parents and positive experiences with physicians is likely to approach surgery calmly and to be able to discuss options openly with the surgeon. However, a patient who grew up with harsh, controlling,

and demanding parents, and who also has had negative interactions with physicians, is more likely to be suspicious of the surgeon and fearful of the surgery. Recognition of the likely source of the patient's reactions to the surgeon is the key to managing these reactions. For example, if a new patient is suspicious and unduly fearful of a usually safe surgical procedure, it may be helpful to give the patient time to discuss the procedure with a trusted partner or friend and then offer to explain the procedure to this person while the patient is present.

Surgeons, like other physicians, may have countertransference reactions to their patients. Clues to negative countertransference reactions to the patient include feelings of anger, irritability, sadness, or boredom. In these situations, it is often helpful for the surgeon to ask him- or herself: "Why am I [angry, sad, or bored or overly involved] with this patient?" The answer may be that the patient has elicited feelings related to another situation in the surgeon's life. Recognition of this fact usually allows the surgeon to refocus on the patient. An example might be an overly solicitous response to a woman shot by an abusive husband; it might be that in this situation, the surgeon was reminded of his own abusive father. Another example is the surgeon who is angry because a patient fails to improve after multiple back surgeries. This reaction may relate to the surgeon's unrecognized and unrealistic grandiose belief that she can conquer any problem.

Staff Coping Mechanisms

Certain surgical situations, such as traumas and burns, particularly among children, elicit powerful emotional responses from the surgeons and nurses working with these patients and their families. Jones (2001) poignantly described the reaction of a patient and her husband to life-threatening surgery and commented that the "impact of physical illness is such that there is potential for the seriously ill to saturate health workers in anxiety and raw feelings" (p. 459). To protect themselves emotionally, the surgeon or nurse may ignore the emotional needs of the patient (and family) and focus solely on the physical aspects of care.

To be able to function effectively, the surgeon must be able to maintain defense mechanisms, including, when appropriate, isolation of affect, denial, humor, and suppression. Treatment team members, including psychiatrists, psychologists, and chaplains, may be able to cope more effectively with the feelings emanating from the patient because they do not have to perform surgery. Although surgeons are often blamed for not attending to the emotional needs of their patients, it may be that it is not usually possible both to empathize fully with the feelings of the patient and to maintain the objectivity needed to perform

surgery. Thus, the emotional needs of both the surgeon and the patient must be respected.

Several recent reports have recognized the stresses experienced by surgeons, particularly when there is an intraoperative death (Taylor et al. 2008) or when palliative surgical care is required. One report (Bradley and Brasel 2007) describes a core competency program in effective interpersonal and communication skills for surgical residents. Case examples and appropriate wording and actions are described for four areas of surgical practice: preoperative counseling, presentation of a devastating diagnosis or poor prognosis, discussion of error, and discussion of death.

Role of the Family

The effect of the family on the patient's experience with surgery and on long-term recovery is known to be very important. Qualitative research methods including narratives have been used to understand the experience of the family during the perioperative period (e.g., Pai et al. 2008). A consistent theme from these reports is that knowing is better than not knowing. Another theme is that families want much more information than was initially realized. For example, one study (Kocylidirim et al. 2007) found that 17 parents who viewed videotapes of their child's cardiac surgery procedure were not distressed by the videotape, found it useful in understanding exactly what happened to their child, and reported that it made it easier to share the experience with other family members and friends. Recent research has also begun to describe responses of family members other than parents. A case series of siblings of children who undergo bone marrow transplant (Wilkins and Woodgate 2007) showed they have definite ideas about how health care professionals should support them. One specific example was that they want to be included in the definition of "family." Finally, it is clear that a more comprehensive view of the role of the family is emerging globally: the three studies cited in this paragraph are from India, the United Kingdom, and Canada.

General Conceptual Model

To conceptualize the problems requiring psychiatric intervention, the perioperative period can be divided into preoperative, intraoperative, and postoperative periods. Although these periods are considered separately because special strategies and different personnel may be required in each, the connection between preoperatively identified psychiatric problems and outcome of surgery has been a topic widely studied. For example, in a study of patients with severe low back pain who underwent surgery, low pre-

surgical neuroticism scores were associated with better postoperative functional improvement (Hagg et al. 2003). In another study of patients with gastroesophageal reflux disorder undergoing laparoscopic antireflux surgery (Kamolz et al. 2003), all the patients had normalized physiological findings after surgery, but the patients with comorbid major depression had significantly more symptoms of postoperative dysphagia and had less improvement in quality of life than did the patients without depression.

Psychiatry is often consulted in the preoperative period around the issues of consent for treatment or refusal of surgery and may be consulted at any time when the patient threatens to sign out against medical advice (AMA). Preexisting psychiatric disorders and their management often are also the reason for psychiatric consultation. Fear of surgery, anesthesia, needles, or machines may result in preoperative panic and necessitate urgent psychiatric intervention.

With the emergence of outpatient surgery and use of drugs that induce a lighter stage of anesthesia, some patients may recall events from the intraoperative period. Psychiatric consultation may be needed to assist the patient in coping with these memories.

In the postoperative period, delirium (including withdrawal from various substances) is a very common cause for consultation. Agitation and management problems are also common. Patients who were admitted because of trauma (including burns) may begin to develop symptoms of posttraumatic stress disorder (PTSD).

General Preoperative Issues

Capacity and Consent

Informed consent is required prior to the performance of any surgical procedure. In this process, surgeons provide patients with information necessary to make an autonomous decision about whether to have surgery and ensure that patients are aware of the risks, benefits, and alternatives. The ethical practice of surgery requires a patient's voluntary informed consent. Valid informed surgical consent includes principles of volunteerism, disclosure, understanding, and capacity for decision making (del Carmen and Joffe 2005). In some instances, however, direct consent is impossible, and surgeons seek permission from surrogates or guidance from written advance directives. Informed consent and decision making are at the core of the preoperative period. The communication of factual information understandable to the patient is the responsibility of the surgeon. It should include diagnosis, reasons that the operation is thought to be the treatment of choice, and expected risks and benefits and their probabilities. Alterna-

tives and their consequences, as well as financial costs, also should be discussed. Informed consent is not merely the provision of information; it also involves ascertaining that patients have an adequate understanding of the procedure they are to undergo. Asking patients to describe, in their own words, the procedure they are about to have is a way the surgeon can assess whether patients have sufficient health literacy to understand the procedures to be performed and the risks, benefits, and alternatives to surgery. Competent patients have a right to decide whether to accept or reject proposed surgery. A psychiatric consultant cannot legally declare a patient incompetent, but he or she can evaluate the medical-legal elements of the decision-making capacity of the patient. Examiners must be aware of the legal standards governing determination of competence in their jurisdiction.

The assessment also includes a determination of the cause of the patient's limitation (i.e., the nature of the mental disorder) and the recommendations for treatment, if treatment is possible. The general principles regarding legal and ethical aspects of capacity and consent are discussed in Chapter 2, "Legal Issues," and Chapter 3, "Ethical Issues."

Preoperative Psychiatric Evaluation

The preoperative period is the time to obtain a psychiatric history. Patients with a history of anxiety disorder, depression, bipolar disorder, or psychosis are at risk for experiencing symptoms of these disorders during the postoperative period. Knowing what medications have been effective or not tolerated in the past is obviously valuable. Certain personality disorders and traits are known to predispose to behavior problems during the postoperative period.

When a surgeon requests a psychiatric consultation, the consultant should establish the urgency. Surgical patients seldom initiate or request a psychiatric consultation themselves and may even assume an adversarial attitude toward the consultant.

Although one of the most common reasons for the underreferral of surgical inpatients for psychiatric evaluation is lack of recognition (or dismissal) of psychological distress by the surgical team, this may be changing. Recent articles originating with surgical and anesthesia teams are exploring issues related to preoperative anxiety and depression (e.g., Perks et al. 2009). In some cases, surgical inpatients have felt the need to refer themselves for psychiatric evaluation of anxiety, although the surgical staff did not consider their anxiety sufficient to warrant a consultation (Fulop and Strain 1985). On the other hand, inappropriate or premature psychiatric consultation sometimes occurs when a patient expresses normal feelings (e.g., starts to cry) that the surgeon finds uncomfortable. One of

the psychiatrist's major tasks is establishing a relationship with the referring surgeon, who may or may not be knowledgeable about psychiatric issues.

Psychiatric Disorders in the Perioperative Period

Depression

The proportion of patients taking antidepressants who undergo surgery is reported to be 35% (Scher and Anwar 1999). Preoperative executive dysfunction and depressive symptoms are predictive of postoperative delirium among noncardiac surgical patients (P.J. Smith et al. 2009). Brander et al. (2003) found that the most severe cases of chronic postsurgical pain after 1 year appeared in those patients with the most severe levels of preoperative depression. Undoubtedly, depression can emerge from the experience of pain. However, in the study of Hinrichs-Rocker et al. (2009), it is suggested that depression, at least in severe cases, represents a risk factor for the development of chronic postsurgical pain.

The question of whether to discontinue a psychiatric drug prior to surgery is both common and complex. The evidence base concerning this issue is thin at best and mostly composed of case reports. Practical and ethical considerations compound the lack of answers and make controlled methodologically sound trials unlikely. In the past, when monoamine oxidase inhibitors (MAOIs) were more frequently prescribed, it was common to discontinue antidepressants prior to general anesthesia. This is no longer the case, since MAOIs can be continued with relative safety prior to surgery by use of specific anesthetic techniques and/or substitution of a reversible MAOI (M.S. Smith et al. 1996). In a study of 80 depressed patients who were scheduled to undergo orthopedic surgery under general anesthesia, Kudoh et al. (2002) concluded that antidepressants administered to depressed patients should be continued. Their group further reported that whereas discontinuation of antidepressants did not increase the incidence of hypotension or arrhythmias during anesthesia, discontinuation did increase the symptoms of depression and delirium. One expert consensus report (Huyse et al. 2006) concluded that the decision of whether to stop a psychotropic drug prior to surgery should be individualized, taking into account the surgical procedure, the patient's condition (e.g., diagnosis, comorbidities, stability), the choice of anesthetic agents, the length of preoperative fasting, and the risks of discontinuation (e.g., withdrawal, relapse). They recommended that MAOIs and tricyclic antidepressants (TCAs) be discontinued in patients prior to surgery and that selective serotonin reuptake inhibitors (SSRIs) be continued in patients who are mentally and physically stable. Other experts caution against discontin-

uation and advise that the safest course of action in the vast majority of cases is to continue the psychotropic drug until the time of surgery, with particular attention to the medications that have the potential to cause a withdrawal syndrome (Nobe and Kehlet 2000).

Schizophrenia

The management of schizophrenic patients requiring surgery can be difficult. Bizarre behavior and communication expression by schizophrenic patients can confuse and upset surgeons, nurses, and other patients, eliciting fear, anger, and nontherapeutic responses. Patients with paranoid delusions may refuse surgery because of psychotic misperception of the surgeon's intentions. Schizophrenic patients also often have deficits in the processing of cognitive or sensory information and concrete reasoning. These deficits may complicate the consent process and the patient's ability to cooperate with treatment, requiring the staff to make changes in management (Adler and Griffith 1991).

Schizophrenic patients are impaired in their biological response to stress and are at increased risk of medical illnesses such as cardiovascular and respiratory diseases as well as diabetes (Goldman 1999). Aside from difficulties with communication, these patients will also present challenges related to concomitant pathology associated with chronic schizophrenia, such as abnormalities of the endocrine, immune, and cardiovascular system. In addition, there may be interactions between antipsychotic and anesthetic drugs. Lanctot et al. (1998) suggested that 21% of patients receiving antipsychotics had a serious side effect such as extrapyramidal symptoms, sedation, or hypotension and disturbances of the cardiovascular and autonomic nervous systems. Nearly half of schizophrenic patients have comorbid medical conditions owing to adverse affects of antipsychotic drugs and poor self-care such as increased smoking or alcohol abuse (Goldman 1999). Pain insensitivity, which may occur in patients with schizophrenia, can have life-threatening consequences. Pain insensitivity can delay the diagnosis and treatment of illness in schizophrenic patients and is partly responsible for many postoperative complications (Herz and Marder 2002). Patients with chronic schizophrenia should continue their antipsychotics preoperatively to minimize exacerbation or relapse of their illness (Kudoh et al. 2004).

Bipolar Disorder

The stress of surgery may psychologically and physiologically destabilize bipolar disorder, and acute relapse into mania in the postoperative period can be extremely disruptive to care, as well as potentially life-threatening. The bipolar spectrum also includes hypomanic periods that may occur even if the patient is receiving pharmacotherapy or other so-

matic treatments. Use of lithium, anticonvulsants, antidepressants, and most antipsychotics is precluded for periods without oral intake in the perioperative period, during which parenteral haloperidol serves as the primary vehicle substitute for mood stabilization. Abrupt discontinuation of anticonvulsant mood stabilizers risks causing seizures. Lithium is difficult to use safely during periods of rapid fluid shifts (e.g., after cardiac surgery and acute burns).

Preoperative Fears

An emerging literature has begun to systematically assess the nature and etiology of common preoperative fears, including fears of surgery, anesthesia, needles, and medical machines. Several new psychological instruments have been developed that assess parameters not previously measured. For example, the Perioperative Adult Child Behavioral Interaction Scale (PACBIS; Sadhasivam et al. 2009) is a real-time tool that measures perioperative behaviors of both children and their parents. Strategies to decrease anxiety are being studied; novel approaches being used (particularly among children) include clowns (Cantó et al. 2008) and music (Walworth et al. 2008). Large and more sophisticated randomized controlled trials (RCTs) are now available. Provision of information often decreases anxiety about surgery; however, with the emergence of day surgery, it has become more difficult to provide such information, because the patient may arrive just before surgery. This problem has been widely recognized, and various solutions are being tested.

Although the preoperative period has been the most widely studied in terms of fears, one interesting study looked at fears 6 weeks after surgery (Oude Voshaar et al. 2006). Among 291 older patients with hip fractures, cognitive impairment and fear of falling at 6 weeks was associated with poorer functional outcome at 6 months post-surgery, leading the authors to suggest that a psychiatric assessment might be most appropriate for this type of patient at discharge rather than at admission.

Fear of Surgery and Anesthesia

Nearly a quarter-century ago, Regal et al. (1985) systematically assessed 150 patients before surgery and found that 54% were anxious or very anxious. Many patients were anxious about the anesthesia: patients often feared that the anesthetic would prematurely wear off or that they would not wake up from the anesthesia. Two decades ago, van Wijk and Smalhout (1990) found that nearly one-third of patients were afraid of anesthesia, as distinct from the operation itself. Since these landmark studies, it has been consistently shown that appropriate provision of information in an empathic relationship can reduce preoperative anxiety and length of hospital stay (Koivula et al. 2002; Ng

et al. 2004). Efforts to alleviate preoperative anxiety may result in decreased postoperative pain, but this is less certain (Rolfson et al. 2009; Vaughn et al. 2007). Timing the delivery of information is even more important today than it was in the past, because day surgeries afford fewer opportunities to provide information. It is also now clearly recognized that the same methods of providing information do not work for everyone. For example, Fitzgerald and Elder (2008) found that a brief one-page informational handout was most effective in reducing the fears of patients who had undergone no previous surgery and who were younger than 40 years and less effective in older patients with a history of surgery.

Treatment of Preoperative Anxiety

Preoperative anxiety has been treated with antianxiety medications, particularly benzodiazepines. A Cochrane Database review of premedication for anxiety in adult day surgery (A.F. Smith and Pittaway 2003) concluded that use of benzodiazepines does not delay discharge after adult outpatient surgery but that less is known about the actual clinical benefit of these medications for preoperative anxiety. Since that review, Pekcan et al. (2005) reported that in comparison with placebo, premedication with oral diazepam (10 mg) in the evening before surgery and midazolam (1.5 mg) at least 15 minutes before surgery resulted in lower preoperative anxiety as well as a reduction in the usual postoperative increase in cortisol. Among women undergoing abdominal hysterectomy, diazepam-treated patients had lower postoperative anxiety and lower incidence of surgical wound infection compared with those receiving placebo (Levandovski et al. 2008). One RCT (C.C. Chen et al. 2008) of 80 women undergoing gynecological surgery found that presurgical administration of 30 mg of mirtazapine plus dexamethasone was associated with a reduction in preoperative anxiety and reduced the risk of postoperative nausea and vomiting compared with presurgical administration of dexamethasone alone. Other medications have also shown promise, including gabapentin (Ménigaux et al. 2005) and clonidine (Caumo 2009). Although several studies have concluded that benzodiazepines (especially midazolam) reduce anxiety, particularly among pediatric dental and oral surgery patients, a Cochrane Database review (Matharu and Ashley 2005) was unable to reach a definitive conclusion on which was the most effective drug or method of sedation for anxious children.

Although providing information and social support may be more time-consuming than prescribing an anti-anxiety agent, it may be more effective than medication in reducing preoperative anxiety and is likely to have postoperative benefits as well.

Children and Preoperative Anxiety

It is estimated that as many as 4 million children undergo anesthesia and surgery annually in the United States, and as many as 40%–60% experience significant anxiety before surgery. It has been postulated that postoperative outcome may be influenced by preoperative anxiety. Kain et al. (1996, 2002) emphasized the importance of educating parents about the possible negative behavioral responses that children may have after surgery. Figure 30–1 illustrates changes in the number of negative behavioral responses after surgery as a function of time. At 2 weeks postoperatively, most children had one to three negative behavioral responses, but only 7.6% had seven or more negative responses. By 1 year, only 7.3% of children had one to three negative responses, and no subjects had more than four negative responses.

In a comparison of four different means of relieving preoperative anxiety in children, Kain et al. (2007) found that the ADVANCE method (a family-centered behavioral approach) was superior to parental presence during induction of anesthesia, oral midazolam, and a control condition (usual care). A careful evidence-based review (Chundamala et al. 2009) also concluded that contrary to popular belief, parental presence does not usually relieve anxiety in either the child or the parent; these reviewers suggested that premedication with midazolam may be helpful, as well as distractions such as “clown doctors” (Vagnoli et al. 2005). Rawlinson and Short (2007) have reviewed books that may help children prepare for surgery. For example, *Going to the Hospital*, by Ann Civardi (2005), is recommended for children ages 2–4 years to help prepare them for undergoing anesthesia, and *Chris Gets Ear Tubes*, by Betty Pace (1987), is recommended for children ages 5–7 years to help prepare them for going to the hospital (or ambulatory surgery center).

Although there is great interest in whether preoperative patient-related factors in children are associated with an increase in emergent delirium following surgery and anesthesia, results of studies are conflicting. One review concluded that intense preoperative anxiety (both in children and in their parents), younger age, and less adaptability to environmental changes may contribute to postanesthesia agitation (Vlajkovic and Sindjelic 2007).

Fear of Needles, Blood, and Medical Equipment

Fear of needles is common and may first arise in the preoperative period. Estimates of the prevalence of needle phobia have ranged from 10% to 21% (Hamilton 1995; Nir et al. 2003), but probably about 8%–10% of adults have unreasonable fears of needles that interfere with treatment. Needle phobia appears to be partly inherited (especially the vasovagal response that may result in fainting) and partly

FIGURE 30-1. Decreases in postoperative negative behavioral symptoms in children shown as a function of time.

learned from conditioned responses, including past fainting spells when injected or after watching others being vaccinated (Hamilton 1995; Neale et al. 1994; Nir et al. 2003). Individuals who experience disgust in response to needles may be more likely to faint (Page 2002). Initial treatments for needle phobia have been primarily described in case reports and included behavioral strategies (exposure techniques and participant modeling), empathy from treating professionals, and anesthesia. In a small controlled trial in children and adults receiving chemotherapy, needles and syringes decorated with butterflies were compared with standard needles and syringes (Kettwich et al. 2007). These devices reduced aversion, anxiety, fear, and overall stress in 76% of children and 92% of adults.

Fear of blood is closely related to fear of needles. There may be a genetic component to these fears as well. In a study of 541 monozygotic twins and 388 dizygotic twins in the Virginia Twin Registry, unreasonable fears of blood, needles, hospitals, and illness were correlated and showed family aggregation (Neale et al. 1994). A recent review of treatments for blood, injury, and injection phobias concluded that data for effective treatment are limited and that exposure techniques might result in the greatest improvements (Ayala et al. 2009). Some patients are fearful of contracting HIV or hepatitis virus from blood transfusions (now a very rare occurrence) or from needles contaminated with blood (although this should never occur, except in very poor countries); correcting misconceptions and providing accurate information can be reassuring.

Blood refusal is common and is usually related to religious beliefs or fear of blood-borne infections. Because Jehovah's Witnesses and others have refused blood transfusions, there has been a rigorous pursuit of alternatives. Many surgeries previously thought to require transfusions are now routinely done without them. A recent review (Hughes et al. 2008) found that increased morbidity and mortality is rarely observed in patients with a hemoglobin concentration greater than 7 g/dL, and the acute hemoglobin threshold for cardiovascular collapse may be as low as 3-6 g/dL. Various other strategies (such as intravascular volume expanders) may eventually permit even fewer transfusions.

If the patient refuses blood, a careful psychiatric assessment may be needed to determine why the patient is refusing and whether the patient is competent to refuse treatment. For anxious patients, cognitive-behavioral interventions and benzodiazepines are helpful. If the patient is a child and the parents refuse transfusion on the basis of the parents' beliefs, legal and ethical consultation should be obtained, but the decision is usually to transfuse the child.

Fear of medical equipment is also common. Claustrophobia in a closed magnetic resonance imaging (MRI) device is the best described and may result in inability to obtain a scan. Use of an open MRI was shown to result in successful scans in 94% of 50 patients with claustrophobia who had been unable to tolerate the closed MRI (Spouse and Gedroyc 2000). A plan to devise an open positron emission tomography scanner has been described (Yamaya

et al. 2008) that may reduce patient stress and permit doctors and nurses to assist patients during scanning. Various coping strategies for the claustrophobia, including patient education and various relaxation techniques, are often helpful but have not been systematically investigated.

Intraoperative Issues—Anesthesia and Awareness With Recall

In 1992, Ghoneim and Block stated: "It is a sobering commentary that after 145 years it is not always possible to determine with certainty whether an anesthetized patient is conscious during surgery" (p. 296). This is still true more than 15 years later, despite multiple efforts to determine whether the patient is conscious. During the past decade, several large studies have concluded that a small percentage of adult patients, between 0.1% and 0.6%, can explicitly recall events that occurred during surgery (for a review, see Errando et al. 2008 and Samuelsson et al. 2007). Although this is a small percentage, given the many surgical procedures performed, a large number of patients are involved. Errando et al. (2008) used the following definition of awareness with recall (AWR): "when the patient (spontaneously or at interview) stated or remembered that he or she had been awake at a time when consciousness was not intended" (p. 179). The incidence of AWR in a large study of 928 children was 0.6% (Blussé et al. 2009), which may be higher than among adults. Several factors are known to influence the likelihood of AWR, including type of anesthesia, type of pre-anesthetic, and depth of anesthesia. A new method to assess the depth of anesthesia—the bispectral index (BIS), developed from a processed electroencephalogram—was initially thought to offer promise in terms of determining a depth of anesthesia that was both safe and decreased the likelihood of AWR. However, in a careful comparative study of 2,000 patients randomly assigned to BIS-guided anesthesia or end-tidal anesthetic gas (ETAG), there was no difference in incidence of AWR between the two groups even when the anesthesia was in the target range for each procedure (Avi-dan et al. 2008).

It has been recognized that during surgery there can be sensory, emotional, and cognitive symptoms associated with awareness and that after surgery there can be early or late psychiatric symptoms. A few patients with AWR have severe lasting psychiatric symptoms often closely associated with PTSD (Samuelsson et al. 2007).

At this time, it is not possible to prevent all cases of intraoperative awareness (and it may be even more difficult as day surgery becomes more common, because a lighter stage of anesthesia is used). Preoperative preparation of the patient for the unlikely possibility of AWR may be

helpful. It is always prudent for the surgical and anesthesia team to avoid inappropriate comments that may be remembered by the patient. If AWR occurs, a psychiatrist should be consulted in the immediate postoperative period and follow-up care arranged to ensure that appropriate treatment is provided if symptoms persist.

General Postoperative Issues

Alcohol Dependence

Chronic alcohol misuse is more common in surgical patients than in psychiatric or neurological patients. Almost half of all trauma beds are occupied by patients who were injured while under the influence of alcohol (Gentilello et al. 1995; Spies et al. 1996). In addition to the life-threatening complications of the alcohol withdrawal syndrome, the rate of morbidity and mortality resulting from infections, cardiopulmonary insufficiency, and bleeding disorders is two to four times greater in patients with chronic alcoholism (Spies et al. 1997). The development of an alcohol withdrawal syndrome can change a normal postoperative course into a life-threatening situation in which the patient requires intensive care unit (ICU) treatment.

Nearly 50% of patients hospitalized in trauma centers have an alcohol-related injury (Soderstrom 2005). Compared with trauma patients who are not intoxicated at the time of injury, intoxicated trauma patients are more likely to suffer another injury within 28 months (Rivara et al. 1993). In one study, patients admitted to trauma centers with a blood alcohol concentration (BAC) greater than zero died from subsequent injury at nearly twice the rate as that in a cohort of patients with negative BAC tests (Dischinger et al. 2001). Methods for screening medical/surgical patients for alcohol misuse are discussed in Chapter 17, "Substance-Related Disorders."

An alcohol-related history is frequently unobtainable in trauma patients because of their injuries (which may include closed head injury) and subsequent endotracheal intubation. Laboratory tests with sufficient sensitivity and specificity may assist in the diagnosis and possible prevention of complications (Sillanauke 1996). If an ordinary alcohol history is not obtainable, the biological marker known as carbohydrate-deficient transferrin is a useful alternative. The carbohydrate-deficient transferrin correlates with alcohol consumption in surgical patients (Tønnesen et al. 1999).

Chronic alcohol intake may produce either enhanced or reduced sensitivity to anesthetics. The net effect varies with the amount of alcohol used, the relative affinity of alcohol and other drugs for the microsomal enzymes, and the severity of any underlying liver injury (Lieber 1995).

Alcohol dependence is often complicated by disorders such as cirrhosis, seizures, pancreatitis, polyneuropathy, cardiomyopathy, and/or other psychiatric conditions. It seems obvious that surgical interventions in an alcoholic patient with one or more of these disorders may be associated with increased morbidity and mortality. An increased risk of complications is seen after both minor and major surgery, as well as after elective and emergency procedures. In general, the risk of postoperative infections is related to decreased immune function and enhanced stress response to surgical trauma. This enhanced stress response is characterized by a greater release of stress hormones and catecholamines in patients with alcoholism compared with control subjects (Moesgaard and Lykkegaard-Nielsen 1989; Tønnesen et al. 1992). Alcoholic patients are at risk for excessive surgical blood loss secondary to coagulopathy from liver disease and platelet dysfunction. Many alcoholic patients are chronically malnourished, which retards wound healing.

Opioid Dependence

There is no evidence to suggest that provision of appropriate doses of opiates for postoperative pain in the hospital creates addiction, yet some patients who fear becoming dependent decline or underuse postoperative opiates. If a surgical patient is receiving methadone maintenance, the dose used for maintenance should be continued throughout the surgical hospitalization. If the opioid-dependent patient does not have an established maintenance regimen, control of withdrawal can, in most cases, be achieved with methadone dosages of 10–30 mg/day. Once-daily dosing is usually sufficient to prevent withdrawal, but the total daily dose can be split into two or three doses to prevent breakthrough symptoms and maximize pain management. If anesthesia is necessary, the anesthesiologist obviously should be provided with the history of the patient's opioid dependence. Pentazocine or other mixed agonist–antagonists such as buprenorphine are contraindicated for analgesia, as they can cause or worsen withdrawal because they compete with other opiates and block their effect, mainly at the mu opioid receptors.

Postoperative opiate-dependent patients require higher doses of opiates to control surgical pain because of tolerance. When such patients are given only “normal” doses, they complain of not receiving enough and often are considered to be inappropriately “drug-seeking” when in fact they are being undermedicated. See also Chapters 17 (“Substance-Related Disorders”), 31 (“Organ Transplantation”), and 36 (“Pain”).

Postoperative Delirium

Both surgical advances and increases in the elderly population have resulted in more operations in patients who

have serious comorbid illnesses that increase the risk for postoperative delirium. The rise in day surgeries also complicates full recognition of risk factors, but efforts are being made to address this issue with the development of rapid screening methods. It has long been suspected that postoperative delirium may either reflect preexisting undetected dementia or be a risk factor for postoperative development of dementia, particularly in older patients.

Postoperative delirium is common; however, the incidence depends on patient variables as well as the type of surgery. In one large study of patients 50 years and older undergoing an operation requiring a postoperative ICU stay, 44% developed delirium that began a mean of 2 days after surgery and had a mean duration of 4 days (Robinson et al. 2009). This percentage is significantly higher than that in younger patients who do not require an ICU stay.

Risk Factors and Preoperative Screening Strategies

Risk factors for postoperative delirium include patient variables and surgical variables. Presurgical patient risk factors for postoperative delirium include dementia, older age, cognitive impairment (especially executive function), and depression (Greene et al. 2009; Kazmierski et al. 2008; Robinson et al. 2009) as well as the underlying illness requiring surgery and various other comorbid conditions (including substance use disorders). “Frailty” among older patients undergoing surgery has been found to be associated with postoperative complications (Dasgupta et al. 2009). Surgical risks include type of surgery and type of anesthetic as well as the experience and skill of the surgeon, anesthesiologist, consultants, nursing team, and hospital support system. Methods for screening and diagnosing delirium are reviewed in Chapter 5, “Delirium.”

Consequences of Postoperative Delirium

Delirium in the surgical trauma patient is independently associated with more days requiring mechanical ventilation, longer ICU and hospital stays (Lat et al. 2009), and higher early mortality rates (e.g., Robinson et al. 2009).

Treatment of Postoperative Delirium

There are several recent reports of various medications for postoperative delirium. Cholinesterase inhibitors have been ineffective (Gamberini et al. 2009; Sampson et al. 2007). Traditionally, the antipsychotics (particularly haloperidol in the past and more recently the atypical antipsychotics) have been utilized for management of behavioral symptoms that are disruptive to required care in postsurgical patients who develop delirium. The evidence for the effectiveness of antipsychotics is slender, but their use is widely practiced.

Prevention of Postoperative Delirium

Despite the cautions regarding cardiac risk with antipsychotic medication, it may be that in some circumstances the benefits outweigh the risk, especially since delirium following surgery can be very hazardous. RCTs in surgical patients have shown that low-dose haloperidol may prevent postoperative delirium (Kaneko et al. 1999) or reduce its severity and duration (Kalisvaart et al. 2005). An RCT in cardiac surgery patients found that 1 mg risperidone given preoperatively reduced the incidence of postoperative delirium significantly (11.1% in risperidone group vs. 31.7% in placebo group) (Prakanrattana and Prapaitrakool 2007). Other possible preventive measures are being considered as well, including bright light therapy immediately after surgery (Taguchi et al. 2007) and preoperative tryptophan (Robinson et al. 2008).

Quite compelling, however, are the reports indicating that reduction of risk for postoperative delirium is more likely to be achieved with a team approach that includes geriatric nurses and consultants working together to reduce the many potential risks (Gurlit and Möllmann 2008; Marcantonio et al. 2001) even though this is easier to accomplish in a hospital setting than in ambulatory care. For further discussion of delirium and its management, see Chapter 5, "Delirium."

Posttraumatic Stress Disorder in the Postoperative Period

In the surgical arena, PTSD has been best studied in trauma patients (especially burn patients) and motor vehicle accident victims (E. Klein et al. 2003), but several studies have shown that a significant percentage of patients also develop PTSD following cardiac surgery or neurosurgery (Powell et al. 2002; Stoll et al. 2000). Although full syndromal PTSD develops in 18%–40% of adult patients after trauma, many more develop some of the symptoms of PTSD. Children who experience traumatic disfiguring injuries seem to be at particular risk, with up to 82% having some symptoms of PTSD 1 month after the trauma (Rusch et al. 2002). Quality of life is significantly impaired in patients who develop PTSD posttrauma or postsurgery compared with patients who do not develop PTSD (Zatzick et al. 2002).

Several studies have tried to identify factors that predict the emergence of PTSD (for a review, see Tedstone and Tarrrier 2003). As expected, better prior emotional adjustment and social support are relatively protective. However, contrary to expectation, the severity of the injury, or the severity of the illness requiring surgery, is not clearly correlated with the emergence of PTSD. Also, alcohol intoxication or concussion at the time of the trauma seems to decrease the

likelihood of PTSD (perhaps because memory for the event is impaired). Furthermore, some patients with no apparent predisposing factors develop PTSD. The course of PTSD is not completely clear, but symptoms usually appear within the first week after a trauma and increase in intensity over the next 3 months. Perhaps the best predictor of PTSD at 1 year is the presence of symptoms during the acute hospitalization after a trauma (McKibben et al. 2008; Zatzick et al. 2002). Although most studies show that symptoms decrease by 1 year, many patients continue to meet full criteria, and many more still have symptoms.

Diagnosis of acute stress disorder, PTSD's predecessor, can be difficult in surgical trauma or postoperative patients who manifest symptoms of delirium. For the diagnosis of PTSD, the duration criterion is often not met in hospitalized patients because of relatively brief hospital stays. Almost all patients who meet full criteria will have nightmares, but among patients with only some symptoms, the cluster of symptoms likely to be affected varies. For example, female burn victims with facial burns have been reported to have predominantly avoidance and emotional numbness symptoms (Fukunishi 1999), whereas re-experiencing and startle symptoms are more likely in other burn patients (Ehde et al. 1999).

In the United States, 20% of general hospital ICU survivors have symptoms consistent with a diagnosis of PTSD (Davydow et al. 2008). The National Comorbidity Survey data (Kessler 1995) suggested that more than 50% of individuals who are symptomatic at 12 months will remain symptomatic at the 5-year posttrauma time point. A more recent report found that among burn patients, once PTSD is established, it usually persists (McKibben et al. 2008). Thus, early PTSD screening and intervention may have the potential to mitigate chronic PTSD after injury.

Treatment of PTSD in medical settings is covered in Chapter 11, "Anxiety Disorders." Few studies of treatment of PTSD have been done specifically in surgical patients, but general principles appear applicable. Cognitive-behavioral therapy has been shown to be more effective than a wait-list control condition or supportive psychotherapy for PTSD among motor vehicle accident survivors (Blanchard et al. 2003). There is general agreement (although not much evidence) that psychotherapy should be the primary treatment of trauma-related PTSD in children and that the SSRIs should be adjunctive (Putnam and Hulsmann 2002).

Postoperative Pain

There have been dramatic advances in the understanding and treatment of postoperative pain, as evidenced by a significant increase in RCTs (75 during the past 10 years, 73 of these in English) (National Center for Biotechnology Infor-

mation database [www.ncbi.nlm.nih.gov]; accessed September 30, 2009). Many of these studies focused on pain relief measures instituted by anesthesiologists (e.g., "Postoperative pain and analgesic requirements after anesthesia with sevoflurane, desflurane, or propofol," by Fassoulaki et al. 2008) and on the use of patient-controlled analgesia (PCA). A Cochrane Database review of PCA (Hudcova et al. 2006) reported on a meta-analysis of 55 studies involving 2,003 patients assigned to PCA compared with 1,838 patients assigned to conventional "as needed" pain relief. Patients assigned to PCA used higher amounts of opioids than did control patients and had more pruritus but a similar pattern of other adverse events. The groups did not differ in length of hospital stay, but the PCA group had better pain control and greater patient satisfaction compared with the conventional as-needed pain relief group.

Despite these encouraging findings, significant misunderstandings about opioids and other pain-relieving measures persist. Although there have been improvements in the management of uncomplicated postoperative pain, this is often not the case if the operation occurred for an illness that has enduring chronic pain, or in patients who have a history of substance use disorders. There have been valiant attempts on the part of various legislative bodies to improve the knowledge base of physicians about pain management; for example, in California, physician licensees are required to take an 8-hour course in pain management. Nonetheless, erroneous beliefs about pain medication continue (especially in regard to a patient who requires more pain medication than the usual uncomplicated patient). It is worth remembering, however, that a dramatic rise in misuse of pain medications (Substance Abuse and Mental Health Services Administration Health Information Network [www.samhsa.gov/shin]; accessed September 30, 2009) among people with substance use disorders occurred at roughly the same time as the Joint Commission on Accreditation of Health Care Organizations implemented its new standards of pain management in 2001 (see Summers 2001 for a review of the development of these guidelines). Thus, the physician managing postoperative pain must consider many factors, including the nature of the surgery, the usual range of requirements for pain medication (which vary widely among patients), the presence of underlying chronic pain, any history of a substance use disorder, and current vulnerability to relapse (if the patient is in remission from misuse of pain medications).

Body Image and Surgery

Body image is the inner mental experience of one's body, with a neurological substrate, also influenced by prior life events and interactions within important relationships. All of the senses contribute to body image, but touch and kin-

esthesia may be the most important. Whereas body image develops throughout life, the changes that occur during childhood, and particularly during adolescence, are relatively enduring. Nonetheless, there can be wide fluctuations in the experiencing of one's body. Adaptations to the new realities of the body (including aging, trauma, and surgical alteration) can occur, but a host of factors influence how readily these changes are incorporated. In three important surgical areas, body image is key to patient outcome: 1) amputation and the phenomenon of phantom limb pain; 2) change in body image that may occur after trauma or surgery, including cosmetic surgery; and 3) body image concerns in bariatric surgery patients.

Phantom limb is the experience of feeling as if an amputated part is still present. It was first described by Ambrose Paré (1649), a seventeenth-century surgeon. In the United States, approximately 134,000 surgical amputations occur annually (Zanni and Wick 2008). Many amputees experience phantom limb sensations, which range from pleasant warmth to discomfort (pain, paresthesias, itching). Chronic phantom limb pain occurs in up to 85% of amputees and is a cause of significant disability and impaired quality of life (see Brodie et al. 2007 for summary). Many previous studies of phantom limb have been complicated by a failure to distinguish between stump pain and various types of phantom limb phenomena (C. Richardson et al. 2006). Multiple interacting factors contribute to distressing phantom limb sensations and pain, including a previous history of pain and passive coping styles (C. Richardson et al. 2007).

The exact etiology of the phantom limb experience and the pain that often accompanies it is complex and poorly understood. Phantom limb pain is considered to be an example of neuropathic, rather than nociceptive, pain (see Chapter 36, "Pain"). This conceptualization underlies ingenious treatment strategies such as "mirror therapy" (Brodie et al. 2007; Chan et al. 2007; Darnall 2009) and the "rubber hand illusion" technique (Ehrsson et al. 2008), as well as the pharmacological options discussed in Chapter 36, "Pain."

There are also patients who request that a healthy limb be amputated. There are several case reports and one case series (First 2005) of a group of 52 patients, 17 of whom did have amputations (either from their own efforts or after enlisting the assistance of a surgeon), and many felt better afterward. This has been called "body integrity identity disorder" and may be an extreme type of body image disturbance. It might also be an unusual variant of body dysmorphic disorder. Consultation-liaison psychiatrists might be asked to evaluate a patient with this problem, which in some ways appears to be the opposite of phantom limb phenomenon.

In addition to amputations, body image can change after trauma or surgery. Trauma, as in the case of burn inju-

ries, may cause dramatic changes in the body that require significant adaptation and integration of these changes into a new body image. However, the ease with which such integration occurs is influenced more by premorbid adjustment and stage of development than by the actual percentage of total body surface area (TBSA) burned.

The literature on body image in obesity is extensive. Stunkard and Burt (1967) studied body image in obese individuals who had lost significant weight. They found that these patients often misperceived themselves as still large and frequently had negative attitudes toward this misperception. The definition of body image in patients with eating disorders has evolved to divide body image into perceptual and attitudinal aspects. Most current studies of body image following bariatric surgery focus on one part of the attitudinal aspect of body image called *body satisfaction*.

General Determinants of Functional Outcome

Functional outcome includes the ability to carry out the activities of daily living, the ability to function in one's usual role, and satisfaction with life. These areas are currently being explored under the category of quality of life. Perhaps the most interesting finding is that the actual severity of the underlying trauma or surgery does not necessarily determine quality of life. For example, the percentage TBSA burned does not directly correlate with the likelihood of PTSD, nor does the size of a scar necessarily correlate with posttraumatic adjustment. It has been repeatedly reported that an adequate social support system is positively correlated with postsurgical and posttraumatic adaptation.

A confluence of factors determines functional outcome. These factors include the condition requiring surgical intervention, presurgical psychiatric status, and surgical strategy. Other factors that may improve outcome include preparation of the patient and family for surgery, detection and management of preoperative fears, respectful attitude of the surgeon and operating room personnel during surgery, detection and appropriate treatment of pain, and detection and management of various psychiatric problems following surgery, including delirium and PTSD.

Specific Topics in Surgery

Burn Trauma

The experience of being seriously burned and the treatment that follows for the survivors is one of the most frightening and painful known to humanity. Perhaps be-

cause of this, several important concepts in medicine have been learned from the study of burn victims. For example, Erich Lindemann (1944/1994) described the evaluation and treatment of survivors, friends, and relatives of people who died in the Coconut Grove fire. He identified five major symptoms of normal grief: somatic distress, preoccupation with the image of the deceased, guilt, hostile reactions, and loss of patterns of conduct. These concepts continue to influence the management of normal and pathological acute grief in burn units and elsewhere.

Imbus and Zawacki (1977) opened an ethical debate over prolongation of life that continues today. An unusual aspect of burns is that even mortally burned patients often have a lucid period that lasts for a few hours during which patients can participate in making decisions about their own care. For every severely burned patient, these investigators searched the literature to determine whether cases of survival had been reported, and, if not, they offered the patients a choice between a full therapeutic regimen and palliative care. They concluded that the mortality rate did not change but that this strategy increased the autonomy of patients and increased the empathy that they received. This report ignited a controversy that has grown to encompass all critical care: when is treatment futile, and who should decide?

The American Burn Association (2007) reports that an estimated 500,000 people a year receive treatment for burns in the United States. There are approximately 4,000 burn-related deaths annually, with 3,500 of these from residential fires. In 2007, there were 40,000 hospitalizations for burn injuries, which included 25,000 admissions to 125 hospitals with specialized burn centers. The percentage of patients admitted to specialized burn centers has progressively increased, from about 50% in 2004 to 60% in 2007. Burn centers now average 200 admissions per year, whereas other U.S. hospitals average fewer than 3 burn admissions per year. Interdisciplinary specialized burn centers are staffed by physicians, nurses, physical and occupational therapists, pain specialists, mental health professionals, social workers, and chaplains. Typically, the burn center is directed by either a general surgeon or a plastic surgeon. Burn Center Verification is an accreditation process intended to enhance the quality of care at specialized burn centers. Since the inception of this program in 1995, 70 centers have met the rigorous requirements for participation. Other important developments include establishment of the American Burn Association National Burn Repository (ABA-NBR), which (as of 2005) included data for more than 31,000 adult patients admitted to these 70 burn centers, and the National Institute on Disability and Rehabilitation Research Burn Model System Database, which included data for 3,400 patients alive at dis-

charge who have consented to follow-up data collection (M.B. Klein et al. 2007).

Psychiatric Disorders Among Burn Patients

Many burn patients have preexisting psychiatric disorders, the most common of which are substance use disorders and mood disorders. The classic studies of adults by Andreasen et al. (1972) and of children by Bernstein (1976) led to the recognition that psychiatric problems are very common among burn patients. A study using ABA-NBR data reported that 12.3% of patients admitted to the burn centers had psychiatric disorders. Of these, alcohol abuse accounted for 5.8%, drug abuse for 3.3%, dementia for 0.3%, and other psychiatric disorders for 2.9% (Thombs et al. 2007). These percentages are significantly lower than those found in other reports, and this study had some notable limitations; for example, not all patients in the ABA-NBR were evaluated by mental health professionals, ICD-9-CM (World Health Organization 1978) codes were utilized rather than DSM criteria, and personality disorders were not considered. By contrast, a recent study at one burn center found that two-thirds of burn survivors had a history of lifetime psychiatric disorders and that those with such a history were more likely to have postburn psychiatric problems (Dyster-Aas et al. 2008). Nonetheless, in the study by Thombs et al. (2007), after controlling for demographic and burn injury characteristics, it was found that preexisting alcohol abuse was a significant predictor of mortality in the burn unit and that preexisting dementia, psychiatric diagnosis, alcohol abuse, and drug abuse were all significantly associated with increased length of hospital stay. Many smaller studies from single burn centers have found that many patients have preexisting maladaptive coping mechanisms or dysfunctional families, and these factors are known to predispose to poorer functional outcomes.

There have been several recent attempts to understand, quantify, and modulate the multiple interacting negative factors that may worsen functional status and quality of life in patients who have had significant burns. A recent consensus summit of burn rehabilitation clinicians from the United States and Canada addressed 15 key topic areas pertinent to clinical burn rehabilitation (Richard et al. 2009). Another group from England and Australia (Falder et al. 2009) identified seven core domains of outcome for adult burn survivors, four of which are particularly relevant to psychiatric assessment and treatment: 1) sensory and pain, 2) psychological function (PTSD and depression), 3) community participation (social integration), and 4) perceived quality of life. In their extensive review, Falder et al. (2009) evaluated questionnaires and instruments that have been used to diagnose the common psychiatric complications following burn injuries. For example, they noted that PTSD

symptoms that occur in the acute phase of treatment are associated with poorer long-term psychological recovery. Methods of assessing PTSD discussed include clinician-administered instruments (Clinician-Administered PTSD Scale; Structured Clinical Interview for DSM) and self-report measures (Impact of Events Scale; Davidson Trauma Scale). The validity and reliability of these instruments in assessing burn patients are clearly described. Regarding depression, the authors noted that very careful assessment of patients who are in the acute phase of treatment is required to accurately distinguish symptoms of depression from physiological symptoms related to the burn injuries (Falder et al. 2009). Use of the recommendations from this review is likely to be very helpful in guiding future research in terms of identifying adult patients with the most common psychiatric complications of burn injuries.

A unique psychopathological topic in burn care is self-immolation, discussed below. The meaning and psychological importance of burn scars (particularly of the face, hands, and genital area) have been studied as well. Equally important in burn care is the delirium that frequently occurs during the acute-care phase. Psychiatric consultants also have described effective methods for the management of pain in burn patients. One method of conceptualizing the psychiatric problems seen in burn patients is to envision a time sequence from preexisting psychiatric problems to problems that develop after the patient leaves the hospital. Thus, there are preexisting psychiatric disorders and psychosocial problems (including those that have resolved but may be rekindled by the trauma), problems that occur at the time of the injury, problems that emerge during acute hospitalization, and psychiatric disorders that develop after discharge from the hospital.

Burns and substance use disorders. Preinjury substance use disorders are common among burn victims. One study found that among 727 deaths from fires, blood alcohol assays were positive in 29%, with a mean blood ethanol level of 193.9 mg/dL; 14.6% of the victims studied had positive results for other substances of abuse (Barillo and Goode 1996). Although 40% of the fatalities were in people younger than 11 years or older than 70 years, 75% of the drug-positive and 58% of the ethanol-positive fatalities were in people between the ages of 21 and 50 years. The authors concluded that substance use disorders are a particular risk factor for death from fires in the middle-aged sector of the population.

Among patients who survive to be treated, several studies have attempted to identify the prevalence of alcohol intoxication, alcohol abuse, or alcohol dependence. One study (J.D. Jones et al. 1991) found that 27% were intoxicated at the time of the burn, and 90% of these were then

identified as having an alcohol abuse diagnosis compared with 11% of the nonintoxicated burn patients. Other reports estimated the prevalence of alcohol abuse and dependence in patients with burn injuries as between 6% and 11% (Powers et al. 1994; Tabares and Peck 1997). The Alcohol Use Disorders Identification Test (developed by the World Health Organization; J.B. Saunders et al. 1993) was more effective in identifying at-risk drinkers than blood alcohol level among a group of 123 burn patients (Albright et al. 2009). Steenkamp et al. (1994) found that 57% of the patients had evidence of alcohol problems on the Michigan Alcoholism Screening Test, and of these patients, 57% thought that the use of alcohol had contributed to the accident.

Among burn patients who are identified as having alcohol or drug problems, referral for treatment occurs in fewer than half of the patients (Powers et al. 1994), and among those who are referred, fewer than half accept treatment (Tabares and Peck 1997). Denial is a key defense mechanism in patients with substance use disorders, but the crisis of a burn trauma may be an opportunity to broach this defense. Psychiatrists (and other mental health consultants) on the burn unit are often in a unique position to help burn patients relinquish the denial that prevents appropriate treatment. Alcohol use has been found to be associated with increased percentage TBSA burned, an increased likelihood of death, longer length of hospital stay, and, consequently, increased medical costs (J.D. Jones et al. 1991; Powers et al. 1994). Silver et al. (2008) found that even after controlling for age, sex, and percentage TBSA burned, patients with admission blood alcohol levels above 30 mg/dL had longer durations of mechanical ventilation, longer lengths of stay in the ICU, and higher hospital charges compared with patients with undetectable blood alcohol levels. The reasons for these deleterious consequences are the subject of intense study at present. For example, ethanol exposure prior to burn injury in mice is associated with elevated proinflammatory cytokines (interleukin 6 [IL-6] and tumor necrosis factor- α [TNF- α]) and aberrant inflammatory responses (Bird and Kovacs 2008). In a recent review, Choudhry and Chaudry (2008) suggested that alcohol intoxication before burn injury suppresses intestinal immune defense, impairs gut barrier functions, and increases bacterial growth, all of which may contribute to postinjury infections.

Withdrawal symptoms from alcohol dependence may be difficult to distinguish from other causes of delirium. Given that many patients who were intoxicated when burned are nondependent binge drinkers (Albright et al. 2009), alcohol withdrawal is less common than one otherwise might predict. The relevant literature regarding the appropriate treatment when alcohol dependence is sus-

pected is limited to a few case reports and case series. The best approach in a burn unit may be a standard withdrawal protocol with a relatively long-acting benzodiazepine (e.g., chlordiazepoxide). Because 90% of intoxicated burn patients abuse alcohol, and because the development of alcohol withdrawal can be particularly dangerous in a burn patient, a liberal approach to prescribing the withdrawal regimen among patients suspected of alcohol dependence is probably the safest course of treatment. Although intermittent administration of benzodiazepines, especially the short-acting ones such as lorazepam, has been advocated, this may not be wise because the complex phenomenology of the acute phase of burn care may obscure the presence of withdrawal symptoms. Haloperidol is frequently added to the regimen for psychotic symptoms during withdrawal but should not be used alone.

Even though burn patients have a high rate of preexisting drug abuse, withdrawal from narcotics is less likely because most patients require narcotic treatment for pain. However, it is helpful to remember that burn patients with preexisting opioid dependence may require a larger dose of narcotics to suppress pain, and this larger dose should be provided.

Self-inflicted burn injuries. The frequency of self-immolation varies widely from nation to nation; the reasons for self-immolation also vary. In a study in Iran, for example, 27% of suicide cases were the result of self-immolation, and 71% of these cases were in females. Suicide by self-immolation was more prevalent in provinces with severe postwar problems and in the Kurdish ethnic group. Self-immolation was more likely to be associated with unemployment but not with psychiatric disorders or lack of access to care (Ahmadi et al. 2008). By contrast, a report from Turkey indicated that 87.5% of self-inflicted burn injuries were in men, and that 62.5% of these men had psychiatric disorders (Uygur et al. 2009). A study in Zimbabwe reported that 22% of adult burn patients had self-immolated; most were married women, and the most common reason for self-immolation was conflict in a love relationship (Mzezewa et al. 2000).

In the United States, the frequency of self-inflicted injuries among patients who are admitted to a burn center ranges from 0.07% to 9% (Daniels et al. 1991; Scully and Hutcherson 1983). Although political and cultural motivations for self-immolation predominate in some cultures, in the United States, most severely burned patients who have self-injured have a preexisting Axis I psychiatric disorder, usually a psychotic disorder (Mulholland et al. 2008). Compared with patients who have been assaulted, patients with self-inflicted burn injuries are more likely to be male, to have a larger percentage TBSA burned, and to

have a longer mean length of hospital stay (Reiland et al. 2006). Substance abuse appears to increase the likelihood of a severe self-inflicted injury. Not all of these patients are actually suicidal; for example, patients with schizophrenia may be responding to command hallucinations.

Among patients who have inflicted less severe burns, personality disorders are common (Cameron et al. 1997), especially borderline personality disorder. The patient may continue to self-injure in the hospital and thereby pose a difficult management problem. The psychiatric consultant is often able to defuse these problems with judicious use of behavioral strategies known to be helpful for patients with borderline personality disorder (Wiechman et al. 2000). Close supervision may be required to prevent further self-harm when the patient moves from an ICU to a unit with less nursing supervision.

Patients with self-inflicted burns often elicit intense countertransference reactions from the entire staff, including the psychiatric team. It is helpful to remember that most patients (at least in the United States) with self-inflicted burns have a chronic mental illness, and that appropriate psychiatric care may not have been available to or effective for the patients. Burn center teams understand chronic medical illness and the need for expert treatment, and this "medical model" analogy may help them better understand and empathize with a patient who has chronic mental illness and who has a self-inflicted burn injury.

PTSD in burn patients. PTSD occurs in a significant minority of patients who have been burned. Estimates range from 21% to 45% (for a review, see Yu and Dimsdale 1999). A study by Zatzick et al. (2007) found that more than 20% of trauma survivors had symptoms of PTSD 12 months after acute inpatient care, and in a large prospective multisite cohort study of major burn injury survivors, psychological stress was common and tended to persist (Fauerbach et al. 2007). The difficulties in estimating frequency are often related to the confounding effects of delirium and mild traumatic brain injury and to the duration criterion requirement of 1 month. Many patients are discharged from the hospital before a month elapses, and less severely injured patients may not be seen again; thus, the diagnosis of PTSD may be missed. Nonetheless, many patients do develop the full syndrome of PTSD, and many more have symptoms in the reexperiencing cluster (particularly nightmares [Low et al. 2006]) even though they do not meet full criteria. Some patients also have PTSD symptoms related to their treatment, especially in regard to the extreme pain inflicted during debridement and dressing changes. Recent work has shown that acute pain is associated with long-term negative effects, including depression, suicidal ideation, and PTSD for as long as 2 years after the

burn injury (Wiechman Askay and Patterson 2008). Some patients also remember psychotic experiences from the delirium that often occurs during the acute phase of treatment, and these memories may elicit symptoms of PTSD.

Several attempts have been made to identify factors that predispose to the emergence of PTSD in burn patients, but clarity has yet to be achieved. Fauerbach et al. (2000) found that the personality characteristic of neuroticism increased risk and that high extroversion was protective. Six independent risk and protective factors for PTSD were identified from assessments of 127 burn victims trapped in a ballroom fire (Maes et al. 2001). The odds of developing PTSD were increased with the number of previous traumas, a history of simple phobia, and a sense of loss of control. In contrast, odds were decreased with a sense of control, alcohol consumption, and alcohol intoxication. In a study of 90 patients hospitalized for severe burns, Van Loey et al. (2008) found that those who attributed the injury to individuals not close to them and who were unforgiving were more likely to have PTSD. Gaylord et al. (2009) found that there was no difference in risk for PTSD between military personnel and civilians who suffered burn injuries; in this study, factors that predicted PTSD were percentage TBSA burned and scores on the Injury Severity Score.

Efforts are under way to determine the factors that increase risk of development of PTSD and modify these factors during the acute treatment phase in the hospital. In the large prospective multisite study described earlier (Fauerbach et al. 2007), it was found that a very high percentage of the burn injury patients (34%) experienced acute stress reactions that included feelings of "alienation" and anxiety in the hospital. Although in a few (12%), there was a change in the nature of the symptoms, the percentage of affected individuals remained high for at least 2 years, resulting in significant impairment in function and quality of life. In a prospective study by this same group (McKibben et al. 2008), the prevalence of in-hospital acute stress disorder in 178 patients was 23.6%, and 35.1%, 33.3%, 28.6%, and 25.4% of the participants met PTSD criteria at 1, 6, 12, and 24 months, respectively. Although not well studied, treatment of PTSD in burn patients is likely to be similar to treatment of PTSD in other patients (see Chapter 11, "Anxiety Disorders"). Thus far, reports of various medications for burn patients with PTSD have not yielded consistently helpful results. Increasing patients' sense of control and alleviating pain, especially during the acute phase of treatment in the burn center, may decrease the likelihood of emergent and enduring stress and anxiety symptoms.

Delirium and psychosis in burn patients. Delirium during the acute care of severely burned patients is common, although this topic has not been well studied. In one un-

published report, one-fourth of the burn patients were noted to be psychotic during their initial acute hospitalization. Most of these patients had delirium related to sepsis, pain medication, or other organic factors (Powers 1996). Other causes of delirium in burn patients include hypoxia from smoke inhalation, massive fluid shifts, and electrolyte imbalance, especially hyponatremia and hypophosphatemia. The psychotic symptoms that occur most often include hallucinations (often visual and not always distressing) and delusions. The delusions are often paranoid and frequently involve nursing care personnel. Because patients with delirium are disoriented, they frequently misinterpret events and may then suspect treatment personnel of malevolent intent. It is often difficult to distinguish between pain, agitation, anxiety, and confusion in the ICU, and the psychiatric consultant is invaluable in this differentiation. The principles of treatment of delirium in the burn unit are the same as described earlier for postoperative delirium (see subsection "Postoperative Delirium" earlier in this chapter; also see Chapter 5, "Delirium"). As the population ages and with continuing advances in burn care, many older patients will survive who are more vulnerable to delirium and will require the expertise of psychiatric consultants (Keck et al. 2009).

Burn Pain Management

Pain in burn care arises from both the pain from various procedures, including dressing changes and wound debridement, and the background pain of the injury itself. The key concept in managing pain on the burn unit is to recognize that it is often undertreated, and this can result in worsening delirium, anxiety, and other management problems. Symptoms resulting from acute distress in the burn center may endure for years after discharge. Depression, anxiety (and associated disorders such as PTSD), and pain influence one another and can result in long-term functional and psychological impairment and poorer quality of life (Ullrich et al. 2009). There is also a bidirectional relationship between sleep and pain. Patients with major burns who had insomnia at hospital discharge had significantly increased pain severity during long-term follow-up (M. T. Smith et al. 2008).

Pain is undertreated for many reasons, but the most important reasons are an unrealistic fear of addiction (both by the patient and by the physician) and fear of respiratory compromise (which, at least in the intensive care portion of most burn centers, can be adequately managed by competent nursing staff). Management of burn care pain requires a flexible therapeutic plan with frequent reassessment. Burn wound debridement (in which the eschar is removed) is an excruciatingly painful procedure, and various techniques are now available to alleviate much

of the pain. When sharp debridement (involving use of a scalpel) is needed, general anesthesia offers the greatest relief of pain and also may facilitate a more thorough debridement (Powers et al. 1993) and may help avoid some of the distress associated with long term psychological and functional impairments. Parenteral narcotics, especially intravenous morphine, are often preferable for blunt debridement (in which scalpels are not used) and dressing changes. A common error is not waiting the 10–15 minutes required for adequate distribution after intravenous injection of the opioid before beginning blunt debridement. Intramuscular injections are often contraindicated because they may add to the pain, and sufficient injection sites may not be available.

The background pain of burn injuries is best managed with oral narcotics whenever possible. Fentanyl is often helpful for intermittent pain because it is short acting and will allow the patient to be awake to participate in rehabilitation, but morphine is the gold standard and can be flexibly utilized (Connard-Ballard 2009; P. Richardson and Mustard 2009). Meperidine is usually contraindicated because it is relatively ineffective orally and may aggravate delirium. Benzodiazepines are often used to promote sedation and reduce anxiety, but the optimal dose is not known. They are often used inappropriately to treat pain. If pain is adequately managed and the patient has anticipatory anxiety, use of benzodiazepines may then be very helpful. Although many different strategies—including music, relaxation therapy, and maybe virtual reality techniques—may also contribute to the alleviation of pain, they should be adjunctive to the appropriate flexible use of opioids.

Treatment of Burns in Children

Several psychosocial research teams have been particularly interested in the treatment of burned children (Martin-Herz et al. 2003; Stoddard et al. 2002). These groups have emphasized the importance of the developmental stage of the burned child and the need for careful age-appropriate assessment and treatment of pain and anxiety. Emerging studies indicate that appropriate management of pain partially predicts the long-term outcome for the child. For example, Saxe et al. (2005) found that two pathways to PTSD are common among burned children and account for 60% of the variance in PTSD. The first pathway is from size of the burn and level of pain following the burn to the child's level of acute separation anxiety and then to PTSD. The second pathway is from the size of the burn to the child's level of acute dissociation following the burn and then to PTSD. Another study by Wollgarten-Hadamek et al. (2009) found that school-age children (ages 9–16 years) who had suffered moderate or severe burn injuries in infancy had alterations in sensory and pain processing. Because early

TABLE 30-1. Guidelines for pain and anxiety management in children with burns

Patient category	Background pain	Background anxiety	Procedural pain	Procedural anxiety	Transition to next clinical state
Category 1: mechanically ventilated acute	Morphine sulfate intravenous infusion	Midazolam intravenous infusion	Morphine sulfate intravenous bolus	Midazolam intravenous bolus	Wean infusions 10%–20% per day, and substitute nonmechanically ventilated guideline
Category 2: nonmechanically ventilated acute	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral or intravenous bolus	Lorazepam intravenous or enteral bolus	Wean scheduled drugs 10%–20% per day, and substitute chronic guideline
Category 3: chronic acute	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral bolus	Lorazepam enteral bolus	Wean scheduled and bolus drugs 10%–20% per day to outpatient requirements and pruritus medications
Category 4: reconstructive surgical	Scheduled enteral morphine sulfate	Scheduled enteral lorazepam	Morphine sulfate enteral bolus	Lorazepam enteral bolus	Wean scheduled and bolus drugs to outpatient requirements

traumatic and painful injuries can induce long-term alterations, management of acute pain in children in a burn center is crucial.

A guideline has been proposed for the management of pain and anxiety in children (Stoddard et al. 2002). It is based on intensity of care, whether the pain is background or procedural pain, and stage in the hospital (see Table 30-1). In designing this guideline, the focus was on safe, effective medications; a limited formulary; and nursing strategies to assess pain (with age-appropriate ratings). The guideline also was designed to contain explicit recommendations. The authors used this guideline in a series of 125 pediatric patients and reported excellent to adequate control of both pain and anxiety in most patients most of the time (Stoddard et al. 2002). One major advantage of the guideline is that the most-recommended drugs (morphine and lorazepam) are well known to most physicians. Only the use of intravenous infusion of midazolam for background anxiety in mechanically ventilated acutely ill pediatric patients would require an anesthesiologist or a critical care specialist.

Although psychological treatments of pain may ultimately prove to be effective for children, the evidence for these treatments is scant. Hanson et al. (2008) reviewed

900 citations for nonpharmacological treatments in children utilizing the U.S. Preventive Services Task Force criteria, and only seven were considered fair or good. Some of the strategies being considered—for example, music and virtual reality strategies—may eventually prove to be helpful adjunctive techniques.

Several studies have attempted to assess outcome in burned children including the reports noted above. One important confounding factor is that many children who are burned have preexisting psychiatric and psychosocial problems that influence long-term outcome. A study from the United Kingdom (James-Ellison et al. 2009) found that among children younger than 3 years who sustained burns (most of whom were thought to have accidental injuries), about one-third had been referred to Social Services by their sixth birthday, and 9.7% had been abused or neglected, compared with 1.4% of control subjects. A study from the Netherlands (Liber et al. 2008) found that adolescents with a history of childhood burns who used more passive coping methods had increased behavioral problems and more symptoms of depression. A better understanding of the long-term course of burned children will require multisite studies with larger numbers of children sharing similar characteristics.

Psychiatric Practice Guideline for Adults With Acute Burns

Although the evidence base is sparse, consensus guidelines have been developed for several areas of burn care, and a guideline has been proposed for the management of psychiatric disorders in adult burn patients during their initial hospitalization (Powers 2002). Figure 30-2 is a revision of this algorithm designed to incorporate recent findings and to guide the clinician in assessment and management of burn patients with psychiatric problems. A major difference is that it is now widely recognized that nearly all patients and their families benefit from having more information and that for most, participation in the planning and treatment process facilitates recovery. One example of this approach, which has been termed "family inclusive care," is described by Sacco et al. (2009).

Facial Disfigurement and Scars

The adaptation to facial disfigurement depends, in part, on the age at which the disfigurement occurs. Children with congenital disfigurement often encounter significant developmental difficulties and are frequently stigmatized by peers, adults, and health care personnel. These problems may be incorporated into an enduring negative sense of self. If the child has a strong social support system and receives well-informed physiological and psychological care, these problems can be mitigated.

The adjustment to facial disfigurement also depends on the patient's preexisting personality and mental defense mechanisms. In his classic book about scarred burn victims, Bernstein (1976) described variables critical to adaptation, including adaptive versus maladaptive defenses; active coping versus passive surrender; loving exchange versus rage; leading and co-managing treatment versus resisting treatment; and denial versus overawareness. For example, a patient who participates in managing his or her own care; who has a flexible, extensive repertoire of mental defense mechanisms; and who has loving exchanges with friends and family is more likely to make a successful adjustment to facial disfigurement.

Irrespective of the cause of facial disfigurement, the objective nature of the disfigurement may not correlate with the patient's self-perception. In a study of 50 patients who received extensive multidisciplinary treatment from birth to age 18 years for cleft palate, no correlation was found between the objective measure of the residual deformities and the patient's subjective judgment of the remaining deformity (Vegter and Hage 2001). Thus, the subjective self-assessment of the deformity is probably more important than the actual nature of the deformity in determining quality of life. There has been little work done to identify ef-

fective treatments for the stress and stigmatization that occur with facial disfigurement. A workshop hosted by the Centers for Disease Control and Prevention identified research on the psychosocial outcomes of children with orofacial clefts as a priority (Yazdy et al. 2007). Using a specially designed assessment questionnaire, the Cleft Evaluation Profile, researchers have found that children with orofacial clefts are often teased and that their self-confidence suffers as a result (Noor and Musa 2007). Despite these promising beginnings, research is needed to determine the efficacy of various psychosocial interventions.

Scars that develop after burn injuries can be very extensive. Scar tissue is different from normal skin and has an aberrant color, a rough surface texture, increased thickness, and decreased pliability and may be associated with pain or pruritus. Assessment of the various treatments for scars (including surgical treatments) has been limited by the lack of any systematic approach to the evaluation of scars (Idriss and Maibach 2009). There is also a marked lack of large, well-designed RCTs of the currently available scar reduction treatments. However, even when better physiological treatments of scars are available, the subjective experience of the scar appears to be more important than the actual physical characteristics of the scar. Sarwer et al. (1998) reported that a subset of patients who underwent surgical revision of their scars had a level of dissatisfaction consistent with body dysmorphic disorder.

Despite the recognition that the *emotional* experience of the facial disfigurement is one of the primary determinants of quality of life, research is only now beginning to assess the problem. Brown et al. (2008) interviewed 24 women with facial scars and identified 44 themes related to quality of life. They classified these themes into five main areas: 1) physical comfort and functioning, 2) acceptability to self and others, 3) social functioning, 4) confidence in the nature and management of the scarring, and 5) emotional well-being.

Pelvic Surgery

Hysterectomy

In patients who have undergone hysterectomy, four stages in the experience have been described (H.J. Krouse 1990):

1. The recognition/exploration stage centers on the discovery of symptoms and diagnosis.
2. The crisis/climax stage occurs when treatment is initiated.
3. The adaptation stage occurs after treatment.
4. The resolution/disorganization stage concerns the long-term sequelae.

FIGURE 30-2. Algorithm for the initial psychiatric assessment of the burn patient during the initial acute hospitalization.

Note. PTSD=posttraumatic stress disorder; SSRIs=selective serotonin reuptake inhibitors.

Guilt, embarrassment, anxiety, isolation, fear, and denial of the disease are hallmarks of the first stage of the hysterectomy experience, whereas anxiety, depression, altered body image, and concerns about changing relationships characterize the second stage. Many women associate the uterus with femininity, the sex drive, sexual attractiveness, and status as a wife or mother. Thus, for some women, a hysterectomy leads to impaired self-image and self-esteem. If concerns about the quality of the marital relationship and the deleterious effect of surgery on sexual functioning arise, they must be addressed. Anxiety and depression are common and should be addressed (see also Chapter 33, "Obstetrics and Gynecology").

Gynecological Cancer

Gynecological cancer treatment leads to deterioration of sexual functioning in 30%–35% of patients in terms of sexual motivation, arousal, and orgasm. Prognostic variables include previous sexual behavior, partner-related factors, availability of education and counseling, dyspareunia, postcoital bleeding, estrogen deprivation, and vaginal stenosis or shortening. The magnitude of the surgery and psychosocial factors (including presurgical body image, pretreatment libidinal level, anxiety, attitude toward sex role, and age) contribute to postsurgical adjustment (Weigman-Schultz and van de Wiel 1992; see also Chapter 16, "Sexual Dysfunction").

Prostatectomy

In prostatectomy, the frequency of postsurgical impotence and incontinence dramatically affects quality of life. Libman et al. (1991) reported that prostatectomy often has a negative effect on erectile function, particularly in older men. Rossignol et al. (1991) evaluated the effect of radical prostatectomy in 429 patients and found that those men who were satisfied with their postsurgical sexual life were younger and had normal sexual function prior to the surgery. Braslis et al. (1995) concluded that despite fairly drastic complications (incontinence and impotence) and associated distress, radical prostatectomy is a well-accepted procedure (see also Chapter 16, "Sexual Dysfunction").

Ostomies

There has been a steady increase in the number of people surviving colorectal cancer at least 5 years following diagnosis (American Cancer Society 2007). Many of these survivors will receive intestinal stomas as part of their treatment; however, patients with stomas face many problems, both physical and psychosocial. In colostomy patients, Wade (1990) reported that physical symptoms such as fatigue, nausea, diarrhea, flatulence, urinary incontinence, and

stoma complications were associated with higher levels of distress. A study by Kelly (1991) found that malfunction of the stoma, skin damage, and poor healing of the perianal wound add their toll to an already trying situation and interfere with functioning and, sometimes, identity. Accidental leakage, or the fear thereof, may limit activity or travel. Several bothersome aspects of caring for ostomies, with resulting changes in daily routines, troublesome side effects, and embarrassing accidental leakage, further stress the patient's resilience and coping skills (Thomas et al. 1988).

Systematically reviewed studies of colorectal cancer patients with and without a stoma have reported significantly higher rates of depression, suicidal thoughts, feelings of loneliness, low self-esteem, and sexual problems in persons with a stoma (Sprangers et al. 1995). The increasing survival rates and acknowledgment of the difficulties experienced by these patients have led to a call for more emphasis on addressing social and psychological concerns (Simmons et al. 2007). Anxiety and embarrassment over a stoma may lead to an alteration in lifestyle and overall self-image (Nugent et al. 1999), and sexuality and intimacy concerns merit special attention (R. S. Krouse et al. 2009). The majority of patients experience sexual dysfunction after rectal cancer surgery as the result of damage to the autonomic plexus that occurs during surgery and radiotherapy (Hendren et al. 2005; Marijnen et al. 2005; see also Chapter 16, "Sexual Dysfunction"). Successful adjustment to colostomy depends on education for ostomy self-care, psychosocial support to help accept the changes in body image, and a social support network (Piwonka and Merino 1999).

Management Strategies After Pelvic Surgery

Pelvic surgery is often associated with pain, changes in body image, self-image distortions, and fear of becoming dependent or abandoned. Patients also fear possible sexual and reproductive changes. Patients undergoing these types of surgery are at risk for poor psychosocial outcome in terms of psychological distress, limitation of activities, and sexual adjustment. Patients and physicians may feel uncomfortable discussing sexual matters, and concerns about sexual functioning may be minimized. This may create severe distress postoperatively. Patients should be fully informed about the sexual effects of surgery, provided ample opportunity to ask questions, and provided assistance in coping with the aftermath of the surgery (see also Chapter 16, "Sexual Dysfunction").

Bariatric Surgery

Extreme obesity is defined as a body mass index (BMI) greater than 40 kg/m². BMI is a calculated number (attained by dividing weight in kilograms by height in meters

squared) and does not provide information about composition. Results from the 2005–2006 National Health and Nutrition Examination Survey (NHANES) revealed a significant increase in the number of extremely obese adults in the United States, with 5.9% of the population affected. Although the overall percentage of overweight and obese adults is stabilizing and may be decreasing, the percentage of extremely obese adults has increased since the 2003–2004 survey. Extreme obesity is also called *morbid obesity* because it is associated with high premature morbidity and mortality, most commonly as a result of complications of type 2 diabetes mellitus, hypertension, hyperlipidemia, or sleep apnea. Although multiple treatments have been tried for extreme obesity, including cognitive-behavioral strategies, very low calorie diets, and pharmacological treatments, bariatric surgery is clearly the most effective, both in terms of weight loss achieved and weight loss maintenance. For example, in the detailed Cochrane Database review of surgical treatments for obesity (Colquitt et al. 2009), six studies (three RCTs and three prospective cohort studies) compared surgical procedures against nonsurgical treatments (including diet, pharmacotherapy, behavioral therapy, and no treatment). These studies found clinically (and statistically) significant greater weight loss after surgery (compared with other interventions) that was maintained at follow-up ranging from 18 months to 10 years. In the Swedish Obese Subjects Study (Sjöström 2008) of 1,845 surgical patients compared with 1,660 control patients, weight loss at 2 years was 23.4% in the surgical patients versus a 0.1% gain in the control patients. At the 10-year follow-up of 655 surgical patients and 621 control patients, weight loss was 19.7% among the surgical patients versus a gain of 1.3% in the control patients.

The current weight criterion for bariatric (or obesity) surgery is a BMI greater than 40 or a BMI greater than 35 with life-threatening comorbidities (American Medical Association 2003; National Heart, Lung, and Blood Institute 2000; National Institute of Diabetes and Digestive and Kidney Diseases 2009). Although there have been studies demonstrating that extremely obese adolescents can lose weight with bariatric surgery, the long-term effects of surgery on their physical and cognitive development remains unclear. As less invasive surgical strategies have been devised, there has been a dramatic rise in the number of obese patients who have had bariatric surgery; for example, one report (Nguyen et al. 2005) estimated a 450% increase between 1998 and 2002 in the United States.

Bariatric surgery works in one of two ways: 1) by restricting a patient's ability to eat (restrictive procedures) and 2) by interfering with absorption of ingested food (malabsorptive procedures). The three most commonly performed operations are the Roux-en-Y gastric bypass, adjust-

able gastric banding, and the biliopancreatic bypass with duodenal switch. The Roux-en-Y gastric bypass combines restriction and malabsorption principles and results in greater weight loss than gastric banding, a restrictive procedure. The restrictive element of the Roux-en-Y gastric bypass involves creation of a small gastric pouch with a small outlet; the malabsorptive element involves bypass of the distal stomach, the entire duodenum, and about 20–40 cm of the proximal jejunum. The biliopancreatic bypass with duodenal switch involves removing a large portion of the stomach (to restrict meal sizes), rerouting food away from much of the small intestine (to prevent absorption of food), and rerouting bile, which impairs digestion. Both the gastric bypass and gastric banding are now often performed as laparoscopic procedures typically requiring very brief hospital stays.

Pories (2008) summarized the improvements that have occurred with bariatric surgery during the past decade. There are now multiple RCTs demonstrating that bariatric surgery produces durable, very significant weight loss with full and long-term remission of type 2 diabetes in the majority of patients. For example, in a report by Dixon et al. (2008), surgical intervention resulted in a remission rate for type 2 diabetes mellitus of 73% (vs. 13% with nonsurgical intervention). Other complications of severe obesity such as hypertension, obstructive sleep apnea, and lipid abnormalities also improve following surgery, but not as dramatically as type 2 diabetes. In terms of some of these other comorbidities, the large prospective-cohort Swedish Obese Subjects Study described earlier (Sjöström 2008) found that significantly greater proportions of people who received surgery (compared with nonsurgical control subjects) showed recovery from their diabetes, hypertension, and hypertriglyceridemia (recovery rates of 72%, 24%, and 62%, respectively) at the 2-year follow-up. However, at the 10-year follow-up, only 36% had maintained recovery from their diabetes. Even though it is clear that surgery confers an advantage in remission (although not necessarily a cure) of various comorbidities, it is not completely clear whether one surgical procedure is more effective than another. Part of the difficulty in ascertaining the comparative efficacy of procedures is that the reports of the various comorbidities are presented differently, patients are assessed over different time periods, and the quality of the reports differ widely.

Evidence from the Cochrane review indicates that there is less weight loss following gastric banding than following gastric bypass (Colquitt et al. 2009). Seven RCTs comparing gastric bypass against vertical banded gastroplasty were reviewed. Five of the seven reported percentage excess weight loss at 1 year and percentage excess weight loss at follow-up ranging from 18 months to 5 years. Percentage

weight loss at 1 year ranged between 62.9% and 78% for gastric bypass procedures and between 44% and 62.9% for gastric banding. At the latest follow-up, percentage excess weight loss ranged from 66% to 84% for gastric bypass and from 37% to 59.8% for gastric banding.

Extremely obese patients present significant surgical risks; nonetheless, there has also been a marked improvement in the safety of bariatric surgery, with significantly lower complication rates. In the large 10-year Swedish Obese Subjects Study (Sjöström 2008), 90-day mortality following date of surgery (and comparison dates for the control subjects) was 5 deaths among the 2,010 surgical patients and 2 deaths among the 2,037 control patients. At 10-year follow-up, there had been 101 (5%) deaths in the surgical group versus 129 (6.3%) in the control group. Thus, there was a statistically significant decrease in all-cause mortality at follow-up in bariatric surgery patients compared with patients receiving conventional treatments. The possible complications of gastric bypass are more severe than those of gastric banding. For example, although perioperative death is uncommon, it is more likely with gastric bypass than with gastric banding. Early complications such as wound infection, ulcer, and abscess occur rarely with either procedure but are more common with

gastric bypass (for a review, see Colquitt et al. 2009). Late complications such as postoperative cholecystectomy are similar between gastric bypass and gastric banding procedures. Figure 30-3 illustrates the Roux-en-Y gastric bypass, and Figure 30-4 is an illustration of a laparoscopic version of gastric banding.

Psychiatric and Psychosocial Aspects

Recent studies have documented a high prevalence of psychiatric disorders among extremely obese patients who present for bariatric surgery. The prevalence of Axis I diagnoses among candidates for bariatric surgery is high. Two recent relatively large studies (Mauri et al. 2008; Rosenberger et al. 2006) utilized the well-validated Structured Clinical Interview for DSM-IV Axis I Diagnoses (SCID-I) to examine the prevalence of Axis I psychiatric disorders in severely obese bariatric surgery candidates. The lifetime prevalence of Axis I diagnoses was very similar in the two studies (36.8% in Rosenberger et al. [2006] vs. 37.6% in Mauri et al. [2008]), and current Axis I diagnosis rate was also very similar (24.1% vs. 20.9%). In both studies, the most common Axis I diagnoses were affective disorders, followed by anxiety disorders and then eating disorders. Interestingly, alcohol and other substance use disorders

FIGURE 30-3. Diagram of Roux-en-Y gastric bypass.

FIGURE 30–4. Diagram of laparoscopic adjustable gastric banding (LAGB) with the LAP-BAND system (INAMED Health, Santa Barbara, CA).

were uncommon in these two studies. This may be because physicians identify patients with substance use disorders and do not refer them for surgery, or it may be that patients do not reveal substance use disorders during the initial evaluation. In the study by Mauri et al. (2008), prevalence of Axis II diagnoses was also determined, with 19.5% meeting criteria for at least one Axis II diagnosis; almost all fell into the Cluster C category, including avoidant, dependent, and obsessive-compulsive personality disorders. Also using the SCID-I, Kalarchian et al. (2007) assessed 288 bariatric surgery candidates and found a lifetime Axis I diagnosis prevalence of 66.3% and a current Axis I prevalence of 37.8%. This group also found that Axis I psychiatric diagnoses were associated with greater obesity and lower functional health status (using the Medical Outcomes Study 36-item Short-Form Health Survey).

One way that psychiatric disorders can contribute to severe obesity is through weight gain caused by various psychotropic medications, particularly the antipsychotics. Most antidepressants and anticonvulsants can also cause substantial weight gain in a minority of patients taking them.

There have been early attempts to determine the effect that the presence or absence of presurgical psychiatric disorders or other negative psychosocial factors have on the

outcome of bariatric surgery. Although some consensus is developing for the effect of presurgical eating disorders on outcome, the effect of other psychiatric conditions remains unclear. Data available are primarily from retrospective studies or from small single-site studies. For example, in a retrospective study (Fujioka et al. 2008) of 121 patients undergoing Roux-en-Y gastric bypass, 32% had a presurgical diagnosis of binge-eating disorder, and 17% had a history of sexual abuse; weight loss at 12 months among the sexually abused group was less than expected, but no effect of binge-eating disorder at 12 months was detected. In another study involving follow-up of 220 female patients after laparoscopic gastric banding (Kinzl et al. 2006), a mail questionnaire was returned by 140 patients; results suggested a less successful outcome in terms of weight loss in those patients who had two or more psychiatric disorders (particularly adjustment disorders, depression, and/or personality disorders).

In a careful recent study assessing quality of life following bariatric surgery, Kolotkin et al. (2009) compared 2-year outcomes among 308 patients who underwent gastric bypass surgery, 253 people who sought (but did not undergo) surgery, and 272 population-based obese individuals. At 2 years, mean weight loss was 34.2% for the gastric bypass patient group, and 1.4% for the group who did not undergo gastric bypass; there was a gain of 0.5% for the population-based group. Effect size changes for physical and weight-related quality of life were very large for the gastric bypass group and small to medium for the other two groups. Effect size changes for the psychosocial aspects of quality of life were moderate to large for the gastric bypass group and small for the two comparison groups. However, this study did not determine the effect of preexisting psychiatric diagnoses on outcome.

Eating Disorders and Bariatric Surgery

Presurgical eating disorders are common. The three careful studies cited earlier utilizing the SCID-I and SCID-II (Kalarchian et al. 2007; Mauri et al. 2008; Rosenberger et al. 2006) found a lifetime prevalence of eating disorders of 13.8%, 29.5%, and 12.8%, respectively. In all three studies, binge-eating disorder was by far the most common diagnosis (9.2%, 27.1%, and 11%), followed by much lower rates of bulimia nervosa and eating disorder not otherwise specified (other than binge-eating disorder). A complicating factor is that many more patients appear to have disordered eating behavior that is not identified as diagnostic of an eating disorder in DSM-IV (American Psychiatric Association 1994). For example, there are a number of other abnormal eating patterns that are more common among candidates for bariatric surgery. For example, night eating syndrome (for which diagnostic consensus may soon oc-

cur [Stunkard et al. 2009]) probably is present in up to 9% of patients presenting for bariatric surgery (Allison et al. 2006). Other abnormal eating patterns also are common including binge eating that does not meet full criteria for binge-eating disorder, preferences for high-sugar or high-fat foods, specific food “addictions,” compulsive eating, emotional eating, lack of restraint in regard to portion size, and grazing (defined as a pattern of repeated episodes of eating small quantities of food over a long period of time, associated with feelings of loss of control). Although the term *grazing* is descriptive (and was initially used by R. Saunders 2004), it also has negative connotations. One important theme emerging from the literature is that among candidates for bariatric surgery, anxiety seems to be a consistent theme in patients with disordered eating or formal eating disorders.

There have been several reports indicating that patients with regular binge eating (not necessarily meeting current research criteria for binge-eating disorder) have weight loss and psychosocial outcomes similar to those without regular binge eating at early follow-up (e.g., White et al. 2006). A recent prospective study of 199 bariatric surgery patients (E. Chen et al. 2009) found that presurgical compensatory behavior (e.g., purging) was a small but significant predictor of lower BMI at 6 months postsurgery but not at 1 year postsurgery. The authors noted that these findings contradict the current clinical guidelines and thus should be interpreted with caution.

Ophthalmological Surgery

Cataract Surgery

Early reports by psychiatric consultants of “black patch” psychosis following cataract surgery ushered in studies of complications following eye surgery (Weisman and Hackett 1958). The initial reports focused on the sensory deprivation that occurred after bilateral cataract removal and led to recommendations that only one eye be operated on at a time. Subsequently, “black patch” psychosis was identified as a postoperative delirium that was relatively uncommon. Milstein et al. (2002) found that following cataract surgery, 4.4% of 296 patients had an immediate postoperative delirium. Factors found to be statistically associated with postoperative delirium included very old age (82 years compared with 73 years) and frequent preoperative use of benzodiazepines.

Cataract is a major public health problem, especially in developing countries: 47.8% of total blindness in the world is due to cataracts (Resnikoff et al. 2004). The number of cataract surgeries performed has increased dramatically in the past few years, in part because of an increase in the number of aging individuals. Risk factors for the development

of cataracts include smoking, steroid use, diabetes, ultraviolet ray exposure, and aging. In addition, the consent process for cataract surgery, satisfaction with surgery, and postsurgery quality-of-life issues have come under scrutiny. Practice guidelines stress the importance of fully informed consent and positive communication between the patient and the treatment team (Canadian Ophthalmological Society Cataract Surgery Clinical Practice Guideline Expert Committee 2008). The key indication for surgery is interference with activities of daily life caused by cataracts. In a prospective study (Pager 2004), improvement in visual function in a patient did not correlate with overall satisfaction. Satisfaction with surgery appears to be closely related to expectations prior to surgery, which should be carefully explored during the consent process. Quality-of-life issues have been investigated, and among patients with clinically significant cataracts, surgery has been shown to reduce the risk of falls by 34% over 1 year and to reduce the annual fracture rate from 8% to 3% in women older than 75 years (Harwood et al. 2005). Another study found that the rate of motor vehicle accidents decreased in a group who had surgery compared with a group who chose not to have surgery (Owsley et al. 2002).

Stigma and Eye Abnormalities

Facial expression and eye contact are critically important in interpersonal relationships. Thus, abnormalities are likely to significantly influence quality of life. Several studies have confirmed this. For example, Bullock et al. (2001) showed pictures of patients with blepharoptosis and dermatochalasis to subjects without such abnormalities and asked them to rate the person in the picture on several dimensions, including friendliness, trustworthiness, mental illness, and happiness. After surgical correction of these eye abnormalities, the ratings of the pictures by the healthy subjects improved significantly.

In another study, patients with serious childhood-onset strabismus (before age 5 years) were evaluated prior to corrective surgery at ages 15–25 years (Menon et al. 2002). Eighty-five percent of the males and 75% of the females reported social problems caused by their continuous squint; they had been ridiculed at school and work, they had greater difficulty obtaining employment, and many avoided social activities. After corrective surgery, more than 90% reported improved self-confidence and self-esteem.

Eye Removal

Self-removal of the eye (autoenucleation), also termed *oedipism*, is a form of self-mutilation that occurs very uncommonly (Shiwach 1998). When it does, the patient is usually psychotic and often has religious preoccupations associated with a literal interpretation of the Bible (“and if thy

right eye offend thee, pluck it out, and cast it from thee"; Matthew 5:28–30). Most reported cases have occurred in patients diagnosed with schizophrenia; however, cases of autoenucleation resulting from substance-induced psychosis, bipolar mania, obsessive-compulsive disorder, PTSD, and major depressive disorder have also been reported. Conjoint management of the patient by ophthalmologists and psychiatrists is crucial, especially because some patients reinjure themselves later. A review of 50 cases found a high (39%) incidence of bilateral autoenucleation (Dilly and Imes 2001). It is important to emphasize the need for treatment of the underlying psychiatric condition and close observation to prevent further harm.

Cosmetic Surgery

In an era and a culture in which people have increased interest in physical attractiveness, cosmetic surgery has dramatically increased. According to data from the American Society for Aesthetic Plastic Surgery (2009), nearly 10 million surgical and nonsurgical cosmetic procedures were performed in the United States in 2009, and Americans spent nearly \$10.5 billion on cosmetic procedures. The most common surgical cosmetic procedures were breast augmentation, lipoplasty, blepharoplasty, rhinoplasty, and abdominoplasty. Women had more than 90% of the cosmetic procedures. Early studies of cosmetic surgery found that patients with psychiatric problems were common among cosmetic surgery candidates. More recent studies suggest that because more people consider cosmetic surgery a reasonable choice, the percentage of applicants with psychiatric disorders may be relatively lower. Most patients do well with cosmetic surgery, although it is thought that so-called type changes (e.g., rhinoplasty) require more extensive psychological adjustments than do restorative changes (e.g., face-lifts) (Castle et al. 2002).

Age at the time of cosmetic surgery is also important; it may be easier to incorporate changes into body image during childhood or adolescence. Cosmetic surgery is usually helpful in adolescents with a true defect if they are selected carefully and if genuine informed consent is obtained before surgery (McGrath and Mukerji 2000).

Because quality of life is significantly influenced by body image, a philosophical question raised by the increased number of aesthetic surgeries is whether cosmetic surgery should be considered medically necessary. The focus on possible negative body image changes after lifesaving surgeries for illnesses such as breast cancer has resulted in trials comparing the effectiveness (in terms of survival) of less disfiguring surgeries with that of more radical approaches. A persuasive argument can be made that improvements in body image and self-esteem may dramatically improve quality of life; this point of view is supported

by many studies (e.g., Litner et al. 2008; Sabino Neto et al. 2008; Stuerz et al. 2008).

Preoperative Assessment

Even though the percentage of patients with psychiatric disorders may be lower among patients seeking aesthetic surgery than in previous decades, the percentage is probably still higher than among most other surgical candidates. Several research groups have attempted to determine which patients should not have cosmetic surgery at all and which patients should have psychiatric treatment before aesthetic surgery. A series of questions designed to detect psychiatric problems has been proposed (Grossbart and Sarwer 1999). One problem in determining who is likely to benefit from cosmetic surgery is that no widespread accepted method is available for determining patient satisfaction with the surgical results. Ching et al. (2003) reviewed the literature and suggested specific measures of body image and quality of life likely to provide valid evidence concerning the question of who should receive surgery. Most patient dissatisfaction with aesthetic surgery is based on failures of communication and patient selection criteria (Ward 1998). It is very important for the surgeon to have a clear idea of the patient's expectations regarding surgical outcome. When the patient's expectations are unrealistic and the surgeon feels he or she cannot meet those expectations, surgery should be refused. Taking a careful psychosocial history is an essential part of patient selection and is a way to establish rapport and ensure that the right operation is performed on the right patient. Blackburn and Blackburn (2008) have devised a method for assessing various parameters found to be relevant in determining whether the proposed surgery is likely to be successful and satisfactory to the patient. A template for taking a history is provided with the acronym SAGA, which stands for **S**ensitization (the patient's sensitivity to the deformity arising from internal or external sources), **A**esthetic self-assessment (the patient's own private evaluation of the feature about which he or she has a complaint), **G**roup comparison (how a patient compares the feature to the same feature in other people), and **A**voidance behavior (strategies used by the patient to camouflage or avoid exposure of the feature of complaint).

Body Dysmorphic Disorder

Body dysmorphic disorder (BDD) is reviewed in detail in Chapter 12, "Somatization and Somatoform Disorders." Also known as dysmorphophobia, BDD has been called the disorder of imagined ugliness. Patients with BDD often present to cosmetic surgeons for correction of trivial or nonexistent defects. Preoccupations commonly involve the face or head, although any body part can be the focus

of concern (Phillips and Diaz 1997). In cosmetic surgery settings, BDD rates of 6%–15% have been reported. Surgical treatment outcomes are poor, especially after multiple operations on the same body part, and patients are often dissatisfied with their treatment and register complaints against their physicians (Fakuda 1977; Phillips and Dufresne 2000). BDD occasionally first makes its appearance after cosmetic surgery (Tignol et al. 2007) and may result in malpractice litigation (Nachshoni and Kotler 2007). It is important for the surgeon to explain to patients with BDD that rather than having a significant dermatological or surgical problem, they have a body image problem consisting of being overly concerned about and affected by how they think they look. They should also be told that BDD is a known and treatable disorder that many people have. In general, it is more fruitful to focus on the distress and impairment that the concerns about appearance are causing the patient than to focus on the patient's actual appearance, and doing so may facilitate referral to a mental health professional.

Conclusion

Psychiatric problems occur in many surgical patients. We have discussed common problems that occur during the preoperative, intraoperative, and postoperative periods. Preoperatively, issues around capacity and consent are important, as well as planning for the surgical and postoperative management of psychiatric disorders known to be present. Preoperative anxiety is common, and appropriate treatment can improve postoperative recovery. Psychiatric reactions to intraoperative recall can often be ameliorated through careful preparation for surgery. Postoperatively, delirium is a key issue and is often associated with alcohol or drug withdrawal syndromes. Postoperative pain, problems related to discontinuation of ventilator support, and PTSD are common reasons for psychiatric intervention. An awareness of specific issues that can arise in burn care, pelvic surgery, bariatric surgery, ophthalmological surgery, and cosmetic surgery is also important. In the past few years, there have been significant advances both in the identification of psychosocial problems among surgical patients and in methods of assessing severity of symptoms and change with treatment. Large controlled trials evaluating various treatments are beginning to emerge. In addition, there is now a global interest in psychiatric issues related to surgery, as reflected by the marked increase in research studies addressing this topic.

Organ Transplantation

Andrea F. DiMartini, M.D.

Jorge Luis Sotelo, M.D.

Mary Amanda Dew, Ph.D.

THE BENEFIT OF SOLID ORGAN transplantation was realized in 1954, when Dr. Joseph E. Murray performed the first successful kidney transplant, with the patient's identical twin as donor. However, for most patients an identical-twin donor was not an option, and more than a decade passed before immunosuppressive medications were available to conquer the immunological barrier. In 1967, the first successful liver transplant was performed, followed a year later by the first successful heart transplant. Yet despite the fact that the surgical challenges of solid organ transplantation had been overcome, it was not until the early 1980s, with the advent of improved immunosuppression, that organ transplantation changed from an experimental procedure to a standard of care for many types of end-stage organ disease.

In that decade, the National Organ Transplant Act established the framework for a national system of organ transplantation, and the United Network for Organ Sharing (UNOS) was awarded the contract with the U.S. Department of Health and Human Services to administer the nation's only Organ Procurement and Transplantation Network (OPTN) (United Network of Organ Sharing 2009). In addition to facilitating organ matching and allocation, UNOS collects data about every transplant performed in the United States and maintains information on every organ type (e.g., wait-list counts, survival rates) in an extensive database available on the OPTN Web site (www.OPTN.org) (United Network of Organ Sharing 2009).

Although immunological barriers still exist for transplant recipients, the greatest obstacle to receiving a transplant is the shortage of donated organs. The number of

wait-listed individuals has increased far beyond the availability of donated organs. Currently, there are more than 100,000 persons active on the U.S. waiting list. As illustrated in Figure 31-1, the numbers of wait-listed patients for kidney transplantation (the most common transplant performed) have increased steadily between 2004 and 2008 (United Network of Organ Sharing 2009). By contrast, the numbers of patients waiting for liver, heart, lung, and pancreas transplants increased only marginally during the same period (see Figure 31-1). Additionally, the numbers of patients receiving transplants in 2008 for each solid organ type (United Network of Organ Sharing 2009) ranged from a low of 437 for isolated pancreas, 1,478 for lung, 2,163 for heart, and 6,318 for liver, to a high of 16,514 for kidney.

For some transplant types (e.g., kidney, liver, and more rarely lung transplantation), living organ donation has become an option to address the organ shortage (see subsection "Living Donor Transplantation" later in this chapter). In 2001 the number of living donors exceeded the number of deceased donors (6,526 vs. 6,081) for the first time, with the majority being kidney donors (United Network of Organ Sharing 2009). However, following two highly publicized U.S. liver donor deaths, the numbers of partial hepatectomy living liver donors decreased from a peak of 520 in 2001 to approximately 250 per year in 2008. Without an identified living donor, transplant candidates may wait years for an organ. The median wait-listed time depends on the organ type and the recipient's blood type and severity of illness at the time of listing. For most major organ types, more than 40% of U.S. wait-listed candidates waited 2 years or more for an organ (United Network of Organ Sharing

FIGURE 31-1. Year-end numbers of wait-listed patients, by organ type: 2004–2008.

Source. United Network of Organ Sharing (UNOS; www.optn.org) 2009.

2009). Although only 0.5% become medically unsuitable and are removed from the waiting list, 2% refuse transplant after being wait-listed, and 12%–20% die while on the waiting list (United Network of Organ Sharing 2009).

Following transplantation, living-donor liver and living-donor kidney recipients experience the highest long-term survival rates (76% alive at 10 years' posttransplantation) (see Figure 31-2). Recipients of deceased-donor kidneys, livers, and hearts have somewhat lower 10-year survival (61%, 59%, and 53%, respectively), and lung and intestine recipients have the poorest 10-year survival (41% and 26%, respectively) (United Network of Organ Sharing 2009). These data are from transplants performed more than 10 years ago, so advances in technology, immunosuppression, and medical care will most likely provide better survival rates for current recipients. Overall graft survival rates are significantly lower than patient survival rates (e.g., 43% for kidney graft survival and 52% for liver graft survival after 10 years), which means that many transplant recipients may have to face a second transplant 5–10 years after their first (United Network of Organ Sharing 2009).

These stark facts highlight the enormous stresses facing transplant candidates, transplant recipients, and their caregivers. These issues have also created a particular environment in which hospitals must evaluate, treat, and select

patients for organ transplantation. The scarcity of donated organs has driven efforts to select candidates believed to have the best chance for optimal posttransplant outcomes. Additionally, the organ shortage has increasingly led to consideration of living kidney donors and, more recently, living liver donors (and, more rarely, living lung donors) as transplantation options.

Pretransplant psychosocial evaluations are commonly requested to assist in candidate and donor selection, and psychiatric consultation is often needed for clinical input during the pre- and posttransplant phases. Although a wide body of knowledge has been developed in the clinical care of transplant candidates and recipients, little longitudinal research is available to answer questions about long-term outcomes or the impact of psychiatric factors (assessed pretransplant and/or in the early years posttransplantation) on outcomes. Research primarily has focused on kidney, heart, and liver transplantation, which in combination currently account for almost 90% of transplants performed in the United States.

In this chapter, we outline the essential areas of the field for psychosomatic medicine specialists and other mental health clinicians involved in the care of transplant patients—pretransplant assessment and candidate selection, emotional and psychological aspects of the trans-

FIGURE 31–2. Survival rates of transplant recipients, by organ type.

Source. Data from 2006 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1996–2005. Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation, Rockville, MD, 2006. Available at: http://www.ustransplant.org/annual_reports/archives/2006/default.htm.

plant process, therapeutic issues, patients with complex or controversial features, psychopharmacological treatment, and neuropsychiatric side effects of immunosuppressive medications. Special pretransplantation topics of emerging importance to psychosomatic medicine specialists are also discussed (i.e., hepatic encephalopathy, ventricular assist devices in heart transplantation, tobacco use, and living donors). The neuropsychiatric sequelae of end-stage organ disease are not covered in this chapter, because those aspects are addressed in the respective chapters on each organ system. Specific transplantation issues are also discussed in Chapter 18, “Heart Disease”; Chapter 19, “Lung Disease”; Chapter 20, “Gastrointestinal Disorders”; Chapter 21, “Renal Disease”; and Chapter 34, “Pediatrics.”

Pretransplantation Issues

Psychosocial/Psychiatric Assessment

Pretransplant psychosocial evaluations have been a traditional role of the psychiatric consultation team in the transplantation process. These evaluations are frequently used to assist in the determination of a candidate's eligibility for transplantation and to identify psychiatric and/or psycho-

social problems and needs that must be addressed to prepare the candidate and family for transplantation. These evaluations are also critical for the identification of psychiatric, behavioral, and psychosocial risk factors that may portend poor transplant outcomes (Crone and Wise 1999; Dew et al. 2000b).

Transplant programs will often refer for evaluation candidates with a known history of psychiatric problems or those who are identified during the initial clinical interviews with the transplant team as having such problems. Pretransplant psychosocial evaluations are also usually requested for patients with substance use disorders (including tobacco) and other poor health conditions and behaviors (e.g., obesity, noncompliance).

Although a truly comprehensive assessment of a potential transplant candidate would require a full psychiatric consultation, the current high numbers of candidates preclude this. To handle the increasing volume of evaluations, some centers employ screening batteries of patient-rated measures to identify candidates with elevated levels of psychological distress, who then undergo a full psychiatric evaluation. Screening instruments can provide baseline cognitive, affective, and psychosocial ratings for candidates; use of these instruments maximizes staff resources

and minimizes costs. For example, using this strategy, Jowsey et al. (2002) identified 20%–44% of liver transplant candidates who had mild to severe symptoms on a range of measures, which prompted a higher level of evaluation.

Emerging evidence shows that preoperatively assessed psychosocial variables can predict posttransplantation psychiatric adjustment among recipients of most organ types (Dew et al. 2000b). These variables are increasingly being investigated as contributing to medical outcomes as well, although a consistent predictive effect has not yet been demonstrated (Dew et al. 2000b). Thus, psychosocial assessment of transplant candidates provides an opportunity to identify potential problems and intervene prior to transplantation, with the goal of improving posttransplant outcomes. Transplant programs vary considerably in their psychosocial assessment criteria and procedures (see Olbrisch and Levenson 1995 for a review of methodological and philosophical issues); in general, however, psychosocial evaluations have 10 objectives (although a given assessment may not include all 10), as enumerated in Table 31-1 (see Levenson and Olbrisch 2000).

Because information on all of these domains may not be obtainable during a single clinical interview, a follow-up reassessment may be necessary to clarify relevant issues, solidify a working relationship with the patient and family, and resolve problems. A multidisciplinary approach is often used with input from psychiatrists, psychologists, psychiatric nurse clinical specialists, addiction specialists, social workers, transplant surgeons, and transplant coordinators to construct a comprehensive picture of the patient and develop a coordinated treatment plan. As with any psychiatric evaluation, verbal feedback provided to the patient and family will serve to reiterate the expectations of the transplant team and the requirements of the patient for listing if indicated. Some centers also use written “contracts” to formalize these recommendations (Cupples and Steslowe 2001; Stowe and Kotz 2001). In difficult cases, these contracts serve to document expectations, thereby minimizing misinterpretation. Written contracts outline a treatment plan that can be referred to with each follow-up appointment. These contracts are particularly useful with transplant candidates who have alcohol or substance abuse/dependence problems, specifying the transplant program’s requirements for addiction treatment, monitoring of adherence (e.g., documented random negative blood alcohol levels), and length of abstinence (see subsection “Alcohol and Other Substance Use Disorders” later in this chapter).

Psychosocial Instruments and Measures

Transplant-specific (e.g., Psychosocial Assessment of Candidates for Transplant [Olbrisch et al. 1989], Transplant Evaluation Rating Scale [Twillman et al. 1993]), disease-

specific (e.g., Miller Health Attitude Scale for cardiac disease [Miller et al. 1981], Quality of Life Questionnaire—Chronic Lung Disease [Guyatt et al. 1987]), and disorder-specific (e.g., High Risk Alcohol Relapse Scale for alcoholism [Yates et al. 1993]) instruments have been used to evaluate transplant candidates and monitor their posttransplant recovery. These instruments have been used in conjunction with general instruments for rating behavior, coping, cognitive and affective states, and quality of life. Psychosocial instruments can be used to identify individuals who require further assessment (as described earlier) or to pursue evaluation of patients already identified as requiring additional screening. The evaluator’s purpose for using such instruments will determine the type and specificity of the instruments chosen; for instance, in the subsection “Hepatic Encephalopathy” later in this chapter, we discuss the use of neuropsychiatric tests to aid in the identification of cognitive impairment. Some instruments are more applicable to transplant populations than others. For example, although there are many instruments and measures for assessing alcoholism, none of these instruments are tailored to transplant candidates; they are focused on general issues of detection and treatment of addiction rather than on issues important in evaluating appropriateness for transplantation. Formal cognitive testing may be appropriate to delineate cognitive deficits, taking into consideration the potential contribution of deficits that may be transient and related to the current degree of illness (e.g., delirium; see subsection “Cognitive Disorders and Delirium” later in this chapter).

Because psychosocial selection criteria differ significantly by program and organ type, development and use of structured evaluation instruments may help to direct and standardize the transplant selection protocols used nationally. The Structured Interview for Renal Transplantation (SIRT; Mori et al. 2000) is a structured yet flexible interview tool designed to guide the clinician efficiently through a comprehensive interview of pertinent information for potential renal transplant candidates. Use of the SIRT requires sound clinical judgment, but the instrument can also be used for training clinicians; the structure of the instrument could be appropriate for research purposes as well (Mori et al. 2000). This instrument is not scored, nor are there ratings for transplant candidacy. Two other instruments commonly used to assess candidates for transplantation are the Psychosocial Assessment of Candidates for Transplantation (PACT) and the Transplant Evaluation Rating Scale (TERS). Different from structured interviews with specific items or questions, these instruments can serve as heuristic tools to aid clinicians in considering and integrating the data gathered from their interviews in the candidacy determination.

TABLE 31-1. Goals of psychosocial screening

1. Assess coping skills; intervene with patients who appear to be unable to cope effectively.
2. Diagnose comorbid psychiatric conditions; provide for pre- and posttransplant monitoring and treatment.
3. Determine the candidate's capacity to understand the transplant process and to provide informed consent.
4. Evaluate the candidate's ability to collaborate with the transplant team and to adhere to treatment.
5. Assess substance use/abuse history, recovery, and ability to maintain long-term abstinence.
6. Identify health behaviors that may influence posttransplant morbidity and mortality (e.g., tobacco use, poor eating or exercise habits) and evaluate the candidate's ability to modify these behaviors over the long term.
7. Help the transplant team to understand the patient better as a person.
8. Evaluate the level of social support available to the candidate for pre- and posttransplant phases (including stable family/others committed to assisting the candidate, adequate insurance and financial resources, and logistical support).
9. Determine the psychosocial needs of the patient and family and plan for services during the waiting, recovery, and rehabilitation phases of the transplant process.
10. Establish baseline measures of mental functioning in order to be able to monitor postoperative changes.

Source. Adapted from Levenson J, Olbrisch ME: "Psychosocial Screening and Selection of Candidates for Organ Transplantation," in *The Transplant Patient*. Cambridge, UK, Cambridge University Press, 2000, p. 23. Used with permission.

The PACT was the first published psychosocial structured instrument specifically designed for screening candidates for transplantation (Olbrisch et al. 1989). It provides an overall score and subscale scores for psychological health (psychopathology, risk for psychopathology, stable personality factors), lifestyle factors (healthy lifestyle, ability to sustain change in lifestyle, adherence, drug and alcohol use), social support (support system stability and availability), and patient educability and understanding of the transplant process. The PACT can be completed in only a few minutes by the consultant following the evaluation but requires scoring by a skilled clinician, without which the instrument's predictive power could be diminished (Presberg et al. 1995). The final rating for candidate acceptability is made by the clinician, with the freedom to weigh individual item ratings variably (Presberg et al. 1995). Thus, a single area, such as alcohol abuse, could be assigned greater weight and could thereby disproportionately influence the final rating.

The PACT has been used to predict mortality in bone marrow recipients (independent of age, gender, or diagnosis), as well as to predict hospital lengths of stay following liver transplantation (Levenson et al. 1994). Its "risk for psychopathology" subscale identifies psychopathology that may require referral and treatment after liver, heart, and bone marrow transplantation (Levenson et al. 1994).

The TERS is used to rate patients' level of adjustment in 10 areas of psychosocial functioning: prior psychiatric history, current psychiatric diagnoses, substance use/abuse, adherence, health behaviors, quality of family support, prior history of coping, coping with disease and treatment,

quality of affect, and mental status (Twillman et al. 1993). In one study, the TERS was significantly correlated with several clinician-reported outcome variables (e.g., adherence, health behaviors, substance use), with particularly high correlations between pretransplant TERS scores and posttransplant substance use ($r=0.64$) (Twillman et al. 1993). The instrument requires administration by a skilled clinician to maintain accuracy (Presberg et al. 1995). The TERS summary score is derived from a mathematical formula in which individual item scores are multiplied by theoretical, predetermined weightings.

Although individual candidates do not always easily fit within one of the three categories of each item on the TERS, the TERS has more items than the PACT, a feature that may prove useful in future research (Presberg et al. 1995). However, the PACT is the more flexible of the two instruments, both in the range of rating individual items and in the manner in which the summary score is determined (Presberg et al. 1995). Together, these instruments are useful in the organization of patient information and can be helpful both as tools for increasing the evaluator's understanding of the candidate and for research purposes.

Maldonado et al. (2008) recently developed a comprehensive standardized psychosocial assessment using data obtained from clinical interview, collateral sources, and a specific structured battery of instruments to create a rating scale for minimal psychosocial listing criteria for transplant candidacy. Their Stanford Integrated Psychosocial Assessment for Transplant (SIPAT) has not yet been validated (Maldonado et al. 2008). The SIPAT can be used either as a stand-alone scale with cutoff scores for minimal

listing criteria or as a comprehensive battery including standardized tests.

Unique Role of the Psychiatric Consultant

Unlike in most psychiatric interviews, the psychiatrist performing the pretransplant assessment while identifying the needs of the transplant candidate will also be proposing what psychiatric issues, if any, the candidate needs to address to become a transplantation candidate. These requirements may be specific to transplantation, and the psychiatric consultant must be candid with the patient about his or her role of providing consultative advice to the transplant team on psychiatric recommendations for candidacy. Careful delineation of specific transplant-related expectations, explanation of the importance of these requirements to the success of transplantation, and exploration of the implications of these criteria for the individual candidate serve to establish a meaningful dialogue with the patient from which the therapeutic alliance necessary for future intervention can develop.

For the clinician, the seemingly reverse nature of this role can be uncomfortable or even anxiety provoking. This is especially true if the clinician is not recommending the candidate for transplantation. Fortunately, many programs do not reject patients outright for psychosocial reasons; rather, they offer such patients the opportunity to work to bring their problematic areas into alignment with the recommendations (i.e., through addiction counseling, behavioral changes, psychiatric treatment, identification of appropriate social supports) and then undergo reevaluation for candidacy. In these cases, the psychiatric consultant can often function as an advocate for the patient and assist in referral for appropriate treatment if indicated. Nevertheless, some patients will be unable to comply with the specified transplant requirements or will not survive to complete their efforts to meet candidacy requirements.

Philosophical, moral, ethical, legal, and therapeutic dilemmas are inherent in the role of transplant psychiatrist, as conflicting team opinions present themselves in the course of work with potential transplant candidates. Team discussions and consultation with other colleagues are the rule in complicated cases. In these instances, team discussions not only aid in resolving candidacy quandaries but also can help alleviate team members' anxiety and discomfort over declining a patient for transplantation. Group or team debriefing may also be desirable, and occasionally consultation with the ethics committee (or consult service), risk management, and/or the legal department of the hospital is needed (e.g., when a candidate is challenging candidacy requirements or the candidacy decision of the transplant team). Thorough documentation is essential in order to delineate the issues

involved, the expectations of the team for transplantation candidacy, and the efforts to work with the patient.

Psychological and Psychiatric Issues in Organ Transplantation

Psychiatric Symptoms and Disorders in Transplant Patients

Similar to other medically ill populations, transplant candidates and recipients experience a significant amount of psychological distress and are at heightened risk of developing psychiatric disorders. The prevalence rates of major depression range from 4% to 28% in liver transplant patients, 0% to 58% in heart transplant patients, and 0.4% to 20% in kidney transplant patients (Dew 2003; Dew et al. 2000b). The range of rates for anxiety disorders appears to be 3%–33% (Dew 2003; Dew et al. 2000b), but there are not enough studies to identify rates for specific types of anxiety disorders. One investigation found that 10% of a cohort of heart or lung transplant recipients experienced posttraumatic stress disorder (PTSD) related to their transplant experience (Köllner et al. 2002). In a prospective study of 191 heart transplant recipients, the cumulative prevalence rates for psychiatric disorders during the 3 years posttransplantation were 38% for any disorder, including 25% with major depression, 21% with adjustment disorders, and 17% with PTSD (Dew et al. 2001a). PTSD related to transplant was limited almost exclusively to the first year after transplantation. In this group of heart recipients, there was a clustering of cases of major depression in the first year, and the cumulative rate of major depression was greater than the rate of any anxiety disorders. Factors that increased the cumulative risk for psychiatric disorders included a pretransplant psychiatric history, a longer period of hospitalization, female gender, greater impairments in physical functioning, and fewer social supports (Dew et al. 2001a). These risk factors were additive, and therefore the cumulative risk of a psychiatric disorder increased along with the number of risk factors. A recent review of depression in lung transplant recipients found that depression rates were high in the transplant candidates, with an improvement in the short term associated with better quality of life. In the long term (>3 years), however, decline in functional status was associated with a dramatic increase in depressive symptomatology. This review also revealed that comorbid personality disorders, poor coping strategies, life stressors, physical complications, corticosteroid use, male gender in the short term after transplantation, and lack of psychosocial support all contributed to depression in lung transplant recipients (Fusar-Poli et al. 2007).

Several studies have suggested an association between psychiatric disorders and transplant health outcomes, although the results have been mixed. A study of wait-listed liver transplant candidates found that candidates whose Beck Depression Inventory (BDI) scores were higher than 10 (64% of patients) were significantly more likely than nondepressed candidates to die while awaiting transplantation (Singh et al. 1997). The higher BDI scores were due more to affective than to somatic symptoms. However, for candidates who reached transplantation, pretransplant depression was not associated with poorer posttransplant survival (Singh et al. 1997). These results were not affected by the severity of and complications from liver disease, or by patients' social support, employment, or education (Singh et al. 1997). A study of lung transplant recipients found that those with a pretransplant psychiatric history (anxiety and/or depressive disorders) were more likely than those without such a history to be alive 1 year after transplantation (Woodman et al. 1999). However, in a study of 191 heart transplant recipients, a DSM-III-R (American Psychiatric Association 1987) diagnosis of PTSD (with the traumatic event being transplant related) was associated with higher mortality (odds ratio = 13.74) (Dew and Kormos 1999). Another study of heart transplant recipients found that patients with ischemic cardiomyopathy and high self-rated depression scores pretransplant had significantly higher posttransplant mortality compared with the low-depression group after adjustment for sociodemographic and somatic symptoms (Zipfel et al. 2002). Havik et al. (2007) followed 147 heart transplant patients for a period of 5 years and found that depressive symptoms (as measured on the BDI) were common, that they increased the risk of mortality, and that the risk remained significant even after adjustment for somatic and lifestyle factors. Although causal directions cannot be inferred from these data, studies in other medically ill populations have demonstrated the substantial contribution of depression and anxiety to health outcomes (see Chapter 8, "Depression," and Chapter 11, "Anxiety Disorders"). Whether treating these disorders will affect patient outcomes is unclear. However, the role of the psychiatrist in evaluating, diagnosing, and treating psychiatric disorders both pre- and post-transplantation is critical.

Adaptation to Transplantation

Transplant candidates typically experience a series of adaptive challenges as they proceed through evaluation, waiting, perioperative management, postoperative recuperation, and long-term adaptation to life with a transplant (Dew et al. 2007b; Olbrisch et al. 2002) (see Figure 31-3). With chronic illness, there can be progressive debility and gradual loss of vitality and of physical and social

functioning. Patients may progressively lose their ability to work, participate in social/family activities, and drive and may even require assistance with activities of daily living. With these losses of functioning will come the loss of important roles in the family (e.g., breadwinner, parent, spouse, caregiver). Adapting to these changes can elicit anxiety, depression, anger, avoidance, and denial and requires the working through of grief (Olbrisch et al. 2002). Patients may express their distress or ambivalence by missing appointments/procedures or failing to complete requirements for transplant listing. Patients who are wait-listed may develop contraindications to transplantation (e.g., infection, serious stroke, progressive organ dysfunction), and both patients and families should be made aware that a candidate's eligibility can change over time for many reasons (Stevenson 2002). During this phase, psychiatrists may provide counseling to patients and families to help them navigate these transitions and prepare for either transplantation or death.

The summons for transplantation can evoke a mixture of elation and great fear. Patients can develop anxiety related to anticipation of the call from the transplant team. Patients may experience a panic attack when they are called for transplantation, and some—due to anxiety, fear, ambivalence, or not feeling ready—may even decline the offer of an organ.

Much of illness behavior depends on the coping strategies and personality style of the individual. In our experience, the adaptive styles of adult transplant recipients often depend on whether patients' pretransplant illness experience was chronic or acute, as delineated in the following broadly generalized profiles.

Patients who have dealt with chronic illness for years may adapt psychologically to the sick role and can develop coping strategies that perpetuate a dependency on being ill (Olbrisch et al. 2002). For these patients, transplantation may psychologically represent a transition from one state of illness to another, and such patients can have difficulty adjusting to or transitioning into a "state of health." They often complain that the transplant team is expecting too fast a recovery from them, and they may describe feeling pressured to get better. Some patients may develop unexplained chronic pain or other somatic complaints or may begin to evidence nonadherence with transplant team directives.

For patients with good premorbid functioning who become acutely ill, with only a short period of pretransplant infirmity, the transplant can be an unwelcome event. These patients can experience a heightened sense of vulnerability, and they may deny the seriousness of their medical situation (Olbrisch et al. 2002). These patients often wish to return to normal functioning as quickly as possible posttransplantation, and they may in fact recover more

rapidly than the transplant team expects; however, they may suffer later as the result of pushing themselves too much (e.g., returning to work before they are physically ready). They may resent being a transplant recipient, with all of the restrictions and regimens inherent in that role, and may act out their anger or denial in episodes of non-adherence (Olbrisch et al. 2002).

Treatment Modalities

A prospective study of kidney transplant recipients demonstrated that individual psychotherapy was effective in resolving transplant-related emotional problems, with significant reductions in BDI scores after therapy (Baines et al. 2002). Three recurring psychological themes were expressed by patients in this study: 1) fear of organ rejection, 2) feelings of paradoxical loss after surgery despite successful transplantation, and 3) psychological adaptation to the new kidney (Baines et al. 2002).

In addition to traditional therapies and pharmacotherapy, various innovative strategies have been employed to deal with specific issues of transplantation and also to address logistical and staffing resource issues. At the University of Toronto, a mentoring program was developed for heart transplant recipients. Mentorship by an already

transplanted recipient augmented patient care by providing information and support from a peer perspective (Wright et al. 2001). The four topics most commonly discussed between mentors and mentees were postoperative complications (70%), medications (70%), wait on the transplant list (70%), and the surgery itself (50%) (Wright et al. 2001). Participants less frequently discussed psychiatric topics such as anxiety (40%) and depression (10%) and personal topics such as sexual relations (20%) and marital problems (10%). The program was well received, and patients were very satisfied with the experience. To increase patient satisfaction with the mentor program, Wright et al. (2001) recommend early introduction of a mentor and matching of mentors with mentees according to demographics and clinical course.

Group therapy for organ transplantation patients and family members has also been successfully used. At the Toronto Hospital Multi-Organ Transplantation Program, group psychotherapy is organized along three dimensions: course of illness (pre- vs. posttransplantation), homogeneous versus heterogeneous group membership (e.g., separate groups for patients and caregivers vs. integrated groups, organ-specific groups vs. cross-organ groups), and group focus (issue-specific vs. unstructured) (Abbey and

Farrow 1998). Increasing levels of group therapy intensity are used, depending on the needs of the patient. Educational groups are mandatory for pretransplant candidates to prepare them for transplantation. From these groups, candidates at risk for psychosocial problems are referred to supportive and psychoeducational groups. Interpersonal and supportive-expressive psychotherapy groups are available to those who require them and have the psychological capacity to benefit from them. Group therapy participants report decreases in negative affect, increases in positive affect and happiness, less illness intrusiveness, and improved quality of life (Abbey and Farrow 1998). Transplant coordinators also report that patients in group therapy require less contact, both in clinic and by telephone for social support (Abbey and Farrow 1998).

Dew et al. (2004) developed an innovative strategy for managing the logistical problem of recipients living at a distance from the transplant program. These researchers designed and evaluated an Internet-based psychosocial intervention for heart transplant recipients and their families. This multifaceted Web-based intervention included stress and medical regimen management workshops, monitored discussion groups, access to electronic communication with the transplant team, and information on transplant-related health issues (Dew et al. 2004). Compared with heart recipients without access to the Web site, intervention patients reported significant reductions in depressive and anxiety symptoms and improved quality of life in the social functioning domain; in addition, caregivers of intervention patients reported significant declines in anxiety and hostility symptoms ($P < 0.05$). Mental health and quality-of-life benefits were greater among more frequent users of the Web site. The subgroup using the Web site's medical regimen workshop showed significantly better adherence at follow-up than did all other patients in attending clinic appointments, completing blood work, and following diet (Dew et al. 2004). Dew and colleagues concluded that a Web-based intervention could improve follow-up care, adherence, and mental health in patients and families as they adjust to heart transplantation.

Patients With Complex or Controversial Psychosocial and Psychiatric Issues

The stringency of selection criteria for transplantation appears to depend on the type of organ transplant being considered, and transplant programs often have strongly formed beliefs about the suitability of candidates with certain types of mental illness. Cardiac transplant programs are more likely than liver transplant programs to consider

psychosocial issues as contraindications, and liver transplant programs in turn are more stringent than kidney transplant programs (Corley et al. 1998; Levenson and Olbrisch 1993). These differences may be attributable to the relative availability of specific types of organs (Yates et al. 1993); alternatively, the extent of experience with specific organ transplants may allow programs to feel more comfortable with less stringent criteria (e.g., kidney transplantation, with more than three decades of experience and more than 300,000 kidney transplants performed in the United States) (United Network of Organ Sharing 2009). In addition, for kidney transplantation, cost-effectiveness research has clearly demonstrated the long-term cost savings of kidney transplantation relative to dialysis (Eggers 1992). With such unequivocal evidence, insurance payers have a strong financial incentive to refer patients early for preemptive transplantation, before the high costs of dialysis begin to accumulate (Eggers 1992). In such a setting, psychosocial factors may have less impact on transplantation candidacy. Other issues influencing the selection process include moral and ethical beliefs, societal views, personal beliefs, and even financial constraints.

Although increasing numbers of poor prognostic indicators during the perioperative period may increase risk for nonadherence posttransplantation (Dew et al. 1996; see subsection "Posttransplant Regimen Adherence" below), it should be emphasized that candidates with any one of these features are not categorically poor recipients or that patients without any of these features do not categorically make the best candidates. What little research is available provides some support for clinical assumptions that patients with certain personality disorders, substance use disorders, poor coping skills, poor adherence, and poor social supports can have worse posttransplant outcomes. Nevertheless, case reports have demonstrated that even some patients who might seem inappropriate for transplant (e.g., patients with active psychosis or with severe personality disorders) (Carlson et al. 2000; DiMartini and Twillman 1994) can undergo transplantation and maintain adequate adherence after the procedure. Such patients should be carefully assessed pretransplant with optimization of their pretransplant condition and ongoing psychiatric monitoring and treatment posttransplantation. Prospective longitudinal studies are needed to clarify pretransplant factors that contribute to increased risk of poor outcomes (both psychological and medical) and the contribution of posttransplant factors on outcomes as well.

Posttransplant Regimen Adherence

Lifelong immunosuppression is a prerequisite for good graft function, and nonadherence with immunosuppressive medication is often associated with late acute rejection

episodes, chronic rejection, graft loss, and death. It might be assumed that transplant patients, in general, constitute a highly motivated group and that their adherence levels would be high. Unfortunately, like other patients living with chronic disease, many organ recipients experience difficulty in maintaining high levels of adherence to the multiple components of their regimen (Dew et al. 2007a; Laederach-Hofmann and Bunzel 2000). A recent study compared heart and lung transplant recipients during the first 2 years posttransplant and found that rates of persistent nonadherence (i.e., nonadherence at ≥ 2 consecutive assessments—a span of approximately 6 months) regarding immunosuppressant medication, diet, and smoking were lower in lung recipients than in heart recipients. Relying on public health insurance and having poor caregiver support increased nonadherence risk in both groups of patients (Dew et al. 2008b). In a recent meta-analysis involving nearly 150 studies of all organ types, the average nonadherence rates ranged from 1–4 cases per 100 patients annually for substance use (including tobacco, alcohol, and illicit drugs) to 19–25 cases per 100 patients annually for a variety of areas of nonadherence (e.g., immunosuppressant medication, diet, exercise, and other transplant health care requirements) (Dew et al. 2007a). Medication nonadherence was especially high, and clinicians can expect to see 23 nonadherent patients for every 100 individuals seen during a given year of follow-up (Dew et al. 2007a). Immunosuppressant nonadherence was also highest in kidney recipients (36 cases per 100 patients annually vs. 7–15 cases for other organs) (Dew et al. 2007a).

Nonadherence to immunosuppressive medication is of particular concern, given these medications' role in preventing graft rejection, related morbidities, and mortality. With organ transplantation, nonadherence impairs both life quality and life span, as it is a major risk factor for graft-rejection episodes and may be responsible for up to 25% of deaths after the initial recovery period (Bunzel and Laederach-Hofmann 2000). Nonadherence leads to waste, as it reduces the potential benefits of therapy and adds to the costs of treating avoidable consequent morbidity. Graft loss from nonadherence is also tragic, given the large numbers of patients on the waiting lists. The global assessment of posttransplant regimen adherence is difficult, and patients can manifest varying degrees of adherence to medical recommendations. Moreover, the medical recommendations pertain to a multifaceted regimen of care. For transplant recipients, adherence to immunosuppressive medications is typically the chief area of focus. Yet the occurrence of clinically measurable events such as rejection episodes, organ loss, or death underrepresents the true amount of medication nonadherence, as some patients who are only partially adherent have not yet experienced a

clinically adverse event (Bunzel and Laederach-Hofmann 2000; De Geest et al. 1995). Although such "subclinical" nonadherence is undetectable as a medical event, it is important as an indicator of those patients having difficulty following their medical regimens (Feinstein 1990).

Some research has examined correlates and outcomes of nonadherence. For example, several reports have found associations between nonadherence to both immunosuppressive medications and other aspects of the medical regimen and increased risk of morbidity and mortality in transplant recipients (De Geest et al. 1995; Dew and Kormos 1999; Dew et al. 1996; Paris et al. 1994). In terms of risk factors for nonadherence, Dew et al. (1996) carried out a "dose-response" analysis of specific factors found to contribute to nonadherence to medications in a preliminary regression analysis. A "dose" variable was created by determining how many of these six psychosocial risk factors—*anxiety, anxiety-hostility, poor support from caregivers, poor support from friends, failure to use active cognitive coping strategies, and use of avoidance coping strategies*—a recipient possessed. The logistic regression model showed a strong dose effect, in that if 0 to 1 psychosocial risk factor was present, the probability of having postoperative adherence difficulties was less than 30%. With 2–3 factors present, the probability rose to about 50%, and if 4 or more risk factors were present, more than 80% of patients encountered significant adherence difficulties. This means that if predictors cumulate, adherence problems are likely to rise dramatically.

From a research standpoint, we continue to have limited understanding of the full range of risk factors for posttransplantation adherence problems (Dew et al. 2007a). One review, which warrants further investigation, found a higher rate of nonadherence among U.S. patients compared with their European counterparts, which may be related to the differences in the health care systems of these regions, among other sociocultural factors (Denhaerynck et al. 2006). However, clinical observation of any given patient will quickly reveal that there can be many reasons for nonadherence, and an attempt to identify, understand, and correct the reasons is the first step in improving adherence. Patients may require ongoing or remedial education about the need for lifelong adherence to immunosuppressive medication. Often, the symptoms of chronic rejection are silent, and recipients may not recognize that they are developing complications, as they do not initially feel any adverse effects from discontinuing their medications. Discomfort with medication side effects should be elicited and alleviated if possible. Unfortunately, if the nonadherence results in acute or chronic graft rejection, the treatment typically requires an increase in the dosage of the primary calcineurin-inhibiting immunosuppressive medication

and/or addition of other immunosuppressive medications including monoclonal antibodies, steroids, mycophenolate mofetil, or sirolimus, which tend to create or exacerbate neuropsychiatric medication side effects (see the section “Neuropsychiatric Side Effects of Immunosuppressive Agents” later in this chapter). Problems with insurance prescription coverage or other financial issues should be assessed. Additionally, depression has been implicated in cases of nonadherence, and mood symptoms should be elicited and treated (see Table 31–2). Some studies have determined that psychiatric problems that persist after transplantation are highly associated with nonadherence (Paris et al. 1994; Phipps 1997). In an extensive literature review of posttransplant adherence for all organ types, Bunzel and Laederach-Hofmann (2000) found that anxiety disorders and, in particular, untreated major depression were significantly associated with nonadherence. In a study of 125 heart transplant recipients (P.A. Shapiro et al. 1995), adherence problems were associated with a history of substance abuse ($P=0.0007$). Cukor et al. (2008) found that among patients who had undergone renal transplantation, those patients who perceived that they had control over their outcomes (internal locus of control) were less depressed compared with those who attributed their outcomes to chance. The belief that health was controlled by chance correlated significantly with depressive affect. In a follow-up study, these investigators found that depression was a significant predictor of nonadherence to medications in both posttransplant and end-stage renal disease patients on hemodialysis, although hemodialysis patients were more depressed and reported lower medication adherence (Cukor et al. 2009).

In comparison with adherence in adults, adherence in pediatric transplant recipients can be complicated by the additional factors of developmental stage, attempts at autonomy/individuation, parental control/support, and parental stress. Dew et al. (2009) found (across all organ types) that nonadherence to clinic appointment and tests was the most common type of nonadherence in pediatric patients, at 12.9 cases per 100 patients annually. The rate of nonadherence to immunosuppressive medications was 6 cases per 100 patients annually. Older age of the child, worse family functioning (e.g., greater parental distress, lower family cohesion), and poorer psychological status of the child (e.g., poorer behavioral functioning, greater distress) were significantly but only modestly correlated with poorer adherence (Dew et al. 2009).

In an attempt to develop a clinically useful measure of adherence, Stuber et al. (2008) recently investigated children and adolescent liver transplant recipients using a unique method to evaluate immunosuppressive medication levels. They calculated the standard deviation (SD) of

TABLE 31–2. Recommendations to clinicians for assessing adherence of transplant recipients

- Inquire about patients' adherence routinely both early posttransplant and in ensuing years.
- Recognize that posttransplant adherence involves multiple activities:
 - Taking medication.
 - Attending clinic appointments.
 - Completing required tests.
 - Adhering to lifestyle requirements (e.g., diet, exercise).
 - Avoiding alcohol, illicit drugs, and tobacco.
- Collect evidence from multiple sources: the patient, spouse/significant other/family, transplant coordinator, laboratory data, and pharmacy records.
- Inquire about correlates of nonadherence (e.g., psychological distress/psychiatric disorders, patient/family supports, insurance/financial issues).
- Consider psychological, characterological, and other behavioral factors and coping strategies possibly playing a role in nonadherence.
- Solutions may require multifaceted interventions to address not only nonadherence but these other contributory factors.

Source. Adapted from Dew et al. 2009.

tacrolimus blood levels over a 1-year period and found that rather than a one-time “snapshot” or a single abnormal blood level, a threshold value SD of 2.5 in the tacrolimus level over the year predicted rejection episodes (Stuber et al. 2008). Tacrolimus SDs were also significantly related to poor quality-of-life measures across domains of physical, social, and school functioning among adolescent liver transplant recipients. Nonadherent adolescents reported poorer health perceptions, lower self-esteem, and more limitations in social and school activities (Fredericks 2008). Better knowledge of medication regimens, using a pillbox to organize medications, and parental involvement in medication administration all contributed to improved adherence among adolescent renal transplant candidates (Zelikovsky et al. 2008). The reader is also referred to Chapter 34, “Pediatrics,” for additional information on health regimen compliance in adolescents.

Surprisingly, the literature on techniques to improve posttransplant compliance is scant and has focused primarily on medication adherence and not on other forms of nonadherence (e.g., diet, substance abuse, health monitoring). A systematic review of the literature on interventions intended to improve medication adherence in transplant patients found only 12 intervention studies, only 5 of

which used randomized controlled trial designs. These studies were hampered by differences in the definition of nonadherence, lack of sufficient detail to replicate the study, and small sample sizes. A combination of cognitive, educational, counseling, and psychological interventions at the patient, health care provider, setting, and system levels was found more likely to be effective in the long term (De Bleser 2009).

Alcohol and Other Substance Use Disorders

Compared with other solid organ transplant candidates, liver transplant (LTX) candidates more often require psychiatric consultation for substance addiction assessment, due to the prevalence of alcoholic liver disease (ALD) and viral hepatitis transmitted through contaminated needles. An estimated 50% of LTX recipients have a pre-LTX history of alcohol and/or drug abuse/dependence (DiMartini et al. 2002). A survey of 69 U.S. liver transplantation programs found that 83% of programs have a psychiatrist or addiction medicine specialist routinely see each patient with ALD during the evaluation phase (Everhart and Beresford 1997). In the optimal situation, the psychiatric clinician is an integral member of the transplant clinical care team and can integrate the addiction treatment plan into the patient's pre- and posttransplant care. The Cleveland Clinic Foundation has formed a chemical dependence transplant team to assess, treat, and monitor transplant patients with addictive disorders (Stowe and Kotz 2001). This program is a model for the integration of such services.

Psychiatric consultation provides a thorough evaluation of the candidate's addiction history, the candidate's understanding of his/her addiction (especially in the context of his/her health and need for transplantation, stability in recovery, and need for further or ongoing addiction treatment), and the presence of other psychiatric disorders. Family and social support for the candidate's continued abstinence both pre- and posttransplantation must also be evaluated. In one study of LTX candidates, those with a history of substance abuse revealed significantly more distress, less adaptive coping styles, and more character pathology than their counterparts (Stilley et al. 1999). Because these features may heighten the potential for relapse, periodic reassessment by the psychiatric consultant provides follow-up on the candidate's progress in recovery, including verifying ongoing participation in rehabilitation as well as monitoring for psychological and affective distress and poor coping styles with therapeutic interventions targeting these problems as they arise. Documentation of treatment participation is desirable, as is random toxicological screening for alcohol and other substances. These measures are especially important for patients early in recovery and for those with a short period of abstinence, de-

nial over their problem, resistance to seeking treatment, or poor social support for continuing abstinence. One study of pretransplant wait-listed ALD candidates found that 15% of candidates had used alcohol at some point after the initial transplant evaluation (Weinrieb 2003).

One-year post-LTX drinking rates (i.e., the percentage who used any alcohol by 1 year post-LTX) range from 8% to 37% (DiMartini 2000b; Everson et al. 1997), with cumulative rates estimated at 30%–40% by 5 years post-LTX (Lucey 1999). Rates of pathological drinking, defined as drinking that results in physical injury or alcohol dependence, are 10%–15% (Everson et al. 1997; Fireman 2000). In one study, 15% of LTX recipients had their first drink within the first 6 months post-LTX, a finding that highlights the importance of early and intensive clinical follow-up to identify alcohol use at its onset (DiMartini et al. 2001). In a meta-analysis of 50 studies of LTX recipients, the average alcohol relapse rates were 5.6 cases per 100 patients per year for any alcohol use and 2.5 cases per 100 patients per year for heavy alcohol use (Dew et al. 2008a). From this same meta-analysis, the rates of relapse to illicit drug use averaged 3.7 cases per 100 patients per year. Interestingly, this rate was significantly lower in liver recipients versus other organ recipients (1.9 vs. 6.1 cases). Although these rates of alcohol or drug use during any given year may appear relatively low, they are cumulative over time (Dew et al. 2008a). Other studies suggest that the rate of alcohol use may attenuate with the passage of time post-LTX (Berlakovich et al. 1994; Campbell et al. 1993); nevertheless, dependent drinking can begin years post-LTX (DiMartini 2000a).

Consistent predictors of posttransplant alcohol use have been difficult to identify. This may be due to the heterogeneity of the ALD transplant population and the potential selection bias whereby the most stable candidates are chosen, making this population different from the general alcohol-abusing/dependent populations (DiMartini et al. 2002). For example, a pretransplant history of illicit drug use has not been consistently associated with increased risk for posttransplant alcohol relapse in ALD recipients (Coffman et al. 1997; DiMartini et al. 2002; Fireman 2000; Foster et al. 1997; Newton 1999), possibly because many ALD recipients had discontinued their drug use many years prior to transplantation (Coffman et al. 1997). In one of the few prospective studies to examine posttransplant alcohol use, a pretransplant history of alcohol dependence, a family history of alcoholism, and prior rehabilitation experience (thought to be a marker for those with more severe addiction) were all found to be associated with posttransplant alcohol use ($P < 0.05$). A prior history of other substance use was associated with a higher (but non-statistically significant) risk of posttransplant drinking (DiMartini 2000b). Similarly, a meta-analysis of LTX

studies showed little correlation between demographics and most pretransplant characteristics, although poorer social support, a family alcohol history, and less than 6 months' pretransplant abstinence were associated with relapse (Dew et al. 2008a).

Compared with LTX candidates with alcohol dependence, LTX candidates with polysubstance dependence are more likely to have multiple prior addiction treatments; more likely to be diagnosed with personality disorders, especially Cluster B type (antisocial, narcissistic, histrionic, borderline); and less likely to have stable housing, a consistent work history, or stable social support (Fireman 2000). Yet despite evidence that this specific population could be at higher risk for relapse, there are few published outcome studies addressing the issue of posttransplant nonalcohol substance use. Most studies have investigated the rates of relapse only in ALD recipients who also had a nonalcohol substance use disorder. One of the few studies to investigate all patients with a pre-LTX addiction history found not only that patients with a pre-LTX history of polysubstance use disorders had a higher relapse rate compared with those with alcohol dependence alone (38% vs. 20%) but also that the majority of polysubstance users demonstrated ongoing post-LTX substance use (Fireman 2000). Studies investigating all transplant recipients are needed to identify the true posttransplant rates of other substance use.

After transplantation, maintaining an open, nonjudgmental dialogue with transplant recipients appears to be the most effective way to identify alcohol and/or other substance use in the posttransplant period, and most recipients are open to discussing their substance use habits with the transplant team (DiMartini et al. 2001; Weinrieb et al. 2000). A review of liver enzymes and biopsy results and a candid discussion of the damage caused by alcohol and other substances provide an opportunity to explore the patient's denial of the consequences of their use. Even in the most difficult cases, patients wish to maintain their health and are willing to listen to advice and recommendations on addiction treatment. In our experience, the transplant team has established a powerful emotional bond with the recipient. Many patients who have resumed substance use were relieved to learn that the transplant team would not abandon them. On the other hand, it is important not to condone or dismiss small amounts of alcohol or other substance use. What may seem supportive can be distorted by the patient with an addiction and become an excuse to use more regularly. In the case of alcohol use, we have found that few patients with alcoholism can drink "socially" posttransplantation (Tringali et al. 1996) and that those who take their first drink often consume moderate to heavy amounts of alcohol (DiMartini et al. 2002). Therefore, total alcohol abstinence is recommended for these patients.

Medications that may reduce cravings and potentially diminish relapse risk for alcohol (e.g., acamprosate, ondansetron, naltrexone) or opioids (e.g., naltrexone) have not been studied in transplant patients. One study that attempted to use naltrexone in actively alcohol-relapsing LTX recipients found that patients were reluctant to use naltrexone as a result of its potential, albeit small, risk of hepatotoxicity (Weinrieb et al. 2001). Naltrexone can be a direct hepatotoxin at dosages higher than recommended (>300 mg/day) and is not recommended for patients with active hepatitis or liver failure. Disulfiram has been used in nontransplant populations to provide a negative reinforcement to drinking alcohol. This agent blocks the oxidation of alcohol, resulting in an accumulation of acetaldehyde, and can create severe nausea, vomiting, and hemodynamic instability. It requires hepatic metabolism for conversion into an active drug. A metabolite of disulfiram is an inhibitor of cytochrome P450 (CYP) 3A4 (Madan et al. 1998), and posttransplantation may interfere with immunosuppressive medication metabolism. Use of disulfiram in transplant recipients could place these individuals at risk for serious harm and is not recommended. In nontransplant patients, selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) can stabilize mood and improve abstinence rates in depressed relapsing alcoholic individuals (Cornelius et al. 2003) and may be the most appropriate pharmacological interventions for transplant recipients if concurrent mood symptoms are present. Anecdotally, acamprosate has been safely used in a number of LTX recipients, with some success in decreasing cravings and alcohol use. It is renally excreted; thus, the dosage may need to be adjusted in renal insufficiency.

Methadone-Maintained Candidates

Transplant program acceptance of opioid-dependent patients receiving methadone maintenance treatment (MMT) is a controversial issue. Several studies have examined candidate selection processes and posttransplant outcomes for this population.

In a survey of U.S. liver transplantation programs (Koch and Banyas 2001), of the 56% of programs that reported accepting patients for evaluation who were taking methadone, a surprising 32% required patients to discontinue their methadone use prior to transplantation. Of even more concern was the overall lack of experience with such patients (i.e., only 10% of the programs had treated more than five MMT patients). Although there are no studies of pretransplant methadone cessation in LTX patients, there exists an abundance of evidence showing that tapering methadone in stable methadone-maintained patients results in relapse to illicit opiate use in up to 82% of these individuals (Ball and Ross 1991). In our opinion, an at-

tempt to taper a recovering opiate addict from methadone should not be made at a time when the patient is struggling with the stresses and pain associated with end-stage liver disease. Until data to the contrary emerge, requiring methadone tapering in stable opiate-dependent patients as a prerequisite for transplant candidacy could be considered unethical. This strategy potentially heightens the risk for relapse, and those that relapse would be denied transplantation.

In regard to posttransplant outcomes of MMT patients, Koch and Banys (2001) found that of the approximately 180 transplant patients on methadone maintenance at the time of the survey, relapse to illicit opiate use was reported for less than 10% of patients. Similar to other reports of nonadherence in transplant patients (see subsection "Post-transplant Regimen Adherence" earlier in this chapter), approximately 26% of MMT patients had adherence difficulties with immunosuppressive medications (Koch and Banys 2001). However, it was not reported whether those who used illicit drugs were also among those who had problems with adherence. In general, the transplant programs did not consider that the nonadherence necessarily affected outcomes, and the transplant coordinator's impressions were that only 7 of 180 patients had poor outcomes (Koch and Banys 2001). In two small series of MMT LTx recipients (5 in each), overall long-term patient and graft survival were found to be comparable to those of other LTx recipients at the transplant centers, with none of the MMT patients evidencing posttransplant nonadherence or illicit drug use (Hails and Kanchana 2000; Kanchana et al. 2002). Liu et al. (2003), in a study of the largest single cohort ($N=36$) of MMT LTx recipients to date, concluded that patient and graft survival were comparable to national averages (they did not use a control group, however). Although four patients (11%) reported isolated episodes of heroin use posttransplantation, relapses were not considered to have resulted in poorer outcomes.

An important clinical consideration is pain management for patients on MMT prior to transplantation. These patients may require higher-than-average doses of narcotic analgesics perioperatively, and the transplant team may need to be alerted to this issue. In one specific example, patients on MMT in whom methadone was also used as the posthospitalization pain medication required an average methadone dose increase of 60% posttransplantation, presumably to adjust for chronic downregulation of mu opioid pain receptors from chronic methadone exposure (Weinrieb et al. 2004) and improvement in metabolism after transplantation. Many clinicians consider methadone to be a useful choice for pain management rather than introducing another narcotic that may inadvertently precipitate a relapse. However, methadone dose increases, if not

reduced to the prior pretransplant dose, may need to be renegotiated with the MMT program at the point the patient transitions back to the program's care. These issues and coordination of temporary leave from the MMT program, the timing of return, and whether the transplant recipient will need to return for daily doses or may be allowed "carry-outs" (especially useful for avoiding contact with other people while immunosuppressed) are important considerations for the psychosomatic medicine specialist to address.

Thus, the descriptive studies demonstrate that MMT transplant recipients can successfully undergo transplantation and do well; however, the lack of control groups makes it difficult to prove that MMT patients' rates of complications and survival are no different from those of transplant recipients in general. Although the small numbers of MMT candidates and recipients preclude large-scale prospective studies, a case-control study conducted by M.J. Gordon et al. (1986) found that posttransplant patient and graft survival rates in the 20 heroin-addicted kidney recipients were similar to those in the control group. The leading cause of death (infection) was the same in both groups. In the study group, only one patient returned to heroin use. Two other study patients who were not suspected of using heroin lost their grafts as a result of medication nonadherence, whereas no patient in the control group lost a graft as a result of nonadherence (M.J. Gordon et al. 1986). In summary, the data to date justify neither automatic exclusion of MMT patients from transplantation nor any requirement that such patients be tapered off methadone prior to transplant.

Personality Disorders

Personality disorders are characterized by persisting and inflexible maladaptive patterns of subjective experience and behavior that may create emotional distress and interfere with the individual's interpersonal relationships and social functioning. The requirements of successful transplantation can be too difficult for such an individual, as the process requires a series of adaptations to changes in physical and social functioning and significant ability to work constructively with both caregivers and the transplant team. By identifying personality traits and disorders, the psychiatrist can potentially predict patterns of behavior, recommend treatment, develop a behavioral plan with the team to work constructively with the patient, and render an opinion as to the candidate's ability to proceed with transplantation. Patients with personality disorders can require excessive amounts of time from the transplant team, which raises the issue of resource allocation as a potential selection criterion (Carlson et al. 2000). Not surprisingly, a majority of programs (50%–60% across organ

types) consider personality disorders to be a relative contraindication to transplantation (Levenson and Olbrisch 1993). Yet all personality disorders should not be viewed similarly, as the behavioral and coping styles of different personality disorders can present varying degrees of concordance with the needs of transplantation. For example, the need for structure and orderliness of a candidate with obsessive-compulsive personality disorder would be more adaptive to the demands of transplantation than the coping style of a patient with borderline personality disorder.

The incidence of personality disorders in transplant populations is similar to that in the general population, ranging from 10% to 26% (Chacko et al. 1996; Dobbels et al. 2000), although in some cohorts estimates have been as high as 33% (in a cohort of heart and lung transplant recipients) (Stilley et al. 2005) or even 57% (predominantly in those with a history of substance abuse) (Stilley et al. 1997). However, the identification of personality disorders depends on the definition and measurement methods used. Unfortunately, studies investigating personality disorders and transplantation outcomes have not distinguished among the various personality disorder types (perhaps because of the low prevalence of each type), which makes generalizations difficult. Nevertheless, case reports of patients with severe character pathology demonstrate the extent of adherence problems that can arise from these disorders, resulting in significant morbidity and recipient death (Surman and Purtilo 1992; Weitzner et al. 1999). The disturbances in interpersonal relationships that can occur with personality disorders also can decrease the likelihood that patients will have stable and reliable social supports during the pre- and posttransplant phases (Yates et al. 1998). Of the personality disorders, borderline personality disorder is considered to represent the highest risk for posttransplant nonadherence (Bunzel and Laederach-Hofmann 2000).

Whereas sociopathy has not consistently been associated with substance relapse in the addiction literature (Vaillant 1997), a survey of transplant programs in the United States revealed that 4 of 14 programs (29%) would reject a candidate with comorbid antisocial personality disorder and alcohol dependence (Snyder et al. 1996). In a study of 73 ALD transplant candidates, patients with severe personality disorders had higher rates of divorce, higher rates of comorbid drug abuse/dependence, lower IQs, higher scores on indicators of emotional impairment, and were more likely, although not significantly so, to return to drug use during the pretransplant follow-up period (Yates et al. 1998). However, of this cohort, 3 patients with serious personality disorders underwent liver transplantation and did not relapse or become nonadherent in the early postoperative phase (Yates et al. 1998). In con-

trast, another study of 91 patients transplanted for ALD and followed for up to 3 years identified 18 patients exhibiting antisocial behavior (Coffman et al. 1997). Of those with antisocial behavior, 50% returned to either alcohol ($n=6$) or prescription narcotic addiction ($n=3$) posttransplantation, which was significantly higher than the 19.8% alcohol use by the total group (Coffman et al. 1997). In a prospective study of 125 heart transplant recipients, personality disorders were associated with posttransplant adherence problems ($P=0.007$) (P.A. Shapiro et al. 1995). Although personality disorders were not associated with survival, those individuals with personality disorders tended to have more graft rejection ($P=0.06$) (P.A. Shapiro et al. 1995). Using the Type D (for "distressed") personality construct (based on two broad and stable personality traits—negative affectivity and social inhibition), Denollet et al. (2007) found significantly higher rates of mortality and early allograft rejection in heart recipients with Type D personality. However, without any posttransplant psychological or compliance measures, the contribution of this personality type or psychological distress to outcomes was speculative (Denollet and Kupper 2007). Using a cross-sectional design to study heart transplant recipients (average of 7 years posttransplant), Pedersen et al. (2006) also found that those with Type D personality were more likely to have worse physical and mental health-related quality of life (3 and 6 times greater risk, respectively), suggesting that this personality construct has important implications for identifying those who may need additional psychosocial support and intervention.

Although not identified as specific personality disorder styles, various coping and behavioral styles have also been shown to influence survival. A study by Chacko et al. (1996) of survival after heart transplantation found that whereas the presence of clinician-rated Axis II disorders (26% of the group) was not associated with survival time, health behaviors, maladjustment, and coping styles represented some of the strongest predictors of survival. Using the same measure of health behavior and coping (Millon Behavioral Health Inventory [Millon et al. 1982]), Coffman and Brandwin (1999) found that wait-listed heart transplant candidates with high scores on the Life Threat Reactivity subscale had significantly higher mortality before transplantation (42% vs. 18%; $P=0.0001$) but not after transplantation. These investigators suggested that one possible explanation was that the detrimental psychological traits of the high-risk group were ameliorated by surviving to be transplanted (Coffman and Brandwin 1999).

Patients with personality disorders do best with ongoing pre- and posttransplant psychotherapy, specifically cognitive and behavioral interventions to promote adherence with the care regimen and to establish a working alli-

ance with transplant team members (Dobbels et al. 2000). These patients should be given clear and consistent instructions on rules and requirements of transplantation, reinforced by regular outpatient appointments. A limited number of transplant center staff should maintain contact with the patient, and staff should communicate regularly among themselves and the outpatient psychiatric team (Carlson et al. 2000) to coordinate care and to reduce opportunities for cognitive distortions and splitting by the patient. A formal written contract can document the expectations of the transplant team and serve as a therapeutic treatment plan whereby the patient and team agree to work together toward common goals for the transplant recipient's health (Dobbels et al. 2000).

Psychotic Disorders

Although chronic and active psychosis is thought by many to be incompatible with successful transplantation, case reports of carefully selected patients with psychosis demonstrate that such patients can successfully undergo transplantation and survive after the procedure (DiMartini and Twillman 1994; Krahn et al. 1998). A survey of transplant psychiatrists at national and international transplant programs identified only 35 cases of pretransplant psychotic disorders in transplant recipients from 12 transplant centers (Coffman and Crone 2002), suggesting that such patients are highly underrepresented among transplant recipients. Results of this survey confirmed previously expressed stipulations that patients with psychotic disorders be carefully screened before acceptance. Candidates should have demonstrated good adherence to both medical and psychiatric follow-up requirements; possess adequate social supports, especially in-residence support; and be capable of establishing a working relationship with the transplant team. In this survey (Coffman and Crone 2002), risk factors for problems with adherence after transplantation included antisocial or borderline personality disorder features, a history of assault, living alone, positive psychotic symptoms, and a family history of schizophrenia. Posttransplant nonadherence with nonpsychiatric medications was found in 20% of patients (7 of 35), and noncompliance with laboratory tests was found in 17% (6 of 35 patients) (Coffman and Crone 2002); however, these numbers are similar to percentages of medication and laboratory testing nonadherence in general transplant populations. Overall, nonadherence resulted in rejection episodes in 5 patients (14%) and in reduced graft function or loss in 4 patients (12%) (Coffman and Crone 2002). Thirty-seven percent of patients experienced psychotic or manic episodes posttransplantation (not necessarily associated with immunosuppression), 20% attempted suicide (with two completed suicides), 20% experienced severe depression or catatonia, 5.7% committed

assaults, 5.7% were arrested for disorderly conduct, and 8.6% required psychiatric commitment (Coffman and Crone 2002).

Although concerns have been raised in regard to the potential of immunosuppressive medications to produce or exacerbate psychotic symptoms, patients with a prior psychiatric history are not necessarily more susceptible to "steroid psychosis" than are patients without such a history (R. C. Hall et al. 1979), and appropriate use of antipsychotic medication is usually adequate to manage these symptoms if they emerge. Because transplant teams often overlook the early postoperative reinstitution of antipsychotic medications, it is essential that the psychiatrist devote careful attention to this issue during the immediate postoperative phase. If quick reintegration of the patient into his or her pretransplant outpatient psychiatric treatment regimen is not possible because of infirmity, interim in-home psychiatric follow-up care should be instituted.

Intestinal Transplantation

Isolated small bowel transplantation and multivisceral transplantation including the bowel are still relatively uncommon procedures, yet with improvements in therapies and longer survival, they are becoming a standard treatment for patients with intestinal failure and parenteral nutrition dependency (Fishbein 2009; Langnas 2004). Candidates for intestinal transplantation typically have experienced complications such as repeated episodes of sepsis or dehydration, early liver disease, or loss of central venous access (Fishbein 2009). For parenteral nutrition-dependent patients without complications who seek to improve their quality of life, the decision to transplant is controversial, and data on posttransplant improvement in patient quality of life are limited (Fishbein 2009). UNOS reported a 5-year survival of only 50% for those transplanted after 2001 ($n=353$) (Langnas 2004), and the 5-year survival of patients treated with total parenteral nutrition is only 63%, even at experienced centers (Fishbein 2009). An international conference in 2003 found that only 28 centers had performed one or more intestinal transplants in the 2 prior years, with the majority of recipients younger than 18 years (Langnas 2004). Perhaps because of small numbers and poor long-term survival, few studies have investigated outcomes beyond the immediate postoperative course and survival. Earlier studies on the psychiatric characteristics of the patient population showed them to be a complex group, often with character pathology and drug and/or alcohol dependence histories and with iatrogenic dependence on high-dose narcotics (DiMartini et al. 1996b). Some of these features could be ascribed to the difficulties of living with a chronic debilitating illness prior to transplantation, the severity and extent of the transplant surgery, and the pro-

longed posttransplantation hospitalizations marked by frequent setbacks.

Patients and their caregivers should be prepared for long and frequent hospitalizations, especially during the first years following transplantation (DiMartini et al. 1996b), although substantial reductions in the initial hospitalization and need for readmission have occurred in recent years (Langnas 2004; O'Keefe et al. 2007). Studies of quality of life among adults in the first years following intestinal transplantation show that patients can be weaned from nutritional support and achieve improvements in anxiety, depression, cognition, stress, parenting, digestive and urinary function, control of impulsivity, medical compliance, quality of social relations, and leisure and recreation (DiMartini et al. 1998; O'Keefe et al. 2007). For candidates or recipients without adequate gut absorption, the use of psychotropics without parenteral formulations is challenging, and other nonenteral routes of administration may need to be considered (Thompson and DiMartini 1999; see also "Alternative Routes of Administration" in Chapter 38, "Psychopharmacology"). Weaning from high-dose narcotics following successful transplantation may be difficult (DiMartini et al. 1996b). Information on the long-term psychological outcomes and functioning of intestinal transplant recipients is lacking.

Special Issues During the Pretransplant Phase

Cognitive Disorders and Delirium

Through the pre- to posttransplant phases, patients frequently experience cognitive dysfunction ranging from subclinical or mild symptoms to frank delirium. Impairment in cognitive function often results from physiological consequences of end-stage organ disease but may also be secondary to other comorbid disease processes (e.g., central nervous system [CNS] vascular disease from diabetes or hypertension), damage from prior alcohol or drug exposures, or previous structural damage to the brain (e.g., head trauma). Persistent cognitive deficits during the pretransplant phase indicate a preexisting dementia or static cognitive impairment. While a fluctuating course suggests a potentially reversible delirium, in some cases such encephalopathy can be chronic and persisting. Gathering information on symptom history over time is important. An electroencephalogram can aid in the diagnosis, especially if the symptoms are subtle or mostly behavioral in nature and not as readily identifiable as encephalopathy (although mild generalized slowing may also be seen in dementia), and imaging may be beneficial to evaluate evidence of structural damage (e.g., small-vessel disease, prior

strokes, edema [as seen in some cases of hepatic encephalopathy]). Aggressive treatment of delirium and its causes should be pursued, with subsequent reassessment of cognition. The reversibility or progression of deficits may in part depend on age, the homeostatic reserve of the brain, prior CNS insults, and the ability to withstand future transplant-related stressors (e.g., prolonged anesthesia, use of cardiac bypass, hemodynamic fluctuations, post-transplant immunosuppressive medications). While the restoration of normal organ function and physiology after transplantation may be expected to correct reversible cognitive impairments, such deficits may take months to years to resolve and may not resolve completely (Arria et al. 1991; DiMartini and Chopra 2009; Kramer 1996; O'Carroll et al. 2003; Rovira et al. 2007).

In heart failure, low cardiac output and CNS hypoperfusion from reduced cerebral blood flow can contribute to cognitive impairment. Even in the absence of acute cerebrovascular events, impaired cerebrovascular reactivity and ischemia may result. CNS microemboli are common in pre-heart transplant patients especially for those on ventricular assist devices. In renal disease, accumulation of metabolic products (e.g., urea, uric acid, others), in addition to hormonal elevations, electrolyte imbalances, malnutrition, and decreased GABA and glycine activity, contributes to encephalopathy. Removal of uremic toxins by hemodialysis, correction of electrolyte imbalances and anemia, and treatment of malnutrition can diminish symptoms and improve cognition. For patients with end-stage lung disease, hypoxia and hypercapnia may cause mild to severe cognitive deficits, particularly in executive functions, attention, and memory (Parekh et al. 2005). Oxygen therapy may improve cognitive function for some lung candidates, and these patients can benefit from lung transplantation, but the extent to which these deficits are reversible is unclear (Parekh et al. 2005). Hepatic encephalopathy and adverse events related to ventricular assist devices are two specific areas considered in detail below.

Hepatic Encephalopathy

Hepatic encephalopathy (HE), a neuropsychiatric syndrome commonly encountered in LTX candidates, is characterized by a constellation of signs and symptoms, such as alteration of consciousness (including stupor or coma), cognitive impairment, confusion/disorientation, affective/emotional dysregulation, psychosis, behavioral disturbances, bioregulatory disturbances, and physical signs such as asterix. (Hepatic encephalopathy is also addressed in Chapter 20, "Gastrointestinal Disorders.") Identification of HE is important, because its symptoms directly affect patient quality and quantity of life; fulminant HE is associated with intracranial hypertension, cerebral edema,

and death pretransplant (Ferenci et al. 2002). Efforts to define HE have emphasized that it reflects a continuum of symptoms. Even subclinical HE is clinically important, because it can impair patient safety (Schomerus et al. 1981) and is associated with persistent cognitive deficits post-LTX (Tarter et al. 1990). Eighty-five percent of patients with subclinical HE were found to be either of questionable fitness or unfit to drive on psychometric testing of driving capacity, and in on-road testing one third performed unacceptably (Schomerus et al. 1981; Wein et al. 2004). By definition, subclinical HE is not identifiable on a typical clinical examination; detection may require additional neuropsychological tests of psychomotor speed, praxis, concentration, and attention. The Trail Making Test (A and B) and the Digit Symbol and Block Design tests from the Wechsler Adult Intelligence Scale—Revised are commonly used to identify subclinical HE impairment. Hepatic disease severity is strongly correlated with impairment in performance on tasks of immediate memory, delayed memory, and attention (Meyer et al. 2006). Whereas the prognostic significance of HE is well known, the long-term impact of subclinical encephalopathy on cognitive functioning requires further investigation.

The predominant strategy for treating HE involves reducing the production and absorption of ammonia from the intestinal tract, although a variety of compounds and metabolites (e.g., mercaptans, false neurotransmitters, manganese, endogenous benzodiazepines, increased concentrations of CNS gamma-aminobutyric acid [GABA]) have also been implicated in HE (Chung and Podolsky 2001; Riordan and Williams 1997). Psychiatric consultants should be familiar with ammonia-reducing strategies, because they are often the clinicians who must recognize and monitor HE symptoms, identify whether patients are being treated for HE, and make recommendations regarding the need for initiating or improving treatment. HE can be precipitated by gastrointestinal hemorrhage, uremia, use of some psychoactive medications or diuretics, dietary indiscretions, dehydration, or electrolyte imbalance (Chung and Podolsky 2001; Riordan and Williams 1997), and these problems should be corrected first. Additionally, patients who undergo shunting procedures to relieve portal hypertension will be at increased risk for ammonia buildup with subsequent HE, and they and their caregivers should be educated on monitoring for signs and symptoms of HE. In one study of patients following treatment with transjugular intrahepatic portosystemic shunting, 45% experienced HE, with more than half exhibiting moderate to severe symptoms (Riggio et al. 2008). Refractory HE may require reduction of the shunt diameter (Riggio et al. 2008). Treatment should strive to normalize ammonia levels, despite the fact that blood ammonia levels are not well correlated

with symptoms of HE (Riordan and Williams 1997). Treatment strategies include administration of a nonabsorbable disaccharide, lactulose, that acts as an osmotic laxative to flush out ammonia; adherence to a protein-restricted diet to decrease the production of ammonia from protein; and prescription of nonabsorbable antibiotics to reduce intestinal bacteria that convert protein to ammonia. Some patients require all three treatments simultaneously. Medications that can contribute to symptoms of encephalopathy—anticholinergic drugs, tranquilizers, and sedatives—should be avoided.

Ventricular Assist Devices in Heart Transplantation

Progress in the development of implantable left ventricular assist devices (LVADs) has dramatically improved both the physical and the psychological health of potential cardiac transplant candidates. (Left ventricular assist devices are also discussed in Chapter 18, "Heart Disease.") The new LVADs consist of a mechanical pump implanted in the abdomen with conduits from the apex of the left ventricle to the device, and from the device to the ascending aorta. Blood returning from the lungs to the left side of the heart exits through the left ventricular apex into the LVAD pumping chamber. Blood is then actively pumped through the LVAD outflow valve into the ascending aorta. One transcutaneous line carries an electrical cable to an external battery pack and electronic controls, which are worn on a shoulder holster or belt.

Prior to the use of LVADs, the need for prolonged inotropic infusions before transplantation could lead to very lengthy hospitalizations for cardiac transplant candidates. These patients would become deconditioned and were at risk for deep vein thrombosis, pulmonary emboli, multiple organ dysfunction, and sudden cardiac death. However, experience with newer LVADs reveals improvement in mechanical/electrical failure rates and lessened risks for thromboembolism (Rose et al. 2001a, 2001b). Patients on LVADs can achieve better hepatic, renal, cerebral, and peripheral perfusion, leading to improvement in overall physical function, exercise tolerance, and well-being (Goldstein et al. 1998; Morrone et al. 1996). These devices are now portable, permitting discharge from the hospital before transplantation and a generally acceptable quality of life (Dew et al. 2000a; Frazier 1993; Loisan et al. 1994). Patients on LVADs can undergo physical and physiological rehabilitation, develop exercise tolerance, and rebuild muscle mass, thus stabilizing their cardiac condition (Goldstein et al. 1998; McCarthy 2002; Morrone et al. 1996). The lack of mobility restriction means that patients often can return to work and engage in activities such as dancing and driving (Catanese et al. 1996). With the urgency for transplantation

diminished, the transplant team can wait for an optimal donor organ. LVADs are now used as "destination" therapy as well as to bridge patients to transplantation. Thus, some patients who may not desire transplantation or who do not meet criteria for transplantation may receive LVADs for permanent support.

However, there continue to be risks and drawbacks associated with either temporary or permanent LVAD therapy. The logistics of arranging outpatient care require a well-trained medical team whose members are available at all times, resulting in significant patient, caregiver, and medical system burden. All persons involved in the patient's care must receive extensive training, arrangements for outpatient housing or maintenance at home must be coordinated, and local emergency paramedical personnel must also be trained. Infection can occur in more than 60% of LVAD recipients (Genovese et al. 2009; S.M. Gordon et al. 2001); in one study of patients with permanent LVADs, 41% of deaths were related to infection (Rose et al. 2001b). Cardiovascular complications, bleeding, and reoperations have also been found to be prevalent adverse events (Genovese et al. 2009). Not surprisingly, in a study of recipients of ventricular assist devices (including both LVADs and biventricular assist devices), the most common concern expressed by patients was risk of infection (52%) (Dew et al. 2000a). In addition, 52% had difficulty sleeping because of the driveline, 46% had pain at the driveline site, 40% worried about device malfunction, and 32% were bothered by device-related noise (Dew et al. 2000a). Finally, although patients on LVADs have improved cerebral perfusion, they are at high risk for microembolic events. While many of the microembolic events are clinically silent (Thoennissen et al. 2005), the chronic effect of such silent microembolic events on cognitive function may be significant over time, and periodic neuropsychological or cognitive testing may be helpful (Komoda et al. 2005). The risk of such events appears to be lower with the newer generation of LVADs, but given that implantation periods have lengthened, routine care of LVAD recipients must continue to consider their cognitive status and the identification of any developing deficits.

In posttransplantation comparisons with heart recipients who did not receive a ventricular assist device (VAD; either biventricular or left ventricular assist device), patients who were bridged to transplantation with a VAD showed similar improvements in physical functioning and emotional well-being, significantly lower rates of anxiety, but poorer cognitive status (Dew et al. 2001b). The cognitive impairments observed in these VAD recipients were believed to be attributable to neurological events (e.g., microemboli, strokes) that occurred during the period of VAD support, and these events occurred at a higher rate among VAD recipients relative to non-VAD patients dur-

ing the waiting period before transplantation. Although mild, these impairments appeared to persist during the first year following transplantation and were associated with reduced likelihood of returning to employment (Dew et al. 2001b).

Tobacco Use and Transplantation

Tobacco use by transplant candidates and recipients has received surprisingly little attention. Even in lung and heart transplantation, tobacco use is not routinely reported. Two meta-analyses of posttransplantation adherence show tobacco use rates of 3.4% of patients per year in the general transplant population and 10% of patients per year for transplant recipients with substance use histories (Dew et al. 2007a, 2008a). Tobacco use coupled with immunosuppressive therapy, which also increases cancer risk (Nabel 1999), may result in higher rates of cancer posttransplantation. In addition to increased risk for oropharyngeal and lung cancers, tobacco suppresses immunity and can aggravate many disease states, resulting in higher rates of infections, vascular thrombosis, and atherosclerosis. Atherosclerosis is especially problematic for transplant recipients already at risk for hypertension, hyperlipidemia, and hyperglycemia induced by immunosuppressive medication.

Studies of heart transplant recipients have reported that 26%–50% of smokers resumed smoking after transplantation (Bell and Van Trigt 1991; Nagele et al. 1997). Compared with nonsmokers, smokers had higher rates of vasculopathy and of malignancies (Nagele et al. 1997); they also had significantly worse survival, with none of the smokers surviving more than 11.5 years after transplantation (vs. 80% of the nonsmokers surviving). When patients were grouped by carboxyhemoglobin level, investigators found that no patients with a level higher than 2.5% were surviving 4 years after transplantation (Nagele et al. 1997). In this cohort, smoking appeared to be much more important than other classical risk factors (Nagele et al. 1997). Similarly, a study of LTX recipients found a higher rate of vascular complications among patients with a history of smoking (17.8% vs. 8% among patients without such a history; $P=0.02$); furthermore, having quit smoking 2 years prior to transplantation reduced the incidence of vascular complications by 58% (Pungpapong et al. 2002). For ALD LTX recipients in one study, the rates of oropharyngeal cancer and lung cancer were 25 and 3.7 times higher, respectively, than rates in the general nontransplant population matched for age and gender (Jain et al. 2000), presumably as a result of tobacco use.

A cross-sectional retrospective study of renal transplant recipients identified cigarette smoking as a factor in the progression of kidney disease (Zitt et al. 2007). Compared with nonsmokers, smokers (22% of the cohort) had

more cardiovascular events, graft failure (33% vs. 21%), and diabetes and showed a fourfold increase in the probability of arteriopathy. Relatively small doses of tobacco use (average of 3 pack years) induced abnormal renal vascular intimal thickening in the allograft (Zitt et al. 2007). In a prospective study of ALD LTX recipients, 53% were found to be using tobacco after transplantation (DiMartini et al. 2002). A study of 60 heart transplant recipients reported that 3 patients had resumed smoking within 6 months following transplantation and that all 3 had also relapsed to drug or alcohol abuse (Paris et al. 1994). Another study of heart transplant recipients found that elevated posttransplant anxiety was associated with a higher risk of resuming smoking (Dew et al. 1996).

Programs vary in whether they consider tobacco use to be a contraindication to transplantation. However, given that tobacco use is a modifiable risk factor that has demonstrated significant and negative effects on both patient and graft outcomes and survival, psychosomatic medicine specialists should make tobacco use a routine part of their assessment, plan for monitoring pre- and posttransplant, and provide smoking cessation assistance when necessary. Cessation of tobacco use (both smoked and smokeless) prior to transplantation is strongly recommended, given the high risk that pretransplant users will resume use posttransplantation. Treatments for smoking cessation include bupropion, nicotine replacement (patches, gum, lozenges, and aerosolized formulations), and behavioral therapies (Hurt et al. 1997; Jorenby et al. 1999). Nicotine replacement strategies have been safely used in patients with advanced liver and lung disease, but severe renal disease may affect nicotine clearance. Nicotine replacement is relatively contraindicated in serious heart disease due to the potential for worsening angina, increasing heart rate, and possibly exacerbating arrhythmias. When nicotine replacement has been combined with bupropion, cases of severe hypertension have been reported, so careful monitoring of blood pressure is indicated. Bupropion should be used cautiously in transplant recipients, who are already at increased risk for seizures from immunosuppressive medications, specifically during the early posttransplant period, when immunosuppressive levels are higher. Nortriptyline has a cessation success rate similar to that of bupropion in non-ill smokers (S.M. Hall et al. 1998), but its anticholinergic effects may increase risk for delirium. Nortriptyline's alpha-adrenergic, antiarrhythmic, and negative inotropic effects are tolerated post-heart transplant (Kay et al. 1991; P.A. Shapiro 1991) but should be carefully monitored in heart transplant candidates. Varenicline is eliminated by renal clearance, so dosage reductions are necessary for patients with renal insufficiency or on dialysis. Its side effects of nausea and vomiting may be problematic in transplant patients.

Living Donor Transplantation

Despite the physical risks, discomfort and pain, expense and inconvenience, and potential psychological consequences of donating an organ, an increasing number of people are becoming donors, and transplant programs are considering living donation as one solution to the organ shortage. Kidneys and portions of the liver, lung, pancreas, intestine, and even the heart (through a domino procedure in which a heart-lung recipient donates his or her heart) are donated for transplantation (Oaks et al. 1994; Rodrigue et al. 2001; Taguchi and Suita 2002).

Donation of an organ—putting one's life at risk to help another—is an incredibly generous and altruistic gift. Yet the evaluation of such donors is a complex process requiring assessment of the circumstances and motives of the donor, the dynamics of the relationship between donor and recipient, the severity of the recipient's illness, and family and societal forces. Current practice guidelines require a psychosocial evaluation for each potential donor, to thoroughly examine these and other issues (Table 31-3) (Dew et al. 2007c; Olbrisch et al. 2001; Surman 2002). All U.S. centers' living donor medical evaluation protocols include pre-donation psychosocial assessments, although the specifics of these evaluations and who performs them vary among centers. These assessments are designed to screen out potential donors with significant psychiatric morbidity (including substance abuse/dependence) and those unwilling or unable to give informed consent for donation (due to the presence of coercion, likely financial gain, and/or impaired cognitive/intellectual capacity). This screening process, combined with rigorous medical evaluation, ensures that living donors are very healthy before donation. Additionally, donors must be fully willing, independently motivated, and completely informed about the surgery. Yet for all donors, and liver donors in particular, long-term sequelae that may affect the donor's future health, functioning, and even ability to obtain health insurance (due to the presence of a preexisting condition) are not known.

Living liver donation is a much more surgically complex and invasive procedure than kidney donation and is therefore potentially more dangerous. Adult-to-adult living donor liver transplantation (LDLT) is a relatively new procedure in the United States, preceded by adult-to-child transplants. Whereas only 9 such procedures had been performed in the United States prior to 1998, in 2001 more than 400 adult-to-adult LDLTs were performed. Although mortality rates have been less than 1% for both kidney and liver donors (both adult-to-adult and to children) (Brown et al. 2003; Najarian et al. 1992), about one-third of liver donors have complications, with serious complications occurring in 14% of donors (Brown et al. 2003; Grewal et al. 1998; Tan et al. 2007b). There have been consensus recom-

TABLE 31–3. Areas of assessment for living donor evaluation

Reasons for donation
Relationship between donor and recipient
Donor's knowledge about the surgery
Motivation
Ambivalence
Evidence of coercion/inducement
Attitudes of significant others toward the donation
Availability of support
Financial resources
Work- and/or school-related issues (if applicable)
Donor's psychological health, including the following:
Psychiatric disorders
Personality disorders
Coping resources/style
Pain syndromes
Prior psychological trauma/abuse
Substance use

mendations that all potential live liver donors be evaluated by an independent physician advocate (i.e., not a member of the transplant team responsible for the recipient's care) as part of the informed consent process (Abecassis et al. 2000; Conti et al. 2002) to avoid conflicts of interest. However, in only 50% of programs does a physician who is not part of the transplant team evaluate the potential donor (Brown et al. 2003).

Kidney donors should expect to miss 4–6 weeks of work and liver donors 8–12 weeks of work, especially if their jobs involve heavy lifting. Since the late 1990s, laparoscopic donor nephrectomy has been increasingly used, a procedure that results in less postoperative pain, shorter hospital stays, overall quicker recovery times, and more favorable cosmetic results. Future research may show that this approach has psychosocial benefits as well. Living lung donation is a much less frequent procedure, with fewer than 10 such donations performed per year since 2004 in the United States. While no lung donor deaths have been reported, nearly 20% of lung donors will have perioperative complications following lobectomy and will lose 10%–20% of their predonation lung functioning even after 1 year postdonation (Sano et al. 2009; Tan et al. 2007a).

Living donors almost uniformly express no regret at having donated, would donate again if that were possible,

and report deep feelings of gratification at being able to help another person (Dew et al. 2007c). Moreover, generic health-related quality of life assessments show that—at least in the early years postdonation—donors' well-being, on average, meets or exceeds that reported in the general population (Beavers et al. 2001; Chan et al. 2006; Diaz et al. 2002). Nevertheless, a growing body of qualitative and small cohort studies suggests that a significant proportion of donors experience major health and psychosocial difficulties. For example, up to 78% of donors experience high psychological distress and/or meet diagnostic criteria for mood or anxiety disorders (Beavers et al. 2001; Coffman and Jowsey 2006; Dew et al. 2007c; Erim et al. 2006, 2007; Fukunishi et al. 2001; Hsu et al. 2006; Jowsey and Schneekloth 2008), up to 33% report that their health is poorer after donation (Chan et al. 2006; Humar et al. 2005; Kim-Schluger et al. 2002; Kusakabe et al. 2008; Walter et al. 2006), up to 50% worry about the lasting effects on their health (Morimoto et al. 1993; Trotter et al. 2001), and over 25% have financial hardships with prominent concerns about current and future insurance status (Dew et al. 2007c; Yang et al. 2007). In one study that examined outcomes of parent-to-child liver donation, psychological testing was found to be useful in identifying families that were more likely to experience problems postdonation (Goldman 1993). Although donor outcomes were reported as good, with donors experiencing increased self-esteem and satisfaction, marital dissolution occurred in 2 of the 20 families following donation (Goldman 1993). More alarming is the finding from a large multicenter study that three donors had attempted suicide, with one completed suicide following donation (Trotter et al. 2007). Trotter et al. (2007) estimated the suicide rate in liver donors at 2 per 1,000 donors, although the contribution of the donation to these events is unclear.

A U.S. live organ donor consensus group recommended the development of a living donor registry to collect demographic, clinical, and outcome information on all living organ donors. The rationale for the development of such a registry included concern for donor well-being, limitations of current knowledge regarding the long-term consequences of donation, the potential to evaluate the impact of changes in criteria for donor eligibility on the outcome of donors, and the need within the transplant community to develop mechanisms to provide for quality assurance assessments (Abecassis et al. 2000). A large multicenter study of adult-to-adult living liver donor outcomes, commissioned by the National Institute of Diabetes and Digestive and Kidney Diseases, is under way and should help provide answers to these questions ("Adult-to-Adult Living Donor Liver Transplantation Cohort Study [A2ALL]" 2003). Similarly, a multicenter study was recently commissioned by the National Institute of Allergy

and Infectious Diseases to examine emotional and medical outcomes of kidney and lung donors (RELIVE: Renal and Lung Donors Evaluation and Study); this study will be collecting data through 2011.

For all donor types, the issue of donor financial hardship is becoming an increasingly prominent concern. Although the recipients' insurance covers the evaluation and immediate postoperative medical care, donors frequently report out-of-pocket costs, and some may have significant long-term difficulties in obtaining or retaining health and life insurance (Dew et al. 2007c; Nissing and Hayashi 2005; Yang et al. 2007).

Japan has extensive experience with living liver donation as a result of cultural beliefs (lack of acceptance of brain death criteria) that hamper cadaveric donation. This created an environment in which living liver donation was necessary for LTX programs to exist. Of the almost 2,000 LDLTs performed in Japan there are no reported donor deaths (Umeshita et al. 2003). Fukunishi et al. (2001) first reported on psychiatric outcomes in LDLT donors and recipients, identifying post-LTX psychiatric disorders (excluding delirium) in 37% of LDLT recipients and "paradoxical reactions" (including guilt about receiving donation, avoidant coping behaviors, and psychological distress) in 34% of recipients, despite favorable medical outcomes for both recipient and donor. Ten percent of liver donors experienced major depression within the first month after donation. Fukunishi et al. (2003) speculated that before donation, the stronger sense of duty of adult children donating to their parents masked their true concerns and fears. Following donation, these concerns manifested as anxiety, fear, and pain. The prevalence of psychiatric disorders was higher in LDLT recipients than in a comparison group of living-donor kidney recipients, suggesting a potential greater need for psychiatric evaluation and care of LDLT patients.

Altruistic donors—those donating to an unknown recipient—pose one of the most complex challenges to transplant evaluation. In these cases, the psychosocial evaluation has particular importance in determining the suitability of the donor, and some believe that the medical standards for such donors should be higher (Friedman 2002). Altruistic donors are commonly viewed with some skepticism and are evaluated with greater caution than related donors. A detailed evaluation is critical, both to understand the motives and psychological meaning of the donation to the donor and to identify any financial or other types of compensation expected for the donation. A study of nondirected donors reported that 21% were excluded for psychological reasons (Matas et al. 2000). Psychological outcomes of altruistic liver donors are unknown.

Posttransplant Organ Function and Pharmacological Considerations

While many transplant-specific psychological stresses can be appropriately managed with psychotherapeutic techniques, pharmacotherapy is an essential treatment component in the psychiatric care of these patients. Given the high prevalence of psychiatric disorders in transplant candidates and recipients and the potential for untreated psychiatric disorders to influence outcomes, including adherence, pharmacological treatment is often required. Unfortunately, psychotropic medications are often not provided because of concerns about patients' medical fragility and the potential risks of psychotropic medications. The fact that psychiatric symptoms may evolve from complex, intertwined psychological and physiological processes should not preclude treatment. Although the treatment of transplant candidates and recipients can be complicated, a thorough knowledge of psychotropic pharmacokinetics in specific types of end-stage organ failure, coupled with careful attention to medication dosing, side effects, and drug interactions, can provide the necessary foundation for pharmacological management. End-stage organ disease alters most aspects of drug pharmacokinetics, including absorption, bioavailability, metabolism, and clearance. For a full review of the changes in pharmacokinetics of psychotropic drugs in general and in hepatic, renal, bowel, heart, and lung disease in particular, the reader is referred to Chapter 38, "Psychopharmacology"; see also Robinson and Levenson 2001 and Trzepacz et al. 2000. Here we discuss the important aspects of pharmacokinetics in the newly transplanted patient during the posttransplant recovery period (see DiMartini et al. 2010 for further pharmacological considerations in transplant patients).

Although organ function may deteriorate slowly over time before transplantation, following transplantation, for the majority of recipients, the newly transplanted organ functions immediately, so that normal physiological parameters are quickly restored and pharmacokinetic abnormalities resolve. Within the first month following transplantation for patients who have stable liver or kidney function, the clearance and steady-state volume of distribution of drugs can be similar to that in healthy volunteers (Hebert et al. 2003). Many transplant recipients can be treated with normal therapeutic drug dosing once they have recovered from immediate postoperative complications (e.g., delirium, sedation, intestinal paralysis). With the resumption of normal organ function after transplantation, any psychotropic medications prescribed at lower dosages prior to transplant to accommodate diminished

metabolism or elimination may need to be adjusted to higher levels.

For some transplant recipients, however, the transplanted organ does not assume normal autonomous physiological function immediately, or the organ may slowly regain normal function over time. Studies examining posttransplantation pharmacokinetics have been mostly conducted in liver and kidney recipients due to the relevance of these organs to drug pharmacokinetics. Additionally, these studies have focused exclusively on immunosuppressive medications due to the need to achieve and maintain stable immunosuppressive medication levels to prevent organ rejection, the ability to monitor serum levels, and the narrow therapeutic range of these drugs. However, these data provide general guidelines on medication prescribing for specific types of posttransplant organ dysfunction.

Delayed Graft Function

Several graft-specific outcomes relevant to pharmacokinetics and patient outcomes in particular deserve definition. Primary nonfunction (PNF), an infrequent but life-threatening complication (3%–4% of renal and liver recipients), is defined as immediate primary graft failure that results in death or requires retransplantation within 30 days of the transplant and thus is less relevant to psychotropic pharmacokinetics.

The most common allograft complication affecting pharmacokinetics in the immediate posttransplantation period is delayed graft function (DGF). DGF prolongs hospitalization, may result in chronic graft impairment, and makes the management of immunosuppressive therapy more difficult (Shoskes and Cecka 1998). DGF occurs in 10%–25% of liver and kidney recipients, although rates can reach 50% of cases if marginal organs are counted (Angelico 2005; Shoskes and Cecka 1998; U.S. Renal Data System 2008). Liver recipients with DGF may require one-half of the typical immunosuppressive medication dose, and dosing requirements may not correlate with body weight, suggesting that in the early posttransplant period, metabolic capacity rather than volume of distribution is the critical factor in pharmacokinetics (Hebert et al. 2003; Luck et al. 2004). In addition, liver recipients with DGF can develop hyperbilirubinemia, ascites, and portal hypertension, further altering pharmacokinetic parameters. For kidney transplant recipients, DGF is defined as the recipient requiring dialysis within the first week of transplant. For kidney recipients, DGF alters pharmacokinetics by mechanisms that increase the free fraction of parent drugs and renally excreted metabolites (Shaw et al. 1998). Severe or acute impairment in renal function after transplant can result in immunosuppressive levels 3–6 times higher than

those in nonimpaired recipients for renally excreted drugs and their metabolites (Bullingham et al. 1998; Shaw et al. 1998). DGF also affects the binding of drugs to plasma proteins even in the absence of hypoalbuminemia (Shaw et al. 1998). DGF does not result in poorer absorption of immunosuppressants (Browne et al. 2003). Perturbed pharmacokinetics can normalize over months, with improving metabolic and renal functions (Bullingham et al. 1998; Shaw et al. 1998).

Acute and Chronic Organ Rejection

Acute cellular rejection occurs in 20%–70% of LTX recipients, typically within the first 3 weeks posttransplant, resulting in transient graft dysfunction. Bilirubin and alkaline phosphatase levels rise initially, followed by elevations in liver enzymes (alanine aminotransferase and aspartate aminotransferase). Recipients may experience fever, malaise, liver tenderness, and occasionally ascites and mental status changes. Sixty-five percent to 80% of cases are effectively treated with high-dose steroids or high-dose steroid bolus followed by a rapid taper over 5–7 days, and most episodes do not lead to clinically significant alteration in liver histology or architecture (Lake 2003). About 15% of cases require additional antibody treatments such as monoclonal therapy or antithymocyte globulin (Lake 2003), and these medications can cause serious neuropsychological side effects (see section “Neuropsychiatric Side Effects of Immunosuppressive Agents” later in this chapter). Chronic graft rejection occurring in 5%–10% of liver recipients, manifests as gradual obliteration of small bile ducts and microvascular changes, and tends to respond poorly to treatment. Patients may experience jaundice and have treatment-resistant pruritus. Persistently elevated serum alkaline phosphatase and bilirubin levels occur early on, but loss of liver synthetic function may not occur until very late in the course (Lake 2003).

Twenty-five percent to 60% of kidney recipients will experience acute rejection, most often within the first 6 months after transplantation. Rejection may not be recognized without a biopsy, and in fact 25%–30% of kidney recipients with stable or improving renal function can actually be in an episode of undetected rejection (Rush et al. 1998; R. Shapiro et al. 2001). Treatment of an identified rejection episode typically restores prerejection functioning; however, subclinical rejection that remains undetected can result in gradually worsening renal function over time with eventual graft loss (Rush et al. 1998).

Nearly 50% of heart transplant recipients will experience an episode of acute rejection (either humoral or cellular) within the first posttransplant year. With rejection some heart recipients may develop unstable symptoms (increasing central venous pressure or pulmonary capillary

wedge pressure, decreasing ejection fraction, arrhythmias, hypotension, or even shock). Even with unstable symptoms, rejection can be effectively treated in 50%–60% of cases with the addition of steroids without the need for monoclonal antibodies therapy (Michaels et al. 2003; Park et al. 1999). Persistent hemodynamic changes occur less often. Sinus node dysfunction or atrioventricular block requiring permanent pacing occurs in up to 19% of heart recipients and may be associated with rejection (Collins et al. 2003). By 5 years posttransplant, nearly 70% of those with humoral rejection will develop early coronary artery disease (Michaels et al. 2003).

If the episode of graft rejection is acute and resolves quickly, no specific change to psychotropic dosages would be required. This is true across all organ types. Chronic rejection tends to evolve over time, with a gradual decrease in organ function and subsequent loss of metabolic/elimination capacity. For all organ types, chronic graft rejection is potentially reversible in the early stages but not once chronic dysfunction has set in and progressive graft failure occurs. In these cases, pharmacokinetics may be seen as similar to the pretransplant state. With all organ types, care must be taken in the choice of medication (see Chapter 38, “Psychopharmacology,” for types of organ failure and medication choices), and additional attention must be paid to potential hemodynamic instability in heart candidates with rejection.

General Issues

In addition to DGF or acute rejection, some recipients will have transient physiological abnormalities in the weeks following transplant that could also affect pharmacokinetics (e.g., liver congestion and/or renal hypoperfusion in heart recipients, fluid overload in renal recipients, and resolving hepatorenal syndrome in liver recipients). The mechanisms causing these derangements are complex and can include perioperative hemodynamic and fluid instability or graft-related factors such as graft harvesting, ischemic or reperfusion injury, or the use of marginal organs. Thus, in addition to the status of the transplanted organ, evaluation of the recipients’ total physiological status is important in drug consideration and dosing.

Finally, for all organ types, calcineurin-inhibiting immunosuppressive medications in chronic use are nephrotoxic. While there may be cumulative causes for renal failure in organ recipients, chronic use of immunosuppressive medications results in renal failure for 10%–20% of recipients by 5 years posttransplant (Ojo et al. 2003). Thus, the quality of renal function should always be considered with medication usage, particularly for long-term transplant recipients and especially if the medication chosen requires renal clearance.

Neuropsychiatric Side Effects of Immunosuppressive Agents

Advances in our understanding of immunology and the development of newer strategies for immunosuppression may significantly reduce the need for—if not obviate completely—long-term maintenance immunosuppression. In the future, transplant recipients of all organ types may require immunosuppressive medication dosages only one or two times a week, or not at all (Starzl 2002). This achievement would remove the final obstacle to long-term successful outcomes for transplant recipients, given that the majority of long-term morbidity and mortality is due to chronic immunosuppression (e.g., infections, renal failure, cancer). Additionally, reduced requirements for immunosuppressive medication would aid in medication adherence and relieve some of the financial burden of long-term immunosuppression. However, for now, transplant recipients will continue to require immunosuppressive therapy and to be subject to their potential neurotoxic and neuropsychiatric side effects. Psychiatrists should be familiar with the signs, symptoms, differential diagnosis, neuroimaging findings, and management of immunosuppressive neurotoxicity and secondary psychiatric disorders in solid organ recipients (Strouse et al. 1998) (see DiMartini et al. 2010 for further discussion of neuropsychiatric side effects of immunosuppressant medications).

Calcineurin-Inhibiting Immunosuppressive Medications

Cyclosporine

Cyclosporine (Gengraf, Neoral, Sandimmune), a lipophilic polypeptide derived from the fungus *Tolypocladium inflatum*, is used as a primary immunosuppressive agent. Side effects are usually mild and include tremor, restlessness, and headache (Wijdicks et al. 1999). A smaller proportion of patients (12%) experience more serious neurotoxicity characterized by acute confusional states, psychosis, seizures, speech apraxia, cortical blindness, and coma (de Groen et al. 1987; Wijdicks et al. 1995, 1996; S.E. Wilson et al. 1988). A higher incidence (33%) of serious neurotoxic side effects was reported in one study of 52 LTX recipients. Seizures were experienced by 25%; less commonly reported effects included central pontine myelinolysis, delirium, cerebral abscess, and psychosis (Adams et al. 1987).

More recent evidence suggests that earlier reports of serious neurological side effects may have been attributable to intravenous administration and higher dosages (Wijdicks et al. 1999). The use of the oral form of cyclosporine (Neoral) results in fewer serious neurological side effects (Wijdicks et al. 1999). Cyclosporine trough levels correlate

poorly with cyclosporine neurotoxicity (Wijdicks et al. 1999), although in most studies symptoms resolved when the cyclosporine was discontinued and subsequently reinstated at a lower dosage (Wijdicks et al. 1999). Anticonvulsants can successfully treat cyclosporine-induced seizures but are not required long-term (Wijdicks et al. 1996), and seizures may cease with reduction or discontinuation of cyclosporine. A few patients with serious clinical neurotoxic side effects have been found to have diffuse white matter abnormalities, predominantly in the occipitoparietal region, on computed tomography (CT) scanning (de Groen et al. 1987; Gijtenbeek et al. 1999; Wijdicks et al. 1995) (see discussion of posterior reversible [leuko]encephalopathy syndrome [PRES] in "Tacrolimus" subsection below). In one case, symptoms of cyclosporine-induced cortical blindness resolved with drug discontinuation, although pathological evidence of CNS demyelination persisted for months afterward (S.E. Wilson et al. 1988).

Several mechanisms may contribute to the CNS neurotoxicity of cyclosporine. Hypocholesterolemia has been found in a high percentage of patients with serious neurotoxicity (de Groen et al. 1987; Wijdicks et al. 1995). Hypocholesterolemia may increase the intracellular transport of cyclosporine by upregulating low-density lipoprotein receptors (Wijdicks et al. 1995). Access of cyclosporine to brain tissue may be particularly high in the white matter, with a relatively high density of low-density lipoprotein receptors (Wijdicks et al. 1995). In addition to hypocholesterolemia, other factors that may contribute to cyclosporine neurotoxicity include hypertension, hypomagnesemia, and the vasoactive agent endothelin (Gijtenbeek et al. 1999).

Tacrolimus

Tacrolimus (FK506, Prograf), a macrolide produced by *Streptomyces tsukubaensis*, is used as primary immunosuppressive therapy, as rescue therapy for patients who fail to respond to cyclosporine, and as treatment for graft-versus-host disease. It is more potent and possibly less toxic than cyclosporine, although the neuropsychiatric side effects appear to be similar (DiMartini et al. 1991; Freise et al. 1991). As with cyclosporine, neuropsychiatric side effects are more common with intravenous administration and diminish with oral administration and dosage reduction. Common symptoms include tremulousness, headache, restlessness, insomnia, vivid dreams, hyperesthesias, anxiety, and agitation (Fung et al. 1991). Cognitive impairment, coma, seizures, dysarthria, and delirium occur less often (8.4%) and are associated with higher plasma levels (DiMartini et al. 1997; Fung et al. 1991). Tacrolimus can produce symptoms of akathisia (Bernstein and Daviss 1992). However, a prospective study of 25 renal transplant recipients found no correlation between tacrolimus plasma levels and scores on

an akathisia rating scale, although higher plasma levels were associated with higher levels of subjective restlessness, tension, and autonomic and cognitive symptoms of anxiety (DiMartini et al. 1996a).

Tacrolimus has low aqueous solubility and cannot be detected in the cerebrospinal fluid of patients with suspected neurotoxicity (Venkataramanan et al. 1991). However, because tacrolimus has been identified in the brain tissue of animals, it is believed to cross the blood-brain barrier in humans. In addition, more serious neurotoxic side effects (e.g., focal neurological abnormalities, speech disturbances, hemiplegia, and cortical blindness) may occur from higher CNS levels in patients who have a disrupted blood-brain barrier (Eidelman et al. 1991). In a study of 294 consecutive transplant recipients on tacrolimus, those with preexisting CNS damage (e.g., from stroke, multiple sclerosis) were at higher risk for neurotoxic side effects (Eidelman et al. 1991). As described above with cyclosporine, both drugs are associated with an uncommon clinico-neuro-radiological syndrome termed posterior reversible (leuko)encephalopathy syndrome (PRES) involving demyelination (particularly in the parieto-occipital region and centrum semiovale) (Ahn et al. 2003; Bartynski and Boardman 2007; Small et al. 1996). PRES typically occurs early postoperatively but can also occur years later. The clinical presentation can be varied and includes mental status changes, focal neurological symptoms, or generalized seizures without a clear metabolic etiology. Thus, moderate to serious symptoms of neurotoxicity warrant investigation with radiological imaging. Characteristic neuroradiological abnormalities (low attenuation of white matter on CT scan or hyperintense lesions on T2-weighted magnetic resonance imaging [MRI] images) are most commonly seen in the cortical and subcortical white matter, typically involving the posterior lobes (parietal and/or occipital), although cases have been reported involving the anterior brain, cerebellum, and brain stem (Bartynski and Boardman 2007). MRI may be better than CT at identifying the radiographic changes seen with PRES (DiMartini et al. 2008). Like other serious neurotoxic side effects, this syndrome is not associated with the absolute serum level of tacrolimus but does resolve on discontinuation of the drug (Small et al. 1996). The mechanism of tacrolimus neurotoxicity is unclear but may include direct activity at the CNS neuronal level (Dawson and Dawson 1994), an immune-mediated cause (J.R. Wilson et al. 1994), or vasogenic edema (Ahn et al. 2003; Bartynski and Boardman 2007). Multifocal sensorimotor polyneuropathy can occur from long-term immunosuppressive medication use and may require either lowering of the dose if possible or medication treatment for painful peripheral neuropathy.

Other Agents for Adjunctive Immunosuppression or Treatment of Rejection

Corticosteroids

Although chronic corticosteroid use has become less essential in immunosuppression for most patients posttransplantation, high dosages of corticosteroids are still employed in the early postoperative phase and also as “pulsed” dosages to treat acute rejection. Behavioral and psychiatric side effects are common, but conclusions regarding the incidence or characteristics of these effects—or the specific dosages required to cause such effects—are not well established. We have observed that some recipients and clinicians may not recognize the energizing and euphoric effects of steroids and may believe that a setback has occurred when patients report loss of energy and motivation and a less ebullient mood after the steroids used early postsurgery are tapered and discontinued. Serious psychiatric side effects occur infrequently (5%–6%) (Kershner and Wang-Cheng 1989; Lewis and Smith 1983) and include a wide range of cognitive, affective, psychotic, and behavioral symptoms (R.C. Hall et al. 1979; Kershner and Wang-Cheng 1989; Lewis and Smith 1983; Varney et al. 1984). These side effects are reviewed elsewhere in this volume, particularly in Chapter 8, “Depression”; Chapter 10, “Psychosis, Mania, and Catatonia”; Chapter 22, “Endocrine and Metabolic Disorders”; and Chapter 25, “Rheumatology.”

Sirolimus

Sirolimus (SRL, rapamycin, Rapamune), a macrocyclic lactone isolated from *Streptomyces hygroscopicus*, is a recent addition to the posttransplant immunosuppressive armamentarium but is not commonly used as primary therapy. The side-effect profile of sirolimus so far does not include neurotoxicity (Watson et al. 1999), perhaps because sirolimus does not block calcineurin (Sindhi et al. 2001). However, a systematic evaluation of sirolimus neurotoxicity has yet to be conducted.

Azathioprine

Azathioprine (Imuran) is a purine analog first used in organ transplantation in 1968. It is primarily used as an adjunctive immunosuppressive agent and is less widely used today because of the availability of alternative agents. Specific neuropsychiatric side effects have not been reported for this agent. Several reports of depressive symptoms in patients receiving azathioprine have been confounded by the concurrent use of other medications (specifically cyclosporine and prednisone) that may have contributed to mood disturbance. Nevertheless, caution is

recommended when using azathioprine in patients with a history of depression.

Mycophenolate Mofetil

Few neuropsychiatric symptoms have been reported with mycophenolate mofetil (CellCept), a relatively new immunosuppressant promoted as an improvement over azathioprine. Adverse CNS events (>3% to <20% incidence) include anxiety, depression, delirium, seizures, agitation, hypertension, paresthesias, neuropathy, psychosis, and somnolence (Roche Pharmaceuticals 2003); however, because the patients in whom these symptoms occurred were being treated with mycophenolate mofetil in combination with cyclosporine and corticosteroids, the precise contribution of mycophenolate mofetil to the symptoms is difficult to interpret.

Monoclonal Antibodies

Monoclonal antibodies to T cells are used for induction immunosuppression or adjunctive therapy when a recipient is experiencing an episode of rejection. Neuropsychiatric side effects, including headache, weakness, dizziness, tremor, and anxiety, are generally mild. Muromonab-CD3 (OKT-3) is an exception, frequently causing more severe headache, tremor, agitation, and depression. It may also cause cerebral edema and encephalopathy with confusion, disorientation, hallucinations, and seizures (Alloway et al. 1998). Rituximab has been associated with progressive multifocal leukoencephalopathy (Kranick et al. 2007).

Drug Interactions Between Psychotropic and Immunosuppressive Medications

Many of the immunosuppressive medications (e.g., tacrolimus, cyclosporine, and mycophenolate mofetil) are metabolized by CYP 3A4; thus, concurrent use of psychotropic medications that strongly inhibit 3A4 should be avoided. Specific CYP 3A4 inhibitors capable of interacting adversely with immunosuppressive medications, in decreasing order of inhibition, are as follows: fluvoxamine, nefazodone > fluoxetine > sertraline, TCAs, paroxetine > venlafaxine (see also Table 38–1 in Chapter 38, “Psychopharmacology”). There are case reports in which nefazodone has caused toxic tacrolimus levels (Campo et al. 1998) and a 70% increase in the trough plasma level of cyclosporine (Helms-Smith et al. 1996). In a study in which fluoxetine and TCAs were used to treat depressed transplant recipients, no difference in cyclosporine blood level-dosage ratios and dose-response relationships was found between those treated and those not treated with antidepressants (Strouse et al. 1996). This finding suggests that

antidepressants with less CYP 3A4 inhibition may not have clinically meaningful drug interactions with these immunosuppressive medications.

Several side effects relevant to immunosuppressant and psychotropic medication combinations deserve mention. Gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea) are common adverse effects of immunosuppressant medications in more than 60% of patients, and additional requirements for supplemental magnesium may aggravate these symptoms (Pescovitz and Navarro 2001). The choice of a psychotropic drug should take into consideration these symptoms, especially prior to administering psychotropics with similar adverse effects (e.g., SSRIs, venlafaxine). Immunosuppressants have significant metabolic side effects (e.g., weight gain, glucose intolerance, hyperlipidemia). Similarly, these side effects must be considered when psychotropic medications with similar effects (e.g., atypical antipsychotics) are to be used. Psychotropic medications with minimal metabolic side effects should be considered.

It is possible that psychotropic medications may alter immune function. Some psychotropic medications induce a variety of neuroendocrine and cellular actions that could have immunological effects, yet this area has not been well investigated (Surman 1993). For example, lithium has been shown to enhance neutrophil migration, increase phagocytosis by macrophages, and amplify mitogen stimulation of lymphocytes (Surman 1993). Although the role of these effects in allograft function is not known, lithium has been used to increase the number of peripheral neutrophils (Ballin et al. 1998) to reduce neutropenia. The modulatory effects of psychotropic drugs on the immune system are largely unexplored but may provide valuable information for the future care of transplant patients (see Kradin and Surman 2000 for a complete review).

Neurology and Neurosurgery

Alan J. Carson, M.B.Ch.B., M.Phil., M.D., F.R.C.Psych.

Adam Zeman, M.A., D.M., F.R.C.P.

Jon Stone, M.B.Ch.B., Ph.D., F.R.C.P.

Michael C. Sharpe, M.A., M.D., F.R.C.P., F.R.C.Psych.

THE DIVIDE BETWEEN neurology and psychiatry is viewed by many as a historical artifact (Baker et al. 2002). Some psychiatrists have taken on primary responsibility for caring for brain injury, epilepsy, early-onset dementias, and sleep and movement disorders while retaining their more traditional role of diagnosing and treating “psychiatric” disorders in patients with neurological disease. Some neurologists have developed interests in cognitive and behavioral neurology and have focused on disorders traditionally considered to be psychiatric. New developments in neuroscience are bringing an understanding of the mechanisms of interaction between biological, psychological, and social aspects of illness, making this one of the most intellectually fascinating areas of work for a psychiatrist.

Psychiatrists working in a clinical neurosciences center are likely to be required to address four main categories of clinical problems:

1. Cognitive impairment—either as a primary presentation or as a secondary complication of a known condition such as multiple sclerosis
2. Neurological disease accompanied by emotional disturbance in excess of the clinical norm
3. Neurological symptoms that do not correspond to any recognized pattern of neurological disease
4. Postneurosurgery complications—usually involving behavioral, cognitive, or emotional disturbance

In this chapter, we concentrate on commonly encountered neurological conditions—stroke, Parkinson’s dis-

ease, multiple sclerosis, amnesic syndromes, dementias with additional prominent neurological signs, epilepsy, headache, movement disorders, and conversion disorder—as well as on selected psychiatric aspects of neurosurgery. The principles of assessment applicable to these disorders are also relevant to other, rarer neurological conditions. Psychopharmacological and psychological treatments are not discussed in detail here because they are covered in other chapters. Although we refer to drug therapies, we wish to remind the reader that for many neuropsychiatric conditions, behavioral management and environmental manipulation are of equal importance.

Neuropsychiatric topics covered elsewhere in this book include the mental status examination (Chapter 1, “Psychiatric Assessment and Consultation”), delirium (Chapter 5, “Delirium”), dementia (Chapter 6, “Dementia”), conversion disorder (Chapter 12, “Somatization and Somatoform Disorders”), traumatic brain and spinal cord injuries (Chapter 35, “Physical Medicine and Rehabilitation”), pain syndromes (Chapter 36, “Pain”), and psychopharmacological interventions in neurological disease (Chapter 38, “Psychopharmacology”).

Stroke

A cerebrovascular accident, or stroke, is a clinical syndrome characterized by rapidly developing clinical symptoms or signs of a focal (and sometimes global) disturbance of cerebral function of presumed vascular origin and of more

than 24 hours' duration. One of two main pathological processes is responsible: cerebral infarction or hemorrhage. *Infarction* may result from thrombosis of vessels or emboli lodged within them. *Hemorrhage* can be either into brain tissue directly or into the subarachnoid space. Infarctions account for 85% of strokes and as a result of their lower immediate fatality rate are a much greater source of enduring disability than are hemorrhages, with approximately 75% survival at 1 year poststroke compared with 33% survival at 1 year after hemorrhage. Strokes are the third most common cause of death in the Western world. The Oxfordshire Community Stroke Project reported a population incidence of 2 per 1,000 for first-ever stroke (Bamford et al. 1988). Age is the major risk factor, although one-quarter of persons affected are younger than 65 years. Stroke occurs more commonly in men.

Psychiatrists are not usually involved in the diagnosis of acute stroke but occasionally are consulted when alterations in cognition, affect, or behavior dominate the clinical picture.

Clinical Features

The classical presentation of *middle cerebral artery* infarction is contralateral hemiparesis and sensory loss of a cortical type. These are often accompanied by hemianopsia if the optic radiation is affected. If the lesion is in the dominant hemisphere, then aphasia may be expected, whereas a lesion in the nondominant hemisphere may be accompanied by neglect, inattention, or perceptual disturbance.

Infarctions affecting the distribution of the *anterior cerebral artery* will lead to contralateral hemiparesis affecting the leg more severely than the arm. A grasp reflex and motor dysphasia may be present. Cognitive changes resembling a global dementia may occur, with incontinence. Residual personality changes (apathy and/or dysexecutive function) of a frontal type can also result.

Posterior cerebral artery infarction presents with a contralateral hemianopsia sometimes accompanied by visual hallucinations, visual agnosias, or spatial disorientation. Transient confusion may obscure the detection of hemianopsia. Vital memory structures are supplied from the posterior cerebral artery, and in some neurologically normal individuals both medial thalamic areas are supplied by a single penetrating artery. Dense amnesic symptoms occur if the hippocampus and other limbic structures are involved bilaterally. Diagnosis may be difficult, because early computed tomography (CT) scan findings are often negative; however, magnetic resonance imaging (MRI) will show the bilateral lesions.

Internal carotid artery occlusion can be entirely asymptomatic, but much depends on the collateral circulation. The clinical picture is often that of middle cerebral artery

infarction. However, in some situations, cognitive and behavioral symptoms are predominant.

Vertebrobasilar strokes can be extremely diverse in their manifestations. Total occlusion of the basilar artery is usually rapidly fatal. Partial occlusions typically affect the brain stem, with a combination of uni- or bilateral pyramidal signs and ipsilateral cranial nerve palsies. One variant of brain stem stroke is the "locked in" syndrome, in which total paralysis is accompanied by full alertness and awareness. Occlusions of the rostral branches of the basilar artery can result in infarction of the midbrain, thalamus, and portions of the temporal and occipital lobes. An unusual consequence of basilar artery occlusion can be peduncular hallucinosis, in which patients have vivid, well-formed hallucinations that they recognize as unreal. One patient described seeing his wife growing a full and bushy black beard! States of bizarre disorientation can also occur and can be mistaken for confabulation or even deliberate playacting.

Cognitive Impairment and Delirium

Delirium affects 30%–40% of patients during the first week after a stroke, especially after a hemorrhagic stroke (Gustafson et al. 1993; Langhorne et al. 2000; Rahkonen et al. 2000). It is important to distinguish delirium from focal cognitive deficits affecting declarative memory. Some clinicians recommend the use of structured scales such as the Confusion Assessment Method or the Delirium Rating Scale (McManus et al. 2009b). Predictors of delirium include preexisting dementia, old age, impaired vision, impaired swallowing, and inability to raise both arms (McManus et al. 2009a; Sheng et al. 2006). The presence of delirium after stroke is associated with poorer prognosis, longer duration of hospitalization, increased mortality, increased risk of dementia, and institutionalization (Gustafson et al. 1991; Henon et al. 1999; Reitz et al. 2008).

Dementia following stroke is common, occurring in approximately one-quarter of patients at 3 months after stroke (Desmond et al. 2000; Tatimichi et al. 1994a, 1994b), and this effect is independent of prior cognitive function (Reitz et al. 2008). This figure rises significantly if focal impairments also are considered. *Vascular dementia* is an imprecise term referring to a heterogeneous group of dementing disorders caused by impairment of the brain's blood supply. These disorders fall into three principal categories: subcortical ischemic dementia, multi-infarct dementia, and dementia due to focal "strategic" infarction. Several sets of diagnostic criteria (e.g., the National Institute of Neurological Disorders and Stroke–Association Internationale pour la Recherche et l'Enseignement en Neurosciences [NINDS-AIREN] criteria) are available, with high specificity but low sensitivity for pathologically defined

vascular dementia (Hachinski et al. 1974; Roman et al. 1993; Wiederkehr et al. 2008a, 2008b).

The common occurrence of relatively subtle cognitive decline, falling short of frank dementia, in the context of cerebrovascular disease has given rise to the broader concept of “vascular cognitive impairment.” Subcortical ischemic dementia and multi-infarct dementia are described in more detail in Chapter 6 (“Dementia”). The term *strategic infarction* describes the occurrence of unexpectedly severe cognitive impairment following limited infarction, often in the absence of classic signs such as hemiplegia. Sites at which infarctions can have such an effect include the thalamus, especially the medial thalamus; the inferior genu of the internal capsule; the basal ganglia; the left angular gyrus (causing Gerstmann’s syndrome of agraphia, acalculia, left–right disorientation, and finger agnosia); the basal forebrain; and the territory of the posterior cerebral arteries (Clark et al. 1994; Kumral et al. 1999; Rockwood et al. 1999; Tatimichi et al. 1992, 1995).

Behavioral Changes

The diverse behavioral changes following stroke are not unique to this condition and can therefore serve as a helpful model for understanding the clinical consequences of focal cerebral lesions of other causes (Bogousslavsky and Cummings 2000).

Aphasia

Global aphasia leads to the abolition of all linguistic faculties. Consequently, the physician must draw inferences about mental state from the patient’s behavior and non-verbal communication. Some accounts associate Broca’s aphasia with intense emotional frustration that may be secondary to problems in social interaction (Carota et al. 2000). Wernicke’s aphasia is characterized by a lack of insight accompanied by irritability and rage, with recovered patients reporting that they believed the examiner was being deliberately incomprehensible (Lazar et al. 2000).

Anosognosia

Anosognosia refers to partial or complete unawareness of a deficit. It may coexist with depression (Starkstein et al. 1990), a finding that both implicates separate neural systems for different aspects of emotions (Damasio 1994) and suggests that depression after stroke cannot be explained solely as a psychological reaction to disability (Ramasubbu 1994). Anosognosia for hemiplegia is perhaps the most often described form of the condition, but anosognosia can occur with reference to any function and is commonly associated with visual and language dysfunction. Patients with anosognosia for hemiplegia have no spontaneous complaints and may indeed claim normal movements in

the paralyzed limb. Behavioral correlates include attempting to walk normally despite the hemiplegia and paradoxical acceptance of a wheelchair while simultaneously maintaining that one has normal function. In extreme cases, ownership of the limb is denied—or, exceptionally, “extra” phantom limb sensations can occur. Anosognosia occurs more frequently with right-sided lesions, particularly those in the region of the middle cerebral artery (Breier et al. 1995; Jehkonen et al. 2006).

Affective Dysprosodia

Affective dysprosodia is impairment of the production and comprehension of those language components that communicate inner emotional states in speech. These components include stresses, pauses, cadence, accent, melody, and intonation. Affective dysprosodia is not associated with an actual deficit in the ability to experience emotions; rather, it is associated with a deficit in the ability to communicate or recognize emotions in the speech of others. Affective dysprosodia is particularly associated with right-hemispheric lesions. A depressed patient with dysprosodia will appear depressed and say that he or she is depressed, but the patient will not “sound” depressed. This is in contrast to a patient with anosognosia, who will both appear and sound depressed but may deny that he or she is depressed.

Apathy

Apathy is common after stroke, affecting up to 25% of patients, and appears to be distinct from depression (Brodaty et al. 2005). Patients with apathy show little spontaneous action or speech; their responses may be delayed, short, slow, or absent (Fisher 1995). Apathy is frequently associated with hypophonia, perseveration, grasp reflex, compulsive motor manipulations, cognitive impairment, and older age; it is also associated with poor functional outcomes (Hama et al. 2007). Apathy is usually a consequence of frontal or anterior temporal brain injury—in particular, lesions affecting the right fronto-subcortical pathways (Brodaty et al. 2005; Starkstein et al. 1993a).

Depression

Although depression following stroke is commonly defined according to DSM-IV-TR (American Psychiatric Association 2000) or ICD-10 (World Health Organization 1992) criteria (Starkstein and Robinson 1989), the imposition of these categorical diagnoses on patients who have suffered a stroke is problematic because it is often unclear which symptoms are attributable to the stroke and which are attributable to depression (Gainotti et al. 1997, 1999). Which definition is adopted has a substantive effect on prevalence rates of depressive illness after stroke (G. Andersen et al.

1994b; Herrmann et al. 1995; House et al. 2001; Morris et al. 1993a; Parikh et al. 1990; Pohjasvaara et al. 2001). Most studies suggest that poststroke depression is a common problem, affecting about one-quarter of stroke patients, although some high-quality studies have reported significantly lower prevalence rates (Brodaty et al. 2007). One solution to the dilemma of differential diagnosis is to focus on symptoms other than somatic ones, using scales specifically designed for that purpose, such as the Hospital Anxiety and Depression Scale and the Geriatric Depression Scale (Sivrioglu et al. 2009). Carota et al. (2005) persuasively argued that particular attention should be paid to crying and overt sadness. However, dismissing the somatic elements of depression may not be an adequate solution, given that the neurobehavioral consequences of cerebral lesions—such as aphasia, indifference, denial, cognitive impairment, and dissociation of subjective from displayed emotion—can obscure and complicate the diagnosis of depression. Most clinicians take a pragmatic approach, treating depression if the patient has symptoms suggestive of low mood or anhedonia accompanied by some somatic symptoms (e.g., insomnia, anorexia) as well as signs of lack of engagement with the environment (e.g., poor participation in physiotherapy).

Most epidemiological studies have suggested an association between depression and increased disability (G. Andersen et al. 1994b; Herrmann et al. 1995; Parikh et al. 1990; Pohjasvaara et al. 2001) and possibly mortality (House et al. 2001; Morris et al. 1993a). However, the direction of causality is unclear and is most probably circular. Some, but not all, pharmacological treatment studies have suggested that effective treatment of the depression leads to a reduction in overall disability (G. Andersen et al. 1994a; Lipsey et al. 1984).

There has been much speculation over the etiological mechanisms of depression after stroke, and emphasis has been placed on the site of the stroke lesion. One hypothesis put forward is that left frontal lesions are associated with an increased rate of depressive illness (Starkstein and Robinson 1989). There are, however, several limitations to this theory. First, it has been consistently found that patients with a premorbid history of depression are at higher risk of developing depression after stroke (G. Andersen et al. 1995). Second, it has proved impossible to clinically distinguish left frontal depression from depression associated with lesions in other brain regions (Gainotti et al. 1997). Finally, a meta-analysis reported that the available scientific literature did not support the left frontal hypothesis (Carson et al. 2000a).

It is generally recommended—but has not been conclusively demonstrated—that treatment for depression should be started early in order to maximize functional

outcome. However, disappointingly few randomized controlled trials have tested this recommendation. Most studies suggest an improved outcome in mood with early treatment, but the effect on measures of functioning have been generally disappointing (G. Andersen et al. 1994a; Chemerinski et al. 2001; Gainotti et al. 2001; Hackett et al. 2008a, 2008b; Lipsey et al. 1984; Robinson et al. 2000; Wiart et al. 2000). Although both selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) have been reported to be effective, the SSRIs are probably preferable because they have fewer adverse effects, particularly for patients in whom cognitive or cardiac function is compromised. Nonetheless, this greater tolerability must be balanced against the finding that nortriptyline was more effective than fluoxetine in the only trial that compared these agents (Robinson et al. 2000). What is clear is that all stroke patients receiving antidepressants should be closely monitored for both treatment effectiveness and adverse drug effects. Whether due to lack of detection or concern about side effects, there is substantive evidence that depression after stroke tends to be undertreated (Paul et al. 2006). The adoption of a care management approach appears to confer significant advantages in the delivery of treatment (Williams et al. 2007). Psychological treatment—in particular, cognitive-behavioral therapy (CBT)—offers a potential solution for patients for whom pharmacotherapy is ineffective or contraindicated, but thus far, psychological approaches have received only limited support (Hackett et al. 2008b; Kneebone and Dunmore 2000; Lincoln and Flannagan 2003). Furthermore, it is likely that only a minority of patients with poststroke depression are suitable for such treatment (Lincoln et al. 1997).

A number of studies have examined the effectiveness of early interventions intended to prevent depression from developing after stroke. A 2008 Cochrane review found that antidepressant drugs were ineffective in preventing the development of depression (Hackett et al. 2008a)—although there have been dissenting voices (Chen et al. 2007)—but that there might be modest benefits to be gained from problem-solving therapy (Hackett et al. 2008a). However, a subsequent comparison of the antidepressant drug escitalopram and problem-solving therapy found the former to be more efficacious (Robinson et al. 2008); the trial itself and the relative effectiveness of treatments remains a controversial issue (J. Leo and Lacasse 2009; Robinson and Arndt 2009; Robinson and Penningworth 2009), and further studies are clearly required.

Anxiety

Anxiety disorders are common after stroke and probably share the same risk factors as depression (Astrom 1996). Estimates of prevalence have varied markedly, depending on

whether the investigators subsumed anxiety symptoms within the construct of major depressive disorder. Thus, the reported prevalence of generalized anxiety disorder ranges from 4% to 28% (Astrom 1996). However, the percentage of patients experiencing anxiety symptoms appears to be 25%–30% (Burvill et al. 1995; De Wit et al. 2008). Female gender, a prior history of anxiety, and early symptoms of anxiety seem to be the main predictors (Morrison et al. 2005).

Stroke is a sudden and unpredictable life-threatening stressor and, not surprisingly, a highly aversive experience (McEwen 1996). Poststroke anxiety states may include posttraumatic stress symptoms, with compulsive and intrusive revisiting of the event, as well as health worries, with checking and reassurance seeking about the risk of recurrence (Lyndsay 1991). These worries can be associated with agoraphobia and the misinterpretation of somatic anxiety symptoms, especially headache and dizziness, as evidence of recurrence. Phobic states have a prevalence of 5%–10%, with an excess found in women (Burvill et al. 1995). Although there is a paucity of controlled-trial evidence, it is our experience that these symptoms respond to standard drug and behavioral therapies.

Emotional Lability

Emotionalism, or emotional lability, is an increase in laughing or crying that occurs with little or no warning. It is frequent in acute stroke but can also occur with delayed onset (Berthier et al. 1996; Cummings et al. 2006). The displayed emotions are not related to the patient's internal emotional state. Whether emotional lability is associated with depression is a moot point; both conditions can exist independently (House et al. 1989; Robinson et al. 1993). Others have suggested a link to executive dysfunction (Tang et al. 2009), although the experimental data show fairly weak correlations.

It has been suggested that the neurological basis is in serotonergic systems and that there is a specific response to SSRIs (G. Andersen et al. 1994a; Choi-Kwon et al. 2006). In practice, the evidence is contradictory, with reports of equivalent response to TCAs as well (House et al. 2004; Robinson et al. 1993). There is no consistently reported associated lesion location; pontine, subcortical, and frontal lesions have all been found (G. Andersen et al. 1994a; Derex et al. 1997; Morris et al. 1993b).

Catastrophic Reactions

Catastrophic reactions manifest as disruptive emotional behavior precipitated when a patient finds a task unsolvable (K. Goldstein 1939). The sudden, dramatic appearance of such marked self-directed and stereotypical anger or frustration can be startling for both staff and relatives. This symptom is often associated with aphasia, and it has been

suggested that damage to language areas is a critical part of the etiology (Carota et al. 2001). Catastrophic reactions generally occur independently of depression in acute stroke; however, many patients who show early catastrophic reactions go on to develop depression (Starkstein et al. 1993b).

Psychosis

Psychosis—and, in particular, mania—has been observed following acute stroke. Its true incidence is unknown, although a rate of 1% has been reported (Starkstein et al. 1987). Psychotic symptoms have generally been associated with right-sided lesions (Cummings and Mendez 1984; Lampl et al. 2005), although we would suggest caution in accepting such claims. Old age and preexisting degenerative disease seem to increase the risk (Starkstein 1998) (see Chapter 10, “Psychosis, Mania, and Catatonia,” for further details and treatment considerations). Reduplicative paramnesias can occur: one memorable patient believed he was being treated on a cruise liner; on looking out of the window and seeing hospital porters delivering goods, he surmised that the ship must be in “dry dock.” Such paramnesias are usually short-lived, although a small number of chronic cases have been reported (Vighetto et al. 1980).

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) has been reported after cerebral infarctions, particularly those affecting the basal ganglia (Maraganore et al. 1991; Nighoghossian et al. 2006; Rodrigo et al. 1997).

Hyposexuality

Hyposexuality is a common complaint after stroke in both men and women (see also Chapter 16, “Sexual Dysfunction”). The symptoms generally are nonspecific, although health worries concerning body image and fear of recurrence may also be relevant. A relationship between reduced libido and emotionalism has also been proposed, suggesting a common serotonergic dysfunction (Kim and Choi-Kwon 2000).

Executive Function Impairment

Executive function, which includes decision making, judgment, and social cognition, is regulated by complex systems that are relatively resistant to damage after stroke (Carota et al. 2002; Zinn et al. 2007), although executive function is commonly impaired as part of a general dementia.

Inhibition Dyscontrol

Deficit of inhibition control occurs with impulsive behavior. The most striking examples of inhibition dyscontrol are grasp reflexes in patients with frontal lesions, but uti-

lization behavior (a tendency to use objects present in the environment automatically), hyperphasia, and hypergraphia have all been described. Such behavior tends to improve during the first few months after stroke (Carota et al. 2002).

Loss of Empathy

Loss of empathy has been reported after bilateral orbitofrontal lesions (V.E. Stone et al. 1998). It has been suggested that this difficulty in understanding and adapting to the needs of others may underlie many of the personality changes associated with frontal lesions. These changes include lack of tact, inappropriate familiarity, loss of initiative and spontaneity, childish behavior, sexual disinhibition, and poverty of emotional expression (Carota et al. 2002).

Parkinson's Disease

Parkinson's disease (PD) is a degenerative condition traditionally characterized by motor features of tremor, rigidity, and bradykinesia. The nonmotor features are, however, numerous and include cognitive and psychiatric symptoms.

Incidence

Two incidence studies of PD, one in Minnesota (Bower et al. 1999) and one in Finland (Kupio et al. 1999), estimated 10.8 cases per 100,000 person-years and 17.2 per 100,000 population, respectively. Both studies found a slight excess in men and confirmed that incidence increases with age. The Finnish study also suggested that PD was more common in rural areas.

Etiology

The cause of PD remains unknown. Genetic forms of the disease have been described, but the implicated genes are not identified in most patients. Similarly, environmental causes have been suggested, but no single exposure has been consistently replicated, with the exception of cases associated with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) (Tanner and Aston 2000). Cigarette smoking is associated with decreased risk (Gorell et al. 1999).

Clinical Features

The core feature of PD is the triad of tremor, rigidity, and bradykinesia (Sethi 2002). Bradykinesia—usually of insidious onset and easily misdiagnosed as depression or boredom—is the most common first sign and ultimately is the most disabling symptom. Resting tremor is the most characteristic feature of PD, affecting more than 70% of patients. In the early stages of the disease, the tremor is described as “pill-rolling.” The rigidity manifests as fixed

abnormalities of posture and resistance to passive movement throughout the range of motion, often with a “cog-wheel” sensation. Postural instability is a common additional feature, giving rise to an increasing liability to falls as the disorder progresses. Abnormal involuntary movements are a result both of the disease process and of dopaminergic therapy. Freezing of gait is particularly distressing to patients, but it is one of the most poorly understood features of PD, because such freezing may occur in response to visual cues (especially freezing during “off” periods), it can be misdiagnosed as willful behavior.

Nonmotor manifestations are common in PD and include autonomic (in particular, orthostatic hypotension and bladder and gastrointestinal dysfunction), sensory (pain), olfactory, sleep, cognitive, and other psychiatric symptoms.

Cognitive Features

Dementia with Lewy bodies (DLB), PD, and PD with dementia share common features, motor symptoms, and responses to treatment. The boundaries between these disorders are not distinct. Hallucinations and delusions occur in 57%–76% of DLB cases, in 29%–54% of cases of PD with dementia, and in 7%–14% of cases of PD without dementia (Aarsland et al. 2001). Delusions are often paranoid in type and mainly involve persecution and jealousy. Hallucinations usually occur in the presence of intact insight and frequently are visual and phenomenologically similar to those of Charles Bonnet syndrome (Diederich et al. 2000); these hallucinations are typically nonthreatening, worse at night, and often involve children and animals (Papa-teropoulos et al. 2008).

In the early days of levodopa (L-dopa) treatment, adverse psychiatric reactions were reported in 10%–50% of patients (Goodwin 1971). Psychosis occurred in about 10% of patients initially, but this percentage rose to 60% after 6 years of treatment (R.D. Sweet et al. 1976). The addition of carbidopa to L-dopa made this adverse effect less common. More recent studies have suggested that dopaminomimetic medication is a significant risk factor for psychosis (Aarsland et al. 1999). Other studies have found correlations between psychotic symptoms and higher rates of cognitive dysfunction and depression (Ozer et al. 2007) but no association with dosage or length of exposure to dopaminomimetic medication (Giladi et al. 2000). The most likely etiology of psychosis in PD is a combination of cortical Parkinson's pathology and age-related loss of central cholinergic function. This is corroborated by the fact that psychotic symptoms in PD are often part of nondopaminomimetic medication-induced toxic (i.e., delirious) states and that psychosis was commonly reported in the pre-levodopa era (Wolters and Berendse 2001). Cognitive impairment and sleep disrupt-

tion are predictive of the development of psychosis (Arnulf et al. 2000). Clinically, one should seek to distinguish dopaminomimetic medication-related psychosis from delirium of acute onset with disorientation, impaired attention, perceptive and cognitive disturbance, and alterations in the sleep-wake cycle. A true dopaminomimetic psychosis is a subacute, gradually progressive psychotic state unaccompanied by a primary deficit of attention. Delirium may be induced by drugs used in the treatment of PD, such as selegiline and anticholinergic medication.

Active treatment for dopaminomimetic psychosis is recommended only if symptoms begin to interfere with daily functioning. Dosage reduction of dopaminomimetic drugs is seldom effective, and antipsychotic drugs are often required (Wolters and Berendse 2001). The atypical antipsychotic drugs clozapine and quetiapine are preferred (Cummings 1999; Rabinstein and Shulman 2000), and high-potency typical antipsychotics should be avoided (see Chapter 10, "Psychosis, Mania, and Catatonia"). Early promising results suggesting a role for cholinesterase inhibitors in the treatment of dementia in PD have not been followed up with subsequent trials (McKeith et al. 2000; Ravina et al. 2005).

Emotional Symptoms

Depression is a common symptom in PD, with a prevalence of around 40%–50%. Timing of onset shows a bimodal distribution, with peaks during early and late stages of the disease (Cummings and Masterman 1999). Several large-scale studies have demonstrated that depression is one of the major determinants of quality of life in PD (Findlay 2002; Peto et al. 1995). The extent to which depression is caused by brain pathology as opposed to a psychological reaction to disability is unknown.

The diagnosis of depression in PD is difficult, because many depressive symptoms overlap with the core features of Parkinson's—motor retardation, attention deficit, sleep disturbance, hypophonia, impotence, weight loss, fatigue, preoccupation with health, and reduced facial expression. Therefore, anhedonia and sustained sadness are important diagnostic features, particularly if they are out of proportion to the severity of motor symptoms (D.J. Brooks and Doder 2001).

Mood changes can accompany the late-stage fluctuations in response to levodopa (known as "on-off" phenomena), and some patients fulfill criteria for major depressive disorder during the "off" phase but not during the "on" phase (Cantello et al. 1986; Menza et al. 1990). Bipolar mood changes reflecting the on-off phases have also been described (Keshavan et al. 1986). There is currently insufficient evidence to offer definitive recommendations for treatment of depression in PD (J. Andersen et al. 1980;

Olanow et al. 2001; Rabey et al. 1996; Shabnam et al. 2003; Wermuth et al. 1998). Although SSRIs are popular, there have been case reports of exacerbation of motor symptoms with fluoxetine, citalopram, and paroxetine (Ceravolo et al. 2000; Chuinard and Sultan 1992; Jansen Steur 1993; R.J. Leo 1996; Tessei et al. 2000). In small-scale trials, TCAs have led to better motor outcomes than have SSRIs; however, TCAs with marked anticholinergic activity (e.g., amitriptyline) should be used with caution because of their potential adverse effects on cognition and autonomic function (Olanow et al. 2001). It may be that drugs such as mirtazapine will offer a compromise (Pact and Giduz 1999). It has been suggested that the non-ergot dopamine agonist pramipexole improves both mood and motivation in PD (Armin et al. 1997; Barone et al. 2006). Case report data suggest that both electroconvulsive therapy (ECT) and transcranial magnetic stimulation (TMS) can be used to treat depression in PD, although TMS is associated with short-lived adverse effects and seizures (Fregni et al. 2004; George et al. 1996; Olanow et al. 2001). The use of ECT in PD is reviewed in Chapter 40, "Electroconvulsive Therapy."

Anxiety phenomena are common in PD; they tend to occur later in the disease process than depression and are more closely associated with severity of motor symptoms (Witjas et al. 2002). In particular, marked anticipatory anxiety related to freezing of gait is common. Treatment with antidepressant drugs (Olanow et al. 2001) and CBT, particularly if delivered in conjunction with an active physiotherapy program, can be helpful. Occasionally, benzodiazepines may be required.

Medication-Related Impulse-Control Disorders

In recent years there has been increased recognition of complex behavioral problems associated with dopamine receptor stimulation in PD (Weintraub et al. 2006). These problems include pathological gambling, hypersexuality, punding (intense fascination with and repetitive handling, examining, sorting, and arranging of objects), compulsive shopping, and compulsive medication use. Sometimes described as "dopamine dysregulation syndrome" (Voon et al. 2007), these behaviors appear to affect up to 14% of patients with PD. Many patients are secretive about these behaviors and will not volunteer the symptoms unless specifically asked.

The etiology of these impulsive behaviors is believed to be linked to dopamine agonist use, although there is not a clear dose-related effect. It has been postulated that neuronal sensitization, particularly in mesolimbic dopaminergic tracts, to the intermittent administration of dopamine agonists leads to an increased behavioral response to similar levels of psychostimulation (Evans et al. 2006; Pesiglione et al. 2006). This process can be modified by a

genetic predisposition to risk taking (there is a general association between PD and low risk-taking traits) and the environment. It is believed that younger age at onset, right-sided onset, and executive cognitive impairments can facilitate this.

Management involves transitioning patients from dopamine agonists to L-dopa and, if possible, reducing the total L-dopa dose. Several small trials have suggested some benefit for impulse-control disorders from SSRI antidepressants and antiandrogens (in hypersexuality). In one case series, subthalamic deep-brain stimulation resulted in improvement of pathological gambling in PD patients (Ardouin et al. 2006); however, a recent meta-analysis cautioned that a history of impulse-control disorders was a risk factor for postoperative suicide (Voon et al. 2007).

Sleep Disorders

Sleep disturbance is a very common symptom in PD. Rapid eye movement (REM) sleep behavior disorder, in which the sufferer acts out his or her dreams, may precede the onset of motor symptoms in PD by many years (Postuma et al. 2006). Daytime somnolence may also be a problem. There is increasing recognition that sudden somnolence can occur in PD, especially in relation to dopaminergic medication. Patients should therefore be warned about this possibility.

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disorder of the central nervous system (CNS) that causes some degree of cognitive impairment in almost half of cases and that can present with unexplained subcortical dementia. It can also be accompanied by affective disorders. The presence of high signal abnormalities on T2-weighted MRI and of oligoclonal bands of immunoglobulin in the cerebrospinal fluid (CSF) helps to confirm the diagnosis.

Demyelinating diseases are the most common non-traumatic cause of chronic neurological disability in young adults. Although a number of inflammatory demyelinating diseases can affect the CNS after vaccinations or systemic viral infection (collectively referred to as acute disseminated encephalomyelitis [ADEM]), MS is by far the most common of these. Other neuroinflammatory conditions include neurosarcoidosis and vasculitis (including cerebral lupus).

MS can occur at any age, but the median age at onset is 24 years, with a tendency for relapsing–remitting disease to present earlier than primary progressive MS. MS is more common in women. Epidemiological studies suggest that an exogenous or environmental factor, possibly viral infection, plays a part, although its nature remains unclear. The

prevalence of the disorder rises with increasing distance from the equator which has given rise to theories that vitamin D deficiency may be a factor. Genetic factors appear to influence susceptibility. A family history in a first-degree relative increases the risk some 30- to 50-fold: the risk for siblings is usually estimated to be 3%–5%, with that for children slightly lower (Franklin and Nelson 2003).

Common neurological syndromes occurring at or close to the onset of MS include optic neuritis (unilateral visual impairment, usually painful), evolving sensory loss, and upper-motor-neuron or cerebellar disorders of the limbs and gait. These deficits typically develop and remit over the course of weeks and result from conduction block in regions of CNS inflammation. Transient worsening of function, lasting for minutes, can occur in partially demyelinated axons as a result of physiological changes (e.g., increase in body temperature). Positive symptoms, including Lhermitte's sign (electric shock-like sensations on flexing the neck) and trigeminal neuralgia, can also occur. Over time, the remissions and relapses of MS tend to give way to a progressive worsening of disability. A minority of patients present with a primary progressive form of the disease, with gradual worsening from onset without remissions (McDonald et al. 2001).

MS is characterized by multifocal areas of inflammatory demyelinating white matter lesions with glial scar formation and (as now recognized) axonal loss (Trapp et al. 1998). However, in recent years there has been emerging evidence of extensive gray matter and subpial lesions. These cortical lesions show distinct pathological features, with a notable lack of T cell and B cell infiltration, microglia activation, and astrogliosis. It has been suggested that this a neurodegenerative process that primarily affects cingulate, frontal, and temporal structures. It appears particularly relevant to the neuropsychiatric clinical features of MS. There is a general theoretical shift toward regarding MS as an inflammatory neurodegenerative condition (Stadelmann et al. 2008).

Patients with unsuspected MS may first present to psychiatrists with changes in cognitive function (Zarei et al. 2003), mood, or personality. More often, however, psychiatrists are involved in the treatment of established cases. MS demonstrates the interactive nature of many of the common symptoms of diffuse neurological disease, in particular the “vicious cycle” of mood symptoms, pain, and fatigue, necessitating intervention across the spectrum of complaints in order to improve outcome.

Cognitive Impairment

Cognitive impairment affects at least half of all patients with MS (W.W. Beatty et al. 1989; Heaton et al. 1985; Rao 1986; Rao et al. 1991). Impairment, when present, is gener-

ally a “subcortical dementia” with impaired attention and speed of processing as the hallmark signs. Executive function deficits are common. Deficits in working, semantic, and episodic memory are reported, but procedural and implicit memory functions are generally preserved. Cortical syndromes such as aphasia, apraxia, and agnosia are relatively rare. Neuropsychological tests such as the Paced Auditory Serial Addition Test (PASAT) appear most sensitive to changes (Hoffmann et al. 2007). At the bedside, tests of verbal fluency are of the most value. In general terms, processing speed is usually more impaired than accuracy (Henry and Beatty 2006). MRI studies show that cognitive impairment correlates with general atrophy; however, attempts to link specific cognitive deficits with particular gray or white matter lesions have so far yielded conflicting results (Rovaris et al. 2006). There is a paucity of well-designed studies on the effects of disease-modifying agents (e.g., beta interferon) on cognition and little evidence as to the utility of acetylcholinesterase inhibitors (Amato et al. 2006). There is slightly more robust evidence showing the utility of treating comorbid depression when present (Feinstein 2006).

Psychosis

A well-conducted population study has challenged the perceived orthodoxy that MS is not associated with an increased risk of psychosis (Patten et al. 2005b). The authors reported an increase in rate of psychosis to 2%–3%, with the highest prevalence, 4%, in 15- to 24-year-olds. In addition, the literature contains numerous case reports of well-described psychosis in MS.

Mood Disorders

Mood disorders are common in MS, with more than half of patients reporting depressive symptoms. Depression may be a direct physiologically mediated consequence of the disease, a psychological reaction to the illness, a complication of pharmacotherapy, or coincidental. Mania and emotional lability are also frequently reported (Joffe et al. 1987; Sadovnick et al. 1996) (see also Chapter 8, “Depression,” and Chapter 10, “Psychosis, Mania, and Catatonia”).

It is important to distinguish depression from the fatigue and pain that are commonly associated with MS (see subsections “Fatigue” and “Pain” below). As in stroke, there has been an attempt to separate out a “biological” depression from a “psychological reactive” depression (Patten and Metz 1997) and to link symptoms to the site of the brain lesions (Fassbender et al. 1998; Honer et al. 1987; Pujol et al. 1997). However, supporting evidence has been inconsistent and hampered by small study samples; for this reason, it appears to be more productive to consider depression in MS as multifactorial. There are few randomized controlled trials of antidepressant drug therapy in

MS, but those available suggest modest efficacy for these agents (Feinstein 1997), similar to their efficacy for depression associated with neurological illness in general (Schiffer and Wineman 1990).

Interferon-beta therapy was reported to cause depression (and fatigue) in 40% of MS patients in an open-label trial (Neille et al. 1996). However, depression is highly prevalent in untreated MS, and other studies have found no increase in depression following interferon-beta therapy (Patten and Metz 2001; Zephir et al. 2003). In one prospective study, the rate of depression actually fell with interferon-beta treatment (Feinstein et al. 2002). This discrepancy may lie in the fact that interferon-beta, particularly early in therapy, can cause symptoms that are mislabeled as depression (Patten et al. 2005a).

Fatigue

Fatigue is the most common single symptom in MS, affecting 80% of those with the disease (Fisk et al. 1994; Freal et al. 1984). It is generally a disabling and aversive experience and affects motivation as well as physical strength. It is important to differentiate fatigue from depression, adverse medication side effects, or pure physical exhaustion secondary to gait abnormalities, because management may differ (Multiple Sclerosis Council for Practice Guidelines 1998). The mechanism of fatigue is poorly understood and almost certainly multifactorial. A number of agents, including amantadine (Krupp et al. 1995; Pucci et al. 2007), 4-aminopyridine (Polman et al. 1994), 3,4-diaminopyridine (Sheean et al. 1997), and modafinil (Rammohan et al. 2002) and other stimulants, have been advocated, but results of studies with these drugs have been inconclusive. Some patients respond to SSRIs or bupropion, and CBT was found to be beneficial in one randomized controlled trial (van Kessel et al. 2008).

Pain

Pain, both acute and chronic, is a common and disabling complication of MS. One study found that one-quarter of MS patients in a large community-based sample had severe chronic pain (Ehde et al. 2003). Mechanisms may include dysesthesia, altered cognitive function, and other MS complications such as spasticity. Of the acute pain syndromes, trigeminal neuralgia is the most common and usually responds to carbamazepine (Thompson 1998). Widespread chronic pain is more frequent and harder to manage. There are small randomized controlled trials showing some benefit of lamotrigine (Breuer et al. 2007), levetiracetam (Rossi et al. 2009), and cannabinoids (Rog et al. 2005) for central pain syndromes in MS. Dysesthetic limb pain is particularly troublesome; treatment is usually with amitriptyline or gabapentin (Samkoff et al. 1997). Pain in the lumbar

area, by contrast, usually tends to respond better to physiotherapy than to analgesia (Thompson 1998; see also Chapter 36, "Pain").

Amnestic Syndromes

The amnestic or amnesic syndrome is an abnormal mental state in which learning and memory are affected out of proportion to other cognitive functions in an otherwise alert and responsive patient (Victor et al. 1971). The most common cause of amnestic states is Wernicke-Korsakoff syndrome, which results from nutritional depletion, particularly thiamine deficiency. Other causes include carbon monoxide poisoning, herpes simplex encephalitis and other CNS infections, limbic encephalitis, hypoxic and other acquired brain injuries, stroke, deep midline cerebral tumors, and surgical resections, particularly for epilepsy. In the majority of cases, the pathology lies in midline or medial temporal structures, but there are also case reports of amnestic disorder following frontal lobe lesions.

Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome results from thiamine depletion, and any cause of such depletion can lead to the syndrome—including, for example, hyperemesis gravidarum and gastric bypass surgery. However, the overwhelming majority of cases are associated with chronic alcohol abuse, which results in both decreased intake and decreased absorption of thiamine. A genetic defect for thiamine metabolism has been described in a small proportion of patients (Blass and Gibson 1977).

The syndrome presents acutely with Wernicke's encephalopathy, which is characterized by confusion, ataxia, nystagmus, and ophthalmoplegia. Peripheral neuropathy can also be present. Parenteral administration of high-dose B vitamins is required as *emergency* treatment if the chronic state of Korsakoff's syndrome is to be avoided. The majority of cases of Korsakoff's syndrome occur following Wernicke's encephalopathy.

On clinical examination, patients with Korsakoff's syndrome may perform well on standard tasks of attention and working memory (serial sevens and reverse digit span) (Kopelman 1985) but may struggle on more complex tasks involving shifting and dividing attention. A severe memory impairment involving both anterograde and retrograde deficits is present (Kopelman et al. 1999). The defective encoding of new information is the core component of this memory disorder (Meudell and Mayes 1982). In addition to a dense anterograde amnesia affecting declarative functions, there is inconsistent, poorly organized retrieval of retrograde memories with a temporal gradient (more im-

pairment for relatively recent than for more remote memories). The retrograde amnesia is more pronounced in diencephalic amnestic syndromes such as Korsakoff's than in amnestic syndromes of hippocampal origin, in which retrograde amnesia is present but with a deficit measured in months rather than years (Kopelman et al. 1999). A limited degree of new learning may be possible, particularly if patients are given a strategy to follow. Confabulation commonly occurs, particularly early in the disorder. Procedural memory remains relatively intact (Schacter 1987).

Other cognitive impairments and behavioral changes may accompany the amnesia. Executive functions are commonly mildly affected, but this impairment may be secondary to chronic alcoholism rather than representing a specific deficit. Disorientation and apathy, often with lack of curiosity about the past, are common, yet such disengaged patients frequently demonstrate labile irritability.

The pathological process is neuronal loss, microhemorrhages, and gliosis in the paraventricular and periaqueductal gray matter (Victor et al. 1971). The mammillary bodies, mamillothalamic tract, and the anterior thalamus are the main structures affected (Mair et al. 1979; Mayes et al. 1988). There is often a degree of generalized cortical atrophy, more marked in the frontal lobes (Jacobson and Lishman 1990). The atrophy may, however, be nonspecific and secondary to alcohol abuse. MRI indicates specific atrophy in diencephalic structures (Colchester et al. 2001; Sullivan and Pfefferbaum 2009).

With vitamin replacement and abstinence from alcohol, the prognosis is fair: one-quarter of patients will recover, half will improve but with some persistent impairment, and one-quarter will show no change (Victor et al. 1971). High-dose B vitamins should be given to all patients acutely and probably continued, but it is unclear how long this therapy should be maintained.

Transient Amnestic Syndromes

Transient amnesia can occur in several contexts. Transient global amnesia (TGA) is a distinctive benign disorder affecting middle-aged or elderly persons, who become amnestic for recent events and unable to lay down new memories for a period of around 4 hours (Hodges and Ward 1989). Repetitive questioning by patients of their companions is a characteristic feature. Episodes can be provoked by physical or emotional stress and are usually isolated; the medium-term recurrence rate is 3% per year (Hodges 1991). There is good evidence that TGA results from reversible medial temporal lobe dysfunction, but the etiological mechanism is uncertain (Stillhard et al. 1990). Although temporal lobe epilepsy occasionally mimics TGA ("transient epileptic amnesia"), episodes are typically briefer (last-

ing less than an hour), recurrent (several per year), and tend to occur on waking (Butler et al. 2007; Zeman et al. 1998). Other causes of transient amnesia include transient cerebral ischemia (usually accompanied by other neurological symptoms and signs), migraine, drug ingestion, head injury, and dissociative disorders.

Dementias Accompanied by Neurological Signs

Dementia refers to a deterioration of intellectual faculties, such as memory, concentration, and judgment, that is sometimes accompanied by emotional disturbance and personality changes. An approach to management of dementing conditions (including Alzheimer's disease, vascular dementia, dementia with Lewy bodies, frontotemporal dementia, Huntington's disease, Parkinson's disease, and normal-pressure hydrocephalus, among others) is described in detail in Chapter 6, "Dementia." In this section, we concentrate on those disorders that are particularly likely to present with other neurological symptoms, often a movement disorder. Other causes of dementia are also discussed elsewhere in this volume: HIV (see Chapter 28, "HIV/AIDS"), other infections (see Chapter 27, "Infectious Diseases"), alcohol and other substance use (see Chapter 17, "Substance-Related Disorders"), toxic and metabolic conditions (see Chapter 22, "Endocrine and Metabolic Disorders," and Chapter 37, "Medical Toxicology"), rheumatological and inflammatory conditions (see Chapter 25, "Rheumatology"), and traumatic brain injury (see Chapter 35, "Physical Medicine and Rehabilitation").

Huntington's Disease

Huntington's disease (HD), also known as Huntington's chorea, was first described in Long Island in 1872 by George Huntington. This disorder is dominantly inherited and causes a combination of progressive motor, cognitive, psychiatric, and behavioral dysfunction.

Epidemiology

HD occurs at a prevalence of 5–7 per 100,000 population in the United States, with wide regional variations (Chua and Chiu 1994). The sexes are affected equally. Onset can be at any age but most commonly is in young or middle adulthood (Adams et al. 1988; Farrer and Conneally 1985). The disorder exhibits the phenomenon of *anticipation*, in which the age at onset tends to decrease over the generations, especially with paternal transmission (Brinkman et al. 1997) (see subsection "Pathology and Etiology" below).

Clinical Features

Chorea—involuntary, fidgety movements of the face and limbs—is the characteristic motor disorder. As the disease progresses, other extrapyramidal features can develop, including rigidity, dystonia, and bradykinesia, as well as dysphagia, dysarthria, and pyramidal signs (Harper 1991). Childhood-onset HD tends to be dominated by rigidity and myoclonus (the "Westphal variant"). Epilepsy can occur. Cognitive dysfunction goes hand in hand with the motor disorder. The dementia of HD is predominantly "subcortical," with impairment of attention, executive function, speed of processing, and memory (Zakzanis 1998). Psychiatric symptoms and behavioral changes are the norm (Mendez 1994; Zappacosta et al. 1996), with depression, apathy, and aggressiveness present in most cases (Burns et al. 1990; Levy et al. 1998) and psychosis, obsessional behavior, and suicide in a significant minority (Almqvist et al. 1999; Cummings and Cunningham 1992; Folstein et al. 1979). Obsessive behavior appears to be a trait marker in subjects who are gene carriers (see "Pathology and Etiology" below). Depression and irritability frequently precede the development of motor and cognitive symptoms. Psychosis, by contrast, rarely precedes the development of motor symptoms. Apathy tends to correlate positively with disease progression (Paulsen et al. 2005; Van Duijn et al. 2007). Progression to a state of immobility and dementia typically occurs over a period of 15–20 years (Feigin et al. 1995). Cognitive and behavioral changes may predate the clear-cut emergence of symptomatic HD (Kirkwood et al. 1999).

Pathology and Etiology

The key pathological processes of HD occur in the striatum, caudate, and putamen. The loss of small neurons in the striatum is accompanied by neuronal loss in the cerebral cortex, cerebral atrophy, ventricular dilatation, and, eventually, neuronal depletion throughout the basal ganglia (De la Monte et al. 1988; Vonsattel and DiFiglia 1998).

The underlying genetic abnormality in HD is expansion of a "base triplet repeat" of the *IT15* gene on chromosome 4, which codes for the *huntingtin* gene. The normal gene contains 10–35 CAG (cytosine-adenine-guanine) repeats; repeat lengths beyond 39 give rise to symptomatic HD over the course of a normal life span (Duyao et al. 1993). Repeat lengths between 36 and 39 can cause disease. Repeats in the 27–35 range appear to be unstable and liable to increase into the pathological range in the next generation. The tendency for pathologically expanded repeats to increase in length between generations, especially in paternal transmission, underlies the clinical phenomenon of *anticipation*. It has been suggested that the likelihood of

psychopathology diminishes with increasing CAG repeat length (Vassos et al. 2008). The function of *huntingtin* remains uncertain.

Investigation and Differential Diagnosis

A number of disorders can cause the combination of chorea and cognitive change seen in HD, including other inherited disorders such as neuroacanthocytosis and dentato-rubro-pallido-luysian atrophy (DRPLA) and acquired disorders such as systemic lupus erythematosus. However, the diagnosis of HD can now be made with confidence by DNA analysis. Counseling by a clinical geneticist is mandatory before presymptomatic testing and should be considered in other circumstances as well (Codori et al. 1997).

Management

Chorea may require treatment, although patients often are not as concerned by it as their caregivers are. A range of agents have been suggested, of which tetrabenazine has the most supportive evidence (Mestre et al. 2009). However, given the cognitive and/or extrapyramidal side effects of the agents used to treat the chorea (neuroleptics, dopamine depleters [e.g., tetrabenazine], or benzodiazepines), this is often best avoided (Rosenblatt et al. 1999). Other psychiatric symptoms should be treated along standard lines (Leroi and Michalon 1998).

Wilson's Disease (Hepatolenticular Degeneration)

First described by Wilson in 1912, Wilson's disease is a very rare, autosomal recessive, progressive degenerative brain disease caused by a disorder of copper metabolism, producing personality change, cognitive decline, extrapyramidal signs, and cirrhosis of the liver.

Clinical Features

The onset of Wilson's disease most commonly occurs in childhood or adolescence but can occur as late as the fifth decade (Bearn 1957). Patients may present to psychiatrists with personality change, behavioral disturbance, depression, irritability, or dementia or to neurologists with a variety of extrapyramidal signs, including tremor, dysarthria and drooling, rigidity, bradykinesia, and dystonia (Walsh 1986; Walsh and Yelland 1992). Although commonly described, schizophreniform psychosis is in fact rare (Akil and Brewer 1995; Denning and Berrios 1989; Shanmugiah et al. 2008). Careful examination reveals these features and also, in virtually all symptomatic cases, the presence of *Kayser-Fleischer rings*—rings of greenish-brown copper pigment at the edge of the cornea (Wiebers et al. 1997). (In suspected cases, an ophthalmologist should be asked to

look for this feature with a slit lamp.) The liver failure and the neuropsychiatric syndrome can occur together or independently.

Pathology and Etiology

The causative genetic mutation is in the copper-transporting P-type ATPase coded on chromosome 13 (Bull et al. 1993). The result is excessive copper deposition in the brain, cornea, liver, and kidneys and increased copper excretion in urine. The caudate and putamen are the brain regions most severely affected, but other parts of the basal ganglia and the cerebral cortex are also involved (Mochizuki et al. 1997; Starosta-Rubinstein et al. 1987).

Investigation and Differential Diagnosis

Ninety-five percent of patients with Wilson's disease have low serum levels of the copper-binding protein ceruloplasmin. Normal ceruloplasmin levels and an absence of Kayser-Fleischer rings render the diagnosis very unlikely in cases with neuropsychiatric features (Ferenci 1998). Uncertain cases may require measurement of urinary copper excretion and liver biopsy for measurement of copper content (Pfeil and Lynn 1999). DNA analysis is becoming increasingly available. The differential diagnosis varies with the type of presentation.

Management

Several copper-chelating agents (e.g., penicillamine, tetraethylene tetramine, zinc acetate) are available to treat patients with Wilson's disease, but the risk of significant side effects mandates care by a specialist (Pfeil and Lynn 1999).

Leukodystrophies

Leukodystrophies—recessively inherited or X-linked disorders of myelination—can be accompanied by neuropsychiatric syndromes, usually with associated neurological features. Metachromatic leukodystrophy, caused by a deficiency of the enzyme arylsulfatase A (Hyde et al. 1992), and adrenoleukodystrophy (see also Chapter 22, "Endocrine and Metabolic Disorders"), an X-linked disorder associated with abnormalities of very-long-chain fatty acids (James et al. 1984), are the most commonly encountered types.

Progressive Supranuclear Palsy

Progressive supranuclear palsy is characterized by supranuclear gaze palsy (an inability to direct eye movements voluntarily, especially vertical eye movements, in the presence of normal reflex eye movements); truncal rigidity, akinesia, postural instability, and early falls; bulbar features, with dysarthria and dysphagia; subcortical dementia; and alteration of mood (including pathological crying

and laughing), personality, and behavior (De Bruin and Lees 1992). Neurofibrillary tangles, consisting of tau protein, are found in neurons of the basal ganglia and brain stem. Midbrain atrophy may be apparent on MRI.

Corticobasal Degeneration

Corticobasal degeneration typically manifests as a combination of limb apraxia, usually asymmetric at onset, alien limb phenomena, limb myoclonus, parkinsonism, and cognitive decline (Rinne et al. 1994). The neuropsychiatric features tend to be those of “frontal” disorders. Interestingly, unlike other parkinsonian syndromes, visual hallucinations appear to be rare (Geda et al. 2007). The pathology involves neuronal loss in both the basal ganglia and the frontal and parietal cortex, with intraneuronal accumulations of tau protein resembling those seen in progressive supranuclear palsy. MRI usually reveals frontoparietal atrophy.

Transmissible Spongiform Encephalopathies (Prion Dementias)

The transmissible spongiform encephalopathies are a group of rare dementias caused by an accumulation of abnormal prion protein within the brain (P. Brown 2001). Related illnesses occur in animals: indeed, one recently described disorder, variant Creutzfeldt-Jakob disease, is thought to result from infection of humans by consumption of beef products from cattle with bovine spongiform encephalopathy (BSE) (Will et al. 1996). The term *prion*, coined by Stanley Prusiner, stands for “proteinaceous infectious pathogen” (Prusiner 1994, 2001).

Epidemiology

All of the transmissible spongiform encephalopathies are rare. Sporadic Creutzfeldt-Jakob disease, the most common human transmissible spongiform encephalopathy, occurs with an annual incidence of one per million, usually affecting people between the ages of 55 and 70 years (P. Brown et al. 1987). At the time of this writing, variant Creutzfeldt-Jakob disease has been diagnosed in 168 individuals, almost all of them in the United Kingdom. Variant Creutzfeldt-Jakob disease more often develops in younger subjects than does sporadic Creutzfeldt-Jakob disease: most cases have occurred during the second through fourth decades of life (Will et al. 1996).

Clinical Features

Sporadic Creutzfeldt-Jakob disease typically causes a rapidly progressive dementia, with early changes in behavior, visual symptoms, and cerebellar signs. Within weeks to months, marked cognitive impairment develops, often progressing to mutism, with pyramidal, extrapyramidal,

and cerebellar signs and myoclonus (P. Brown et al. 1994). The median duration of symptom onset to death is only 4 months, although in rare cases the disorder evolves over several years. Younger patients with sporadic Creutzfeldt-Jakob disease tend to have a more prolonged course and an early symptom profile closer to that of variant Creutzfeldt-Jakob (Boesenberg et al. 2005). Iatrogenic cases of Creutzfeldt-Jakob disease have occurred when CNS tissue from patients with sporadic Creutzfeldt-Jakob disease has unwittingly been transferred from patient to patient by surgical instruments or used in medical procedures as a source of growth hormone, gonadotropins, dura mater, or corneal grafts (P. Brown et al. 2000).

Variant Creutzfeldt-Jakob disease differs markedly from sporadic Creutzfeldt-Jakob disease (M.D. Spencer et al. 2002). The initial symptoms are usually psychiatric, most commonly anxiety or depression, and often of sufficient severity to lead to psychiatric referral. Limb pain or tingling is common early in the course of the illness. After some months, cognitive symptoms typically develop, causing difficulty at school or work, together with varied neurological features including pyramidal, extrapyramidal, and cerebellar signs and myoclonus. The disorder evolves more slowly than does sporadic Creutzfeldt-Jakob disease, with an average duration of 14 months from symptom onset to death.

Three other varieties of human transmissible spongiform encephalopathy have been described. *Kuru*, now extremely rare, causes a cerebellar syndrome with progression to dementia. It is confined to the Fore Indians of Papua New Guinea and was caused by cannibalism of CNS tissues from affected relatives (Gajdusek 1977). *Gerstmann-Strausler-Scheinker syndrome* is an autosomal-dominant prion dementia characterized primarily by cerebellar dysfunction and dementia with a protracted clinical course (Piccardo et al. 1998). *Fatal familial insomnia* is a very rare autosomal dominant prion disorder with severe insomnia and autonomic disturbance manifesting early in the course of the disease (Gambetti et al. 1995).

Pathology and Etiology

The light microscope reveals “spongiform change” in the brains of patients with transmissible spongiform encephalopathies; this change is associated with neuronal loss, gliosis, and deposition of “amyloid.” Immunocytochemistry and direct biochemical analysis indicate that the amyloid is composed of a protease-resistant form of prion protein (PrP) (Prusiner 2001).

Investigation and Differential Diagnosis

In sporadic Creutzfeldt-Jakob disease, the electroencephalogram (EEG) shows 1- to 2-per-second triphasic waves in

80% of cases at some time during the course of the illness (Steinhoff et al. 1996). Detection of 14–3–3 protein in CSF has a sensitivity and specificity of approximately 90% for sporadic Creutzfeldt-Jakob disease (Hsich et al. 1996). Brain biopsy is usually diagnostic but is rarely performed. In variant Creutzfeldt-Jakob disease, the EEG and CSF examination are less useful, but characteristic MRI abnormalities (especially high signal in the pulvinar nucleus) are found in a substantial proportion of cases, with a reported sensitivity of 78% and a specificity of 100% (Zeidler et al. 2000). Tonsillar biopsy has also been used as a confirmatory test, because prion protein scrapie (PrPSc) is found in lymphoid tissue in variant Creutzfeldt-Jakob disease (Hill et al. 1999). In suspected cases of familial transmissible spongiform encephalopathy, sequencing of the *PrP* gene will identify the causative mutation.

Management

At present, there is no proven remedy for the disease.

Whipple's Disease

Whipple's disease is rare but important, because it is treatable. Infection with *Tropheryma whippelii* typically causes a multisystem disorder with prominent steatorrhea, weight loss, and abdominal pain (Fenollar et al. 2007; Fleming et al. 1988). CNS involvement is common, and neurological and psychiatric symptoms and signs occur in the absence of systemic features (A.P. Brown et al. 1990; Louis et al. 1996). Small-bowel biopsy, lymph node biopsy, brain MRI, and CSF examination, including polymerase chain reaction studies to identify the causative organism, can all be helpful in diagnosis (Louis et al. 1996). Antibiotic treatment can be effective.

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare complication of childhood measles in which intraneuronal persistence of a defective form of the virus in the CNS results in a continuing immune response, with high levels of measles antibody in the CSF. Neurological signs, including myoclonus, accompany the dementia (Garg 2008; Lishman 1997; Risk et al. 1978). Average life expectancy from onset is 1–2 years.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy is caused by activation of JC papovavirus within the CNS in an immunocompromised patient. The resulting demyelination gives rise to pyramidal signs, visual impairment, and a subcortical dementia, usually with progression to death within months (Lishman 1997; Richardson 1961).

Limbic Encephalitis

Limbic encephalitis (LE) is an autoimmune-mediated inflammation centered on the limbic system. It can have a range of psychiatric and neurological presentations, including focal seizures, memory impairment, confusion, and alterations of mood, personality, and behavior (Schott 2006). LE may occur as a paraneoplastic phenomenon or (more often) as a primary autoimmune disease. The diagnosis is supported by MRI, which sometimes shows high signal change in the medial temporal lobes. The CSF often contains oligoclonal bands of immunoglobulin.

Paraneoplastic LE is most commonly caused by small-cell lung cancer, although breast, ovarian, renal, and testicular carcinoma and lymphoma can also be responsible. The tumor may be small and sometimes is initially undetectable by imaging. A range of antineuronal antibodies in serum or CSF may be found, most commonly "anti-Hu." Forty percent of cases are antibody-negative (Darnell and Prosser 2003).

Clues to the diagnosis of an autoimmune LE include hyponatremia and antibodies to voltage-gated potassium channels (Vincent et al. 2004). Some patients improve markedly with immunosuppressive treatment, with corresponding drops in antibody levels (see also Chapter 23, "Oncology").

Hashimoto's Encephalopathy

Hashimoto's encephalopathy, a severe encephalopathic illness manifesting in the presence of high serum antithyroid antibody concentrations, responds dramatically to steroids. Seizures, psychosis, confusion, stroke-like episodes, and raised CSF protein, often with normal MRI findings, are the common features. There is still controversy regarding whether thyroid autoantibodies are the cause of the illness or epiphenomena, leading to calls for the entity to be renamed steroid-responsive encephalopathy with autoimmune thyroiditis (SREAT) (Chong et al. 2003).

Amyotrophic Lateral Sclerosis (Motor Neurone Disease)

Amyotrophic lateral sclerosis (ALS) (known as *motor neurone disease* in Europe) is a neurodegenerative disorder, usually of unknown etiology, typically presenting in the seventh decade with progressive weakness either of limbs (limb onset) or of speech and swallowing (bulbar onset). Five percent to 10% of cases have a genetic basis. The diagnosis is made on the basis of progressive mixed upper and lower motor neuron signs in three limbs or in two limbs with bulbar symptoms (B.R. Brooks et al. 2000). Traditionally, ALS was thought of as one of the few neurodegenerative conditions without neuropsychiatric features. However, it is now

clear that ALS has quite specific neuropsychiatric complications.

Around 5% of patients with sporadic ALS and 15% of those with familial ALS develop frontotemporal dementia. This may be a typical frontal syndrome (with impaired executive functions, apathy, and breakdown of social behavior) or a more specific focal dementia, especially primary progressive aphasia and semantic dementia. Because dementia often precedes the onset of motor symptoms, patients with frontotemporal dementia should be monitored for the development of ALS.

A large proportion of patients with ALS can be found to have subtle executive deficits on testing in the absence of symptoms (Abrahams et al. 2005). Emotional lability is also common in ALS, affecting up to 20% of patients (Palmeri et al. 2009).

CNS Tumors, Hydrocephalus, and Subdural Hematoma

CNS tumors, hydrocephalus, and subdural hematoma are discussed in the section "Neurosurgical Issues" later in this chapter.

Epilepsy

Epileptic seizures are transient cerebral dysfunctions resulting from an excessive and abnormal electrical discharge of neurons. The clinical manifestations are numerous. As a result, psychiatrists commonly encounter epilepsy, both when considering whether epilepsy is the primary cause of paroxysmal psychiatric symptoms and when treating its significant psychiatric complications.

Epidemiology

Problems with case definition and ascertainment complicate epidemiological estimates. However, incidence rates of 40–70 per 100,000 population in developed countries and 100–190 per 100,000 in developing countries are generally accepted. The prevalence of active epilepsy is around 7 per 1,000 population in the developed world (Bell and Sander 2001; Kotsopoulos et al. 2002; Sander and Shorvon 1996). Reasons for the higher incidence in developing nations are believed to include increased rates of birth trauma and head injury and lack of health services to manage them, and poor sanitation leading to high rates of CNS infection (e.g., cysticercosis; see Chapter 27, "Infectious Diseases"). Most studies show a bimodal distribution for age of incidence, with increased rates in persons younger than 10 years and older than 60 years. Epilepsy is more common in men and may be more common in black Africans (Sander and Shorvon 1996).

A specific etiological mechanism is identified in less than one-third of cases. These mechanisms include perinatal disorders, learning disabilities, cerebral palsy, head trauma, CNS infection, cerebrovascular disease, brain tumors, Alzheimer's disease, and substance misuse. In addition, many so-called idiopathic seizures are likely to have a genetic basis.

Estimates of seizure recurrence after a first event are widely varied and depend on the population being studied (Cockerell et al. 1997; Sander 1993). However, if seizures are going to recur, they usually do so within 6 months of the first event; the prognosis improves as the seizure-free period lengthens. In patients with established epilepsy, the prognosis is extremely variable. In some benign childhood epilepsies, anticonvulsant medication is unnecessary and remission the rule. In the majority of patients with epilepsy, remission occurs with treatment, and it may be possible to withdraw treatment in the long term. In some epilepsy syndromes, such as juvenile myoclonic epilepsy, treatment is effective but must be continued indefinitely. In around one-third of patients with epilepsy, anticonvulsants fail to provide adequate control of seizures. This is particularly likely in patients with aggressive pediatric epilepsy syndromes (e.g., infantile spasms, Lennox-Gastaut syndrome) or in patients whose epilepsy has a defined structural or congenital cause.

Clinical Features

Epilepsy constitutes a heterogeneous group of disorders with multiple causes, and its clinical features reflect this diversity. The key clinical distinction is between seizures with a focal and seizures with a generalized cerebral origin. The former are more likely to be associated with a detectable and potentially remediable cerebral lesion, whereas the latter are more likely to start in childhood or adolescence and to be familial. Despite the wide variety of possible seizure manifestations, an individual patient's seizures are usually stereotyped. Their clinical features result from a recurrent pattern of cortical hyperactivity during the ictal event followed by hypoactivity in the same area postictally.

Documentation of the clinical features of the seizure is the key to diagnosis. Because firsthand observation is seldom possible unless seizures are very frequent, the history of the episode, including an eyewitness account (or a home/mobile phone video), is of paramount importance.

Tonic-Clonic Seizures

Tonic-clonic seizures are the most dramatic manifestation of epilepsy and are characterized by motor activity and sudden loss of consciousness. In a typical seizure, a patient has no warning (with the possible exception of a couple of

myoclonic jerks) of its onset. The seizure begins with sudden loss of consciousness and a tonic phase during which there are sustained muscle contractions lasting 10–20 seconds. This is followed by a clonic phase of repetitive muscle contractions that last approximately 30 seconds. A number of autonomic changes, including increase in blood pressure and pulse rate, apnea, mydriasis, incontinence, piloerection, cyanosis, and perspiration, may also occur. In the postictal period, the patient is drowsy and confused. Abnormal neurological signs are often elicited.

Partial Seizures

Partial seizures are categorized according to whether they are simple (without impairment in consciousness) or complex (with impairment of consciousness). This classification may be difficult to apply in practice, however.

Simple partial seizures. The clinical features of simple partial seizures depend on the brain region activated. Although the initial area is relatively localized, it is common for the abnormal activity to spread to adjacent areas, producing a progression of seizure pattern. If the activity originates in the motor cortex, there will be jerking movements in the contralateral body part. This can cause progressive jerking in contiguous regions (a phenomenon known as “Jacksonian march”). Activity in the supplementary motor cortex causes head turning with arm extension on the same side—the classic “fencer’s posture.”

Seizures originating in the *parietal lobe* can cause tingling or numbness in a bodily region or more complex sensory experiences such as a sense of absence on one side of the body, asomatognosia. Seizures in the inferior regions of the parietal lobe can cause severe vertigo and disorientation in space. Dominant-hemisphere parietal lobe seizures can cause language disturbance.

Seizures of the *occipital lobe* are associated with visual symptoms, which are usually elementary (e.g., simple flashing lights). However, if the seizure occurs at the border with the temporal lobe, more complex experiences can occur, including micropsia, macropsia, and metamorphosis, as well as visual hallucinations of previously experienced imagery.

Seizures affecting the *temporal lobe* can be the most difficult to diagnose, but this lobe is also the most common site of onset, accounting for 80% of partial seizures. Symptoms may include auditory hallucinations, ranging from simple sounds to complex language. Olfactory hallucinations, usually involving unpleasant odors, follow discharge in the mesial temporal lobe. Seizures in the Sylvian fissure or operculum will cause gustatory sensations; ictal epigastric sensations such as nausea or emptiness gener-

ally have a temporal lobe origin. The well-known emotional and psychic phenomena of temporal lobe seizure activity can occur in simple seizures but are more common in complex partial seizures.

Complex partial seizures. In a complex partial seizure, the patient frequently experiences an aura at the onset of the seizure. The aura is a simple partial seizure lasting seconds to minutes. It should be distinguished from a prodrome, which is not an ictal event and which can last for hours or even days before a seizure. Prodromes usually consist of a sense of nervousness or irritability. The content of the aura will depend on the location of the abnormal discharge within the brain. Thus, it may contain motor, sensory, visceral, or psychic elements. These can include hallucinations; intense affective symptoms such as fear, depression, panic, or depersonalization; and cognitive symptoms such as aphasia. Distortions of memory can include dreamy states, flashbacks, and distortions of familiarity with events (*déjà vu* or *jamais vu*). Occasionally, rapid recollection of episodes from earlier life experiences occurs (panoramic vision). Rage is rare; when it does occur, it is characterized by lack of provocation and abrupt abatement. This phase is followed by impairment of consciousness and a seizure usually lasting 60–90 seconds, which may generalize into a tonic-clonic seizure. Automatism may occur and can involve an extension of the patient’s actions prior to seizure onset. Common facial automatisms include chewing or swallowing, lip smacking, and grimacing; automatisms in the extremities include fumbling with objects, walking, or trying to stand up. Postictal confusion is usually significant and typically lasts 10 minutes or longer.

Complex partial seizures of frontal lobe origin tend to begin and end abruptly, with minimal postictal confusion. They often occur in clusters. The attacks are usually bizarre, with motor automatisms such as bicycling or with sexual automatisms and vocalizations.

Absence Seizures

Absence seizures are well-defined clinical and EEG events. The essential feature is an abrupt, brief episode of decreased awareness that occurs without any warning, aura, or postictal symptoms. At the onset there is a disruption of activity.

A *simple* absence seizure is characterized by only an alteration in consciousness. The patient remains mobile, breathing is unaffected, and there is no cyanosis or pallor and no loss of postural tone or motor activity. The ending is abrupt, and the patient resumes previous activity immediately, often unaware that a seizure has taken place. An at-

tack usually lasts around 15 seconds. A *complex* absence seizure involves additional symptoms such as loss or increase of postural tone, minor clonic movements of the face or extremities, minor automatisms, or autonomic symptoms such as pallor, flushing, tachycardia, piloerection, mydriasis, and urinary incontinence.

Violent Behavior

Epilepsy, in particular epilepsy involving the temporal lobe, may cause emotional symptoms and very occasionally can result in undirected violent behavior (Kotagal 1997). However, in the majority of cases of epilepsy-related violence, the behavior occurs in response to being restrained during a seizure. One should be very cautious in attributing other violent assaults to a seizure. Indeed, a recent systematic review concluded that overall, patients with epilepsy have a reduced risk for violence compared with control subjects (Fazel et al. 2009). This issue is discussed in more detail in Chapter 7, "Aggression and Violence," which includes criteria for determining whether a violent act resulted from an epileptic seizure.

Differential Diagnosis

Differentiating epilepsy from nonepileptic attack disorder (psychogenic epilepsy or pseudoseizures) and syncope can be difficult (Roberts 1998). Other paroxysmal disorders should also be considered; these include transient ischemic attacks, hypoglycemia, migraine, transient global amnesia, cataplexy, paroxysmal movement disorders, and paroxysmal symptoms in multiple sclerosis. Attacks during sleep can pose particular difficulties, as informant reports are less useful.

Nonepileptic Attack Disorder

Nonepileptic attack disorder (NEAD)—also known as "pseudoseizures," "dissociative seizures," and "psychogenic seizures"—is the most common alternative diagnosis, accounting for about 30% of patients presenting to clinics with suspected epilepsy (Reuber and Elger 2003), and with a reported community prevalence of 33 cases per 100,000 population (Benbadis and Allen 2000). The terminology is confusing, and it is unclear whether NEAD is a specific diagnosis or a collective term for a number of psychiatric diagnoses or symptoms that may cause seizure-like spells, including conversion, panic attacks, hyperventilation syndrome (see Chapter 19, "Lung Disease"), post-traumatic stress disorder (PTSD), and catatonia. We personally favor the view that NEAD is often a variant of panic disorder with prominent dissociation (L.H. Goldstein and Mellers 2006). Although rates of psychiatric comorbidity are higher in patients with NEAD than in those with epi-

lepsy, NEAD patients are paradoxically more likely to have an external locus of control in regard to health and to deny that psychological factors might contribute to their illness (J. Stone et al. 2004). Some patients have both epilepsy and nonepileptic attacks, but probably only about 10% of individuals with NEAD fall into this category (Benbadis et al. 2001; Reuber et al. 2002). Many of these patients are learning disabled and at increased risk of both epilepsy and psychiatric disorders.

The diagnosis of NEAD can often be made on the basis of a careful history and examination. Clinical clues include the presence of prior somatoform disorders; atypical varieties of seizure, especially the occurrence of frequent and prolonged seizures in the face of normal intellectual function and normal interictal EEG; a preponderance of seizures in public places, especially in clinics and hospitals; and behavior during an apparent generalized seizure that suggests preservation of awareness (e.g., resistance to attempted eye opening, persistent aversion of gaze from the examiner). Compared with patients with epilepsy, those with recent-onset NEAD are more likely to think that psychological factors are less important than somatic ones and have a greater tendency to deny nonhealth life stresses (J. Stone et al. 2004). Eye closure during the spell has been considered to be a reliable indicator that a spell is not epileptic (Chung et al. 2006), although this belief has been challenged (Syed et al. 2008). Previous childhood sexual abuse is common but not universal among those with the diagnosis (Binzer et al. 2004). When doubt remains after careful clinical assessment and standard investigations, the gold standard for diagnosis is observation of attacks during videotelemetry. A normal EEG during or immediately following an apparent generalized seizure also provides strong evidence for NEAD. However, surface EEG may be normal during focal seizures.

The diagnosis of NEAD is regarded as distinct from deliberate falsification of attacks (i.e., malingering or factitious disorder). The majority of patients will be cooperative with investigation and diagnosis, even when they know in advance that the purpose is to confirm NEAD and refute epilepsy (McGonigal et al. 2002).

Syncope

Syncope, usually due to temporary interruption of the blood supply to the brain, is often accompanied by myoclonic jerks that are frequently regarded as epileptic by lay and medical onlookers (Lempert et al. 1994). The occurrence of more complex movements, eye deviation, eyelid flicker, or vocalizations can confuse the diagnosis further, as can aura symptoms, which are recalled by the majority of subjects and which include epigastric, vertiginous, visual, and somatosensory experiences (Benke et al. 1997).

Sleep Disorders

Sleep disorders—including sleepwalking, night terrors, and confusional arousals, all of which occur during slow-wave sleep; REM sleep behavior disorder; and a variety of other parasomnias, including bruxism, rhythmic movement disorder, and periodic limb movements—must all be distinguished from epilepsy (see Chapter 15, “Sleep Disorders”).

Investigation of Seizures

Epilepsy is above all a clinical diagnosis, and the use and interpretation of tests should reflect this. Routine blood tests should include a complete blood count and routine chemistries, including serum calcium and magnesium. An electrocardiogram (ECG) should always be performed. An EEG is helpful in confirming the diagnosis and in clarifying the type of epilepsy (i.e., generalized versus focal, a distinction particularly relevant for children and adolescents). However, the EEG is insensitive: a single interictal EEG will detect clearly epileptiform abnormalities in only about 30% of patients with epilepsy. Therefore, a normal EEG does not exclude epilepsy, just as minor nonspecific abnormalities do not confirm it. Serial recordings, including sleep-deprived recordings, increase the diagnostic yield to around 80% (Chabolla and Cascino 1997). EEG can be supplemented with video recording to allow examination of the correlation between the clinical symptoms and the EEG abnormalities (videotelemetry). Twenty-four-hour ambulatory monitoring is sometimes helpful.

Some form of neuroimaging should be performed in all patients with epilepsy, unless EEG has clearly demonstrated a syndrome of primary generalized epilepsy in a young patient. CT is adequate to exclude tumors and major structural abnormalities and has the benefit of ease of access in most developed countries; however, CT may miss subtle pathologies. MRI is undoubtedly the imaging modality of choice, capable of detecting pathological abnormalities in up to 90% of patients with intractable epilepsy, including mesial temporal sclerosis (S.S. Spencer 1994). It can, however, be difficult to access in some countries.

Prolactin will rise after a generalized seizure but not, as a rule, after a nonepileptic attack. However, interpretation of the test requires knowledge of the basal prolactin and concurrent drug treatment (e.g., antipsychotics). Partial seizures and syncope can also elevate prolactin (Oribe et al. 1996; Pohlmann-Eden et al. 1997).

Additional cardiac investigations that may be helpful in selected cases include 24-hour ambulatory ECG to identify cardiac dysrhythmias; echocardiography, to identify structural cardiac abnormalities; and tilt-table testing, to help confirm orthostatic syncope.

Psychiatric Complications

Record-linkage studies (Bredkjaer et al. 1998; Jalava and Sillanpaa 1996) have reported an increase in psychotic symptoms, particularly schizophreniform and paranoid psychoses, in men but not women with epilepsy. Studies have also shown a fourfold increase in overall rates of psychiatric disorder in both men and woman with epilepsy compared with individuals in the general population but not compared with patients with other medical diagnoses.

Psychosis

Psychotic symptoms may be categorized as transient postictal psychosis and chronic interictal psychosis. Patients with transient postictal psychosis often present with manic grandiosity with religious and mystical features (Kanemoto et al. 1996b). A number of small studies have suggested that such patients are more likely than other epilepsy patients to have psychic auras, bilateral interictal spikes, and nocturnal secondarily generalized seizures (Devinsky et al. 1995). In general, psychotic episodes do not start immediately after a seizure, but instead occur after a lucid interval of 2–72 hours. In one study, patients with chronic interictal psychosis had a higher frequency of perceptual delusions and auditory hallucinations than did patients with postictal psychoses (Kanemoto et al. 1996a).

Transient psychosis was reported in 1% of patients following temporal lobectomy for epilepsy. Men with right-sided foci who were not seizure free after surgery appeared to be at particular risk for this symptom (Manchanda et al. 1993). There may be an increased risk of postictal psychoses in patients with temporal lobe epilepsy and hippocampal sclerosis (in comparison with those with temporal lobe epilepsy and no sclerosis) (Kanemoto et al. 1996b). How mesial temporal sclerosis relates to psychosis is unclear.

The work of Landolt in the 1950s drew attention to the occurrence of psychosis in some patients in whom epileptiform EEG abnormalities were normalized by treatment (“forced normalization”) (Krishnamoorthy and Trimble 1999; Landolt 1958). The concept remains controversial.

Psychosis is also a potential side effect of anticonvulsants, most frequently associated with levetiracetam and topiramate, but also with phenytoin, valproate, lamotrigine, zonisamide, pregabalin, and vigabatrin (Mula et al. 2003). This effect occurs more commonly in patients with a history of psychiatric illness.

Cognitive Disorders

Cognitive disorders are commonly associated with epilepsy (Hermann and Seidenberg 2007). Mild, generalized cognitive deficits, especially in memory, can be detected within months of onset; in children, academic records sug-

gest that these deficits may predate onset (Oostrom et al. 2003). Quantitative volumetric MRI studies suggest associations with temporal lobe abnormalities (Bonilha et al. 2004; Lawson et al. 2002; Woermann et al. 1999). The impairment can be progressive but is not inevitably so, and patients can be reassured that they will not progress to dementia. Poor seizure control and cumulative effects of medication appear to be risk factors for deterioration. The direct impairments can be compounded by the indirect effects of epilepsy on scholastic achievement.

Depressive and Anxiety Disorders

It is well established that epilepsy is a significant risk factor for depressive illness (Jalava and Sillanpaa 1996; Kanner and Balabanov 2002; Stefansson et al. 1998). Depression arising from learned helplessness may occur in patients with epilepsy as a consequence of repeatedly experiencing unpredictable and unavoidable seizures (Weigartz et al. 1999). The stress of having to live with a stigmatized chronic illness may also be relevant. Finally, the antiepileptic drugs used in the treatment of epilepsy can themselves be a cause of depression. The relationship between depression and epilepsy is bidirectional (i.e., each is a risk factor for the other). Depression is an independent risk factor for unprovoked seizures (Hesdorffer et al. 2000). This effect seems to be particularly marked for partial seizures. However, recent data from three population-based studies have also shown that depression is associated with a four- to sevenfold increased risk for developing epilepsy (Kanner 2006). This bidirectional relationship does not imply causality but rather suggests common pathogenic mechanisms shared by both conditions, including abnormal CNS monoamine activity; atrophy of temporal and frontal lobe structures; decreased 5-HT_{1A} binding in mesial structures, raphe nuclei, thalamus, and cingulate; and disruption of the hypothalamic-pituitary-adrenal axis (Kanner 2006). Depressive symptoms not only affect onset of epilepsy but also are associated with poorer response to treatment and reduced quality of life.

Depressive disorders can be typical of their DSM-IV-TR mood disorder description (Jones et al. 2005), can be characterized by their relationship to the ictal event, or can present as "interictal dysphoric disorder" (Kanner et al. 2000). The latter concept was used originally by Kraepelin and then Bleuler to describe a pleomorphic pattern of symptoms consisting of prominent irritability intermixed with euphoria, anxiety, anergia, insomnia, and pain. Interictal dysphoric disorder is said to have a chronic relapsing remitting course but to respond well to antidepressants. Similarly, anxiety in epilepsy may have a complex etiology (M.A. Goldstein and Harden 2000). Anticipatory anxiety related to having a seizure without warning can lead to agoraphobic-like symptoms and behavior.

Treatment of depressive and anxiety disorders in epilepsy is generally the same as that of anxiety and depression in the medically ill (Hermann et al. 2000; see also Chapter 8, "Depression," and Chapter 11, "Anxiety Disorders"). Increased seizure risks associated with specific psychiatric drugs are reviewed in Chapter 38, "Psychopharmacology." Care needs to be taken not to exacerbate the epilepsy, given that TCAs, but not SSRIs, can lower the seizure threshold (Alper 2007). However, this effect is often exaggerated, and, in general, undertreatment has caused far more problems than overtreatment. Similarly, the risk of seizures with bupropion has been overstated in many sources; a systematic review concluded that the risk was lower than that associated with TCAs (Ruffmann et al. 2006).

Treatment

The basic principles of epilepsy treatment are as follows:

1. Use a single drug whenever possible. The Standard And New Antiepileptic Drugs (SANAD) trial has provided additional data on the relative merits of commonly used drugs, with lamotrigine suggested as first-line treatment for focal seizures and sodium valproate for generalized seizures (Marson et al. 2007).
2. Increase the dose slowly until either the seizures are controlled or toxicity occurs.
3. If a single drug does not control seizures without toxicity, then switch initially to another drug used alone.
4. Drug-level monitoring is generally unnecessary except in the case of phenytoin and carbamazepine and is sometimes misleading: some patients do well with drug levels below or above the "therapeutic range."
5. Consider using two drugs only when monotherapy is unsuccessful.
6. Be aware that the metabolism of drugs may be different in the young, the elderly, pregnant women, and patients with chronic disease, particularly chronic hepatic and renal disease, and be on the lookout for drug interactions.

Approximately 20%–30% of patients do not achieve seizure control with drug therapy. In carefully selected cases, surgery can be dramatically effective. Most surgical series report seizure freedom in the range of 50%–85%. The criteria for selection generally include the presence of a focal lesion on neuroimaging, evidence from videotelemetry that the lesion is the source of the habitual seizures, and neuropsychological evidence that resection of the lesion should not cause major cognitive deficits. Psychological factors are also often relevant to the decision to perform surgery (see section "Neurosurgical Issues" later in this chapter).

Vagal nerve stimulation has been shown to reduce seizure frequency in some patients with refractory epilepsy (Privitera et al. 2007), but it probably is no more effective than the addition of the newer anticonvulsants to established therapy.

Tic Disorders

Tics are habitual spasmodic muscular movements or contractions, usually of the face or extremities that are associated with a variety of disorders.

Gilles de la Tourette's syndrome (GTS) is characterized by a combination of multiple waxing and waning motor and vocal tics. These vary from simple twitches and grunts to complex stereotypies. Premonitory sensory sensations in body parts that "need to tic" are a common feature and complicate the picture, because their temporary suppressibility lends them a voluntary component. Other features are echolalia and coprolalia, particularly in severe cases. GTS is strongly associated with OCD but many claim that it is qualitatively different from pure OCD, with greater concern with symmetry, aggressive thoughts, forced touching, and fear of harming oneself in OCD-GTS compared with a more frequent focus on hygiene and cleanliness in pure OCD. Depressive symptoms are common (Cavanna et al. 2009). The prevalence of GTS is about 5 per 10,000 population, with a male:female ratio of 4:1. A debate exists as to whether OCD in itself constitutes a specific psychopathological entity comorbid with GTS or whether diverse pathological disorders—including attention-deficit/hyperactivity disorder (ADHD), eating disorders, anxiety, and substance misuse—should also be considered part of the phenotype. This issue clearly has implications for genetic studies, which have suggested a strong hereditary component in the disorder. Similarly, the neurobiology of GTS remains elusive, with evidence supporting dysfunctions in dopaminergic basal ganglia circuitry receiving the most attention. Structural imaging findings in GTS are usually normal; functional imaging data are contradictory.

A syndrome known as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) has been proposed (Swedo et al. 1998), consisting of OCD accompanied by tics with abrupt onset or exacerbation associated with beta-hemolytic streptococcal infection (see Chapter 27, "Infectious Diseases") and the presence of anti-basal ganglia antibodies (ABGA). Studies finding ABGA in PANDAS, Sydenham's chorea, and GTS have excited interest in this area (Martino et al. 2007). However, there is continuing controversy regarding the status of PANDAS, with some studies suggesting that streptococcal infection is just one of many agents that can exacerbate tics (Shulman 2009).

Management of GTS is multidisciplinary, with clear need to address the educational, social, and family consequences of the disorder. Dopamine antagonists remain the mainstay of pharmacological management. Haloperidol has been the most widely used antipsychotic, but many authors advocate use of atypical antipsychotics on the basis of fewer extrapyramidal side effects. Of the newer antipsychotics, risperidone has attracted interest and sulpiride, (not available in the United States) is potentially useful (Scahill et al. 2003). Pimozide was shown to be superior to haloperidol in one of the few randomized controlled trials conducted, but potential cardiac side effects generally limit its use (Pringsheim et al. 2009). Tetrabenazine, a pre-synaptic monoamine depletor with postsynaptic blockade, has shown considerable efficacy in case series studies (Janjovic and Beach 1997), without a risk of dystonia or tardive dyskinesia but with a high risk of depression. Clonidine is used widely in the United States, but in the United Kingdom its use is generally restricted to patients with comorbid ADHD symptoms (Leckman et al. 1991). Deep brain stimulation is an emerging treatment for severe GTS, although it carries the usual risks of functional neurosurgery and as yet has not been proven in a sham-controlled trial (Servello et al. 2008). Behavioral treatments including habit reversal have also shown promise (Wilhelm et al. 2003). In establishing treatment priorities, one should bear in mind that the associated OCD and ADHD symptoms probably cause more functional and educational disability than the tics themselves. For many patients, tics are only a problem because of the attitudes of others.

Dystonias

The dystonias are a group of disorders characterized by involuntary twisting and repetitive movements and abnormal postures. The traditional clinical categorization is based on age at onset, distribution of symptoms, and site. Early-onset dystonia often starts in one limb, tends to generalize, and frequently has a genetic origin. By contrast, adult-onset dystonias usually spare the lower limbs, frequently involve the cervical or cranial muscles, and have a tendency to remain focal. They appear sporadic in most cases. Dystonias tend to improve with relaxation, hypnosis, and sleep. With the exception of cervical dystonia, pain is uncommon. Erroneous attribution of dystonia to a psychogenic cause was common because of the fluctuating nature of the symptoms, their often dramatic appearance, the ability of patients to use "tricks" to suppress them, and their association with task-specific symptoms (e.g., writer's cramp) (Eldridge et al. 1969). Dystonic movements may, however, be seen as the presentation of a conversion disorder. Psychogenic dystonia typically presents with a fixed

posture, usually a clenched fist or inverted plantar-flexed foot (Schrag et al. 2004).

Generalized dystonia is associated with an expanding range of largely autosomal dominant genetic mutations (Geyer and Bressman 2006). The most common generalized dystonia is *primary torsion dystonia*, caused by a mutation in the *DYT1* gene. This usually begins in childhood in one limb and then generalizes to other body parts.

Focal dystonia is the most prevalent form. It starts in adulthood and usually remains localized (e.g., as an isolated torticollis [focal cervical dystonia], writer's cramp, blepharospasm, and musician's dystonia). The majority of cases are sporadic, although some family pedigree studies have shown an increased risk of focal dystonias in other family members.

Dopa-responsive dystonia is characterized by childhood onset, diurnal fluctuation of symptoms, and a dramatic response to L-dopa therapy. It may be confused with spastic paraparesis, leading to diagnostic delay. It generally has autosomal dominant inheritance associated with a mutation in the *DYT5* gene, although recessive forms associated with mutations in the tyrosine hydroxylase gene have been described (Clot et al. 2009).

It is important to remember the role of exposure to medications (e.g., antipsychotics, antiemetics) in the development of both acute and tardive dystonias (R.A. Sweet et al. 1995).

Medical treatment involves botulinum injections, oral drugs, and potentially neurosurgery. Botulinum therapy (both type A and type B) is more effective than placebo for focal dystonias such as cervical dystonia or writer's cramp (Kruisdijk et al. 2007; Snaith and Wade 2008). In generalized dystonia, a trial of L-dopa should be considered in all early-onset cases, given the possibility of dopa-responsive dystonia. Thereafter, oral drug treatment can be tried, although effects are usually disappointing. High-dose anticholinergics such as benhexol can be of some effect. Occasionally, combination treatment with baclofen, tetrabenazine, and a dopamine antagonist can be considered. Surgical treatment can involve selective peripheral denervation or deep brain stimulation (Kupsch et al. 2006). Comorbid psychiatric disorders are commonly associated with dystonias, particularly OCD, panic disorder, and depression, and they should be actively treated in their own right.

Headache

Acute Headache

Headache of abrupt onset that is very severe and prolonged can be due to *subarachnoid hemorrhage*, usually from a ruptured aneurysm, or to migraine, meningitis, or other cra-

nial infection such as otitis media or sinusitis. The diagnosis of subarachnoid hemorrhage is suggested by the rapidity of onset ("thunderclap" headache, at its worst within 1 minute or so) and associated loss of consciousness, photophobia, vomiting, and neck stiffness. A headache with these features requires immediate neurological referral for assessment with CT scan (which reveals subarachnoid blood in the majority of cases) and lumbar puncture, when CT is negative, to examine for xanthochromia (which is reliably present from 12 hours after subarachnoid hemorrhage) (Al-Shahi et al. 2006). Psychiatrists are predominantly involved in the management of the associated brain injury following subarachnoid hemorrhage. (For a further discussion of these management principles, see the section "Stroke" earlier in this chapter and Chapter 35, "Physical Medicine and Rehabilitation.")

Migraine can mimic subarachnoid hemorrhage. The diagnosis is usually suggested by a history of more typical intermittent headaches with evolving prodromal visual (or other focal neurological) disturbance and a hemicranial throbbing headache, worse on exercise, with photophobia and nausea or vomiting. *Meningitis* is suggested by a severe headache, usually worsening over hours, with photophobia, nausea, and neck stiffness in association with fever and other features of infection. There are many other causes of acute headache, such as spontaneous intracranial hypotension and venous sinus thrombosis.

Chronic Headache

Headache is an almost universal experience (see also Chapter 36 "Pain"). The exhaustive International Headache Society classification of headaches is available free online (<http://ihs-classification.org/en/>). *Migraine with aura* (previously classical migraine) has the features described above. In migraine without aura (previously common migraine), there is a throbbing hemicranial in the absence of focal neurological symptoms such as visual disturbance. *Tension-type headache* is familiar to most of us as a global headache, usually of mild to moderate severity, sometimes with a "bandlike" or pressing quality. It often worsens as the day goes on or following stress and has few associated symptoms. *Chronic tension-type headache*, defined as more than 15 headache days per month, is just one cause of chronic daily headache (CDH). Most patients with CDH have underlying migraine, which is frequently made worse by *analgesic overuse headache*. Prolonged exposure to any analgesic (not just opiates or ergotamine) can lead to overuse headache; analgesic withdrawal often results in improvement, although this must be done with careful explanation to the patient (Weatherall 2007). Thus, it is important in CDH to assess how much of the problem is migraine versus tension-type headache versus analgesic overuse headache.

A large literature has shown a close, probably bidirectional, association between CDH and psychiatric comorbidity, especially depression and anxiety (Hamelsky and Lipton 2006). The presence of psychiatric comorbidity is associated with poorer outcome. CDH is indicative of the need for more sophistication in our approach to understanding the complex interactions between brain biology, psychological processes, and behavioral responses. Treatment of comorbid mood disorders with antidepressants and CBT can be helpful (Kroenke and Swindle 2000).

Patients with chronic migraine headaches have often been described as having a “typical” personality characterized by conscientiousness, perfectionism, ambitiousness, rigidity, tenseness, and resentfulness; however, controlled studies have not consistently supported this profile. Specific personality traits in migraine appear more likely to be a consequence rather than a cause of suffering from recurrent headaches (Pompili et al. 2009). A community-based survey found more neuroticism and 2.5 times more psychological distress in migraine sufferers than in matched control subjects, but there was no relationship between headache frequency and the severity of psychological distress or personality abnormality (Brandt et al. 1990; Breslau et al. 2003).

Cervicogenic headache is strictly defined by the International Headache Society as headache arising from clearly defined pathology such as tumors, fractures, infections, and rheumatoid arthritis. Cervical spondylosis is a normal feature of aging and cannot be deemed a cause of cervicogenic headache. *Temporal arteritis* is a disorder of older people (it is very rare in persons younger than 55 years) that causes scalp pain and tenderness, jaw claudication, malaise, and an elevated erythrocyte sedimentation rate (usually >50 mm/hour). Treatment with corticosteroids should be started immediately and arrangements made for confirmatory temporal artery biopsy. *Raised intracranial pressure* typically causes a headache that is worse on lying down (and can be relieved by standing), disturbing sleep and present in the mornings. The pressure eventually causes nausea and vomiting and, if brain stem compression occurs, a progressive reduction of consciousness. The raised pressure can result from space-occupying lesions (e.g., tumors, subdural hematomas), hydrocephalus, or idiopathic intracranial hypertension. The typical features of raised intracranial pressure (i.e., headache, ataxia, drowsiness, confusion, coma) are not always present. If they are, or if headache is associated with papilledema or focal neurological signs, a CT scan should be obtained urgently. *Low CSF volume headache* is an increasingly well-recognized syndrome with features inverse to those of the headache of raised intracranial pressure: the headache comes on after getting up and is relieved by lying down. This type of headache is often iatrogenic

(e.g., following lumbar puncture), but it can also occur as a result of spontaneous CSF leaks.

Certain “headaches” are felt mainly in the face. *Cluster headache*, a rare type of headache that is more common in young men, gives rise to severe retro-orbital pain occurring in bursts lasting an hour or so, that recur over a period of days to weeks (the “cluster”). The headache often wakes the sufferer in the middle of the night and usually makes him or her extremely restless (in contrast to migraine, which sends sufferers to their beds) (Matharu and Silver 2008). *Trigeminal neuralgia* causes stabs of lancinating pain in one of the three divisions of the trigeminal nerve (Graff-Radford 2000). *Atypical facial pain* is a diagnosis of exclusion, the facial equivalent of chronic daily headache.

Somatoform and Conversion Disorders in Neurology

Somatic symptoms unexplained by neurological disease are commonly encountered in neurological practice and may be diagnosed as somatoform disorders. Other names include medically unexplained symptoms, psychogenic disorders, and functional disorders. DSM-IV and its text revision DSM-IV-TR use the term *somatoform disorders*, although patients may prefer the term *functional disorders* (J. Stone et al. 2002).

Conversion disorder is regarded as a subgroup of somatoform disorders. The term is reserved to describe patients with motor and/or sensory symptoms or blackouts that suggest a neurological or other general medical condition but in whom no such condition is found by appropriate examination and investigation. DSM-IV-TR also requires that the psychological factors be judged to be associated with the symptoms because their initiation or exacerbation is *preceded by* conflicts or other stressors. This requirement is controversial, as its theoretical basis is unconfirmed. Furthermore, because psychological factors are common in all neurological presentations, the requirement is non-specific and likely to be unreliable. Common conversion symptoms include paralysis, weakness, seizures, anesthesia, aphonia, blindness, amnesia, and stupor. Conversion disorder is also discussed in Chapter 12, “Somatization and Somatoform Disorders.” (The epidemiology and clinical features of nonepileptic attacks were discussed earlier in this chapter under “Epilepsy.”)

Epidemiology

Neurological symptoms in the absence of neurological disease or disproportionate to disease are observed in approximately one-third of patients attending neurological clinics (Carson et al. 2000b). Conversion weakness and paralysis

have an incidence of at least 5 per 100,000 (Binzer and Kullgren 1998), a rate similar to that of multiple sclerosis. In less than half of patients do the symptoms remit spontaneously (Carson et al. 2003; Sharpe et al. 2010). Early expectation of nonrecovery, nonattribution of symptoms to psychological factors, and receipt of health-related benefits at the time of the initial consultation predict poorer outcome (Sharpe et al. 2010).

Clinical Features

A careful history is essential to diagnosis, first concentrating on the somatic symptoms, and only then exploring psychological and social factors. In considering the diagnosis, particular attention should be paid to the presence of multiple somatic symptoms (multiple symptoms make a somatoform disorder more likely), depression or anxiety (particularly panic), and a history of previous functional symptoms or of multiple surgical operations in the absence of organic pathology (Barsky and Borus 1999). Childhood abuse and neglect, personality factors, recent stressful life events, secondary gain (financial or otherwise), and strong beliefs about the causation may all be relevant to management, but these factors occur in all kinds of disease, and their presence does not allow one to infer a diagnosis of conversion disorder (J. Stone et al. 2005a).

At onset, patients with conversion weakness will often describe symptoms suggestive of depersonalization or derealization at the time of onset. These symptoms may be associated with a panic attack, physical trauma (often minor), or unexpected physiological events (e.g., postmicturition syncope, sleep paralysis) (J. Stone et al. 2009a).

The neurological examination has a crucial role in diagnosis of conversion disorder. Because of the difficulties in relying on features in the history, the diagnosis must usually be made in the presence of positive physical signs of internal inconsistency or marked incongruity with recognized neurological disorder. Helpful signs include Hoover's sign (Ziv et al. 1998), collapsing ("giveaway") weakness, and co-contraction (Knutsson and Martensson 1985), although none of these should be interpreted in isolation, as there may be false positives. A conversion tremor typically demonstrates variable frequency, marked attenuation with distraction, and entrainment (where the frequency entrains to a contralateral limb voluntarily making a 3- to 4-Hz movement). *Fixed dystonia* is a term used to describe the sustained posture of a limb, usually a clenched hand or a plantar-flexed inverted foot (Hallett et al. 2005; Schrag et al. 2004). Further evidence that an abnormality represents a conversion symptom must come from improvement after hypnosis, sedation, or placebo. There are many tests of visual conversion symptoms (S. Beatty 1999). The finding of

a tubular visual field deficit at the bedside or of spiral fields on perimetry testing is suggestive. All of these signs should be demonstrated to patients in a collaborative, rather than confrontational, manner (J. Stone et al. 2005b).

Pathology and Etiology

The etiology of conversion disorder remains unknown, and there is value in remaining neutral about the relative contributions of biological, psychological, and social factors. In particular, one should be aware that although Freudian theory portrays conversion disorder as a mechanism for dealing with unconscious conflict and traumatic experience, this model can only be applied to some patients. Functional imaging studies (J. Stone et al. 2007; Vuilleumier et al. 2001) and neurophysiological investigations (Espay et al. 2006) have yielded intriguing results. The psychological and social risk factors for conversion disorder are similar to those for other somatoform disorders, as described in Chapter 12, "Somatization and Somatoform Disorders."

Investigation and Differential Diagnosis

Further imaging or neurophysiological testing may be required, depending on the symptoms present, but ultimately the diagnosis should be made at the bedside, not on the basis of normal test results. Diagnostic error has been a cause for concern for psychiatrists, although a systematic review of 27 studies found that the error rate since 1970 has been on average 4%. This is equivalent to the diagnostic error rates for most neurological and psychiatric conditions (Carson et al. 2003; J. Stone et al. 2005c, 2009b). Misdiagnosis may be more common in the presence of known psychiatric comorbidity, in patients with gait and movement disorders, and in patients who have not seen a neurologist. Although clinicians tend to worry about missing "organic" disease and therefore are often very conservative in making a diagnosis of conversion disorder, available evidence suggests that the reverse problem, misdiagnosing conversion disorder as "organic" disease, is more common, leading to iatrogenic complications of unneeded treatment and invalidism (Fink 1992; Nimnuan et al. 2000).

Management

The basis of treatment is an explicit acceptance of the reality of the symptoms and a nonstigmatizing, positive explanation of the diagnosis that emphasizes the potential reversibility of the problem. Explanation about how the diagnosis has been made and why this indicates the absence of neurological disease is likely to be more successful than simple reassurance alone (J. Stone et al. 2005b). Dismissing

the symptoms as “nothing wrong” risks antagonizing or humiliating the patient and is rarely a good basis for collaborative management. Neurologists and psychiatrists need to work closely together for effective management of these patients. Neurologists who make the diagnosis need to be consistent in their explanations with the psychiatrists to whom they refer patients. Psychiatrists, for their own part, need to understand the positive basis on which the diagnosis has been made—first, to reduce their own uncertainty about the diagnosis, and second, so that they can explain this rationale to the patient. Only after the patient and doctor are reasonably satisfied that the diagnosis is correct can further treatment continue. In our own experience, conceptualizing the symptoms as functional symptoms—a problem with the functioning of the nervous system, in distinction to a structural disorder—works both theoretically and practically with patients (Sharpe and Carson 2000). The alternative approach of attempting to persuade patients that their symptoms are psychogenic or a manifestation of somatization is a more difficult route.

There is evidence for moderate effectiveness of antidepressant drugs, particularly TCAs, in other somatic symptom syndromes, with an odds ratio for improvement of 3.4 compared with placebo, regardless of the presence of depression (O'Malley et al. 1999), but unfortunately there are no studies of antidepressants in conversion disorder. A critical review of controlled trials evaluating the efficacy of CBT in patients with somatic symptom syndromes found that CBT-treated patients improved more than control subjects in 71% of the studies (Kroenke and Swindle 2000). Although studies of other treatment approaches are promising (Reuber et al. 2007; Ruddy and House 2005), there is little randomized evidence. Patients with physical disabilities need physical treatments like physiotherapy. There may be a role for hypnosis or therapeutic sedation in some conversion syndromes, especially those involving fixed dystonia (see Chapter 12, “Somatization and Somatoform Disorders,” for further discussion of management).

Neurosurgical Issues

Many of the psychiatric issues arising in neurosurgical settings are described in other chapters in this book. Of particular relevance are Chapter 5, “Delirium”; Chapter 35, “Physical Medicine and Rehabilitation” (which discusses brain injury); and Chapter 36, “Pain.” High doses of corticosteroids are used by neurosurgeons to reduce elevated intracranial pressure; the psychiatric adverse effects of corticosteroids are reviewed in Chapter 25, “Rheumatology.” Mood disorders are frequent after neurosurgery, and their assessment should be guided by the discussion in the earlier sections of this chapter, particularly the section on stroke.

Central Nervous System Tumors

Psychiatric aspects of cancer are reviewed in Chapter 23, “Oncology.” Psychiatrists generally become involved in neuro-oncology cases after tumor diagnosis, when the clinical issues are adjustment, mood disorder, or cognitive impairment. Patients with primary and metastatic CNS tumors typically present with headache, focal neurological signs, or seizures, but these tumors can also cause cognitive impairment, and occasionally their presentation mimics a dementing illness (Lishman 1997). Some brain tumors initially manifest with predominantly psychiatric symptoms, including depression, panic attacks, psychosis, disordered eating, and personality change. CT scanning should reveal their presence, although diffusely infiltrating tumors are sometimes missed in the early stages.

Hydrocephalus

Hydrocephalus is caused by dilatation of the ventricles within the brain resulting from elevation of CSF pressure. Hydrocephalus is termed *communicating* when the blockage to CSF flow is outside the ventricular system, *noncommunicating* when the blockage is within the ventricles. In “compensated” hydrocephalus, the clinical signs and CSF dynamics stabilize at an elevated level of CSF pressure. Normal-pressure hydrocephalus (NPH) describes ventricle enlargement with normal CSF pressure, possibly as the result of persistent elevation or intermittent surges of high pressure.

Clinical Features

Hydrocephalus can cause a wide range of psychiatric symptoms and signs. These include enlargement of the head (if present in infancy), depression, headache, sudden death due to “hydrocephalic attacks” with acute elevation of intracranial pressure, progressive visual failure, gait disturbance (often “gait apraxia”), incontinence, and subcortical cognitive impairment progressing to dementia. NPH in older individuals is classically associated with the triad of gait apraxia, incontinence, and cognitive decline. However, this triad is not specific for NPH and may occur in vascular dementia or other degenerative diseases.

Diagnosis

In younger persons, the radiological signs of hydrocephalus are usually clear-cut on CT scanning. This may also be the case in some elderly patients, but in other older patients apparent hydrocephalus is often due to *ex vacuo* atrophy of the subcortical white matter. The presence of easily visible cortical sulci should alert the clinician to this possibility. When enlargement of the ventricles raises a suspicion of communicating hydrocephalus in an older

person, determination of whether the scan appearance is relevant to the clinical problem requires specialized studies—usually either serial lumbar punctures with observation of the clinical effects or neurosurgical studies of CSF pressure. However, there is no one test that can confirm a diagnosis of NPH or predict response to shunting, which means that appropriate investigations for NPH are controversial (Shprecher et al. 2008). Ultimately, only the insertion of a shunt can reliably determine whether a patient will benefit from shunting.

Management

Shunting of hydrocephalus—diversion of CSF from a CSF space to the venous system or peritoneum—can be beneficial in the long term (Pujari et al. 2008). However, the procedure is prone to complications—including subdural hematoma and shunt infection—in nearly half of patients (Hebb and Cusimano 2001) and thus should not be undertaken lightly.

Subdural Hematoma

Subdural hematoma is caused by accumulations of blood and blood products in the space between the fibrous dura mater and the more delicate arachnoid membrane that encloses the brain. Acute subdural hematomas accumulate rapidly following head injury; chronic hematomas can often (although not always) be traced back to a head injury.

Clinical Features

Acute subdural hematomas are, by definition, diagnosed close to the time of trauma, as a result of symptoms present at the time—headache, depressed level of consciousness, focal neurological signs—or seen on CT scan. Chronic subdural hematomas give rise to more gradually evolving symptoms and signs. Although they also can cause headache, depressed consciousness, and focal signs, chronic subdural hematomas sometimes result in predominantly cognitive features, including confusion and dementia, which can be reversed with surgery (Ishikawa et al. 2002). Marked variability of the mental state, and sometimes also of the neurological features, is often a clue to the diagnosis. Seizures can occur. Both acute and chronic subdural hematomas are especially common in alcoholic individuals, who frequently do not recall having experienced head trauma (Selecki 1965).

Pathology

The variability of the clinical features is explained by the tendency of the size of a chronic subdural hematoma to wax and wane as a result of alternating phases of bleeding and of breakdown of the contents of the hematoma (McIn-

tosh et al. 1996). Subdural hematomas exert their effects both by local compression and irritation of adjacent cortical tissue and by global “brain shift” (with the risk of brain herniation and secondary brain stem compression).

Investigation and Differential Diagnosis

Subdural hematomas can generally be diagnosed on CT scanning. They are occasionally of the same density (“isodense”) as adjacent brain tissue and therefore easily missed, especially if bilateral (Davenport et al. 1994). It is important to recognize that a small subdural hematoma can be an incidental finding; for example, cerebral atrophy occurring in the course of a dementing illness predisposes to subdural hematoma as vulnerable bridging veins are stretched between the dura and the arachnoid. In these circumstances, treatment of the subdural hematoma is unlikely to be helpful.

Management

Management requires liaison with a neurosurgical team. Small subdural hematomas often resorb spontaneously. If a subdural hematoma is considered to be relevant to a patient’s problems and drainage is required, several surgical approaches are available. Reaccumulation is more likely for bilateral subdural hematomas and for subdural hematomas in patients receiving antiplatelet therapy (Tori-hashi et al. 2008).

Subarachnoid Hemorrhage

Severe, prolonged headache of abrupt onset can be due to a subarachnoid hemorrhage, usually arising from a ruptured berry aneurysm. A diagnosis of subarachnoid hemorrhage is suggested by the rapidity of onset (“thunderclap” headache, at its worst within a minute or so) and associated loss of consciousness, photophobia, vomiting, and neck stiffness (Al-Shahi et al. 2006). Psychiatrists are rarely involved in the diagnosis of subarachnoid hemorrhage but are frequently asked to evaluate patients in the postacute phase, as for stroke. In the first 21 days after a subarachnoid hemorrhage, one-third of patients may develop a fluctuating clinical course due to cerebral vasospasm. CT perfusion is a promising technique to monitor this condition (Wintermark et al. 2006). Symptoms and signs vary according to the territory affected, but variable akinetic mutism is particularly common in patients with vasospasm after an anterior cerebral artery aneurysmal hemorrhage.

Fitness for Surgery

Psychiatrists may be requested to assess patients for fitness for neurosurgery. Such requests occur most commonly for patients with epilepsy and with Parkinson’s disease. A gen-

eral assessment of capacity (see Chapter 2, "Legal Issues") and consideration of specific issues relevant to the operation in question are required, necessitating special attention when the operation is considered investigational.

Epilepsy Surgery

A psychiatric opinion should be sought prior to surgery if there are significant associated behavioral or social problems. Such problems include anticipated noncompliance with medication, severe personality disturbance, psychosis, severe mood disorder, unrealistic expectations of surgery, and an absence of social support. The presence of mental retardation is not an absolute contraindication to surgery but can complicate postsurgical care (Sperling 1994). The most commonly performed procedures are temporal lobectomy and amygdalohippocampectomy. Other procedures include extratemporal cortical resections, hemispherectomy, and white matter transections, including corpus callosotomy (Engel 1993). Approximately two-thirds of patients will become seizure free after surgery. Mortality is extremely low, and the rate of neurological complications has dropped significantly over the past few years, with hemiparesis now being exceptionally rare (S. Spencer 2008). Reported rates of complications after temporal lobectomies range from 0.4% to 4%, including partial hemianopsia, aphasia, and cranial nerve palsies (S. Spencer 2008). Cognitive changes—in particular, a decline in verbal memory—are reported in about one-third of patients (S. Spencer 2008). The likelihood of a new mood disorder is most closely related to preexisting mental state and whether the patient becomes seizure free (S. Spencer 2008). De novo development of psychosis is recognized, but the risk factors for its development are not (S. Spencer 2008). It is noteworthy that poor psychological outcomes occasionally accompany good postoperative seizure control, and some patients need considerable psychological help in adjusting to life without seizures (Vickrey et al. 1993).

Parkinson's Disease Surgery

Neurosurgery for Parkinson's disease is an evolving field. A number of different surgical interventions have been suggested (Olanow 2002), most of which can cause psychiatric complications (e.g., corticobulbar syndromes and psychic akinesia after bilateral pallidotomy) (de Bie et al. 2002; Merello et al. 2001). Subthalamic nucleus deep brain stimulation (STN DBS) appears the most promising technique (Deuschl et al. 2006). STN DBS is an effective treatment for motor symptoms in advanced Parkinson's disease; however, neurobehavioral side effects are relatively common and include executive impairments, delirium, depression, mania, hallucinations, and impulse-control disorders

(Meagher et al. 2008). However, there is little evidence of any consistent effect of STN DBS in causing neuropsychiatric disturbance, although numerous study biases in terms of disease progression, medication effects, and control group selection may be influencing reporting. At the time of writing, it does seem likely that STN DBS is associated with significant neuropsychiatric complications, but how common they are is far less certain.

Conclusion

The practice of psychiatry in a neurological or neurosurgical setting is both challenging and rewarding. One of the challenges is the often complex task of determining the relationship between comorbid neurological and psychiatric symptoms. In this chapter we have outlined general principles of assessment and management in relation to the more commonly encountered conditions. These same principles apply to the more rarely encountered problems. Working closely with colleagues who share an interest in disorders of the brain can be very rewarding, and new developments in neuroscience are providing a greater understanding of the mechanisms by which biological, psychological, and social factors interact to cause both neurological and psychiatric illness. Consequently, the interface between these specialties is rapidly becoming one of the most intellectually fascinating areas of work for the specialist in psychosomatic medicine.

Obstetrics and Gynecology

Donna E. Stewart, M.D., F.R.C.P.C.

Simone N. Vigod, M.D., F.R.C.P.C.

Nada Logan Stotland, M.D., M.P.H.

UNDERSTANDING OF WOMEN'S mental health is incomplete without consideration of the social context of their lives and reproductive factors across the life span. Traditionally, medical research has not taken sex differences into account when explaining behavior and illness nor when investigating treatment. However, the care of female patients requires an understanding not only of the biological substrates of reproduction and the nature of obstetric and gynecological diseases and treatments but also of the psychological considerations and social contexts at each stage of the reproductive life cycle. The interface between psychiatry and obstetrics and gynecology presents an important opportunity to understand the interaction between the two fields. Psychiatrists have a role in enhancing the care delivered by obstetricians and gynecologists, particularly as these specialists usually receive little training in mental health.

This chapter reviews a variety of topics relevant to reproductive psychiatry from a biological, psychological, and social perspective: gender identity, fertility, contraception, sterilization, hysterectomy, abortion (both spontaneous and induced), chronic pelvic pain, premenstrual mood disturbance, psychiatric disorders during pregnancy and postpartum, menopause, and urinary incontinence. Eating disorders are covered in Chapter 14, and cancers in women are discussed in Chapter 23.

It is important to note that some of the phenomena described in this chapter vary by culture and sexual orientation. Most research findings are derived from presumably heterosexual women in North America and Europe. Lesbian women, an often-neglected minority group, may be reluctant to seek health care because they fear or have ex-

perienced disapprobation and misunderstanding and may therefore suffer adverse health outcomes. Psychiatrists can help gynecologists and other primary care physicians to phrase questions about sexual orientation and activity in nonjudgmental terms. When possible, this chapter highlights some important considerations for treatment of women in often-overlooked minority groups, including immigrants and refugees. Unfortunately, it is beyond the scope of this chapter to address global variations in presentations and care.

Gender Identity

The first question about a newborn (or fetus) is whether it is a boy or girl, a determination made on the basis of the external genitalia. Ambiguous genitalia cause consternation; physicians and parents must decide whether to live with the ambiguity or assign the child to one gender or the other. Some believe that gender assignment should be made and carried out as early as possible so that the child can grow up with a clear gender, and others think that the child should be left as born and allowed to make a personal gender assignment when of age. Reproductive organs are the first defining feature of each human being, and gender remains a core aspect of identity throughout life. Sex hormones influence not only physical development and a host of physiological functions but also brain structure and activity. Environmental factors influence developing anatomy and ongoing physiology. A lifelong active interplay occurs among genetics, anatomy, physiology, social influences, and individual psychology.

The term *sex* refers to narrowly defined biological characteristics. The term *gender* includes social roles and an individual's sense of femininity or masculinity. Some evidence indicates that girls are aware of their sexual organs and identity as early as toddlerhood. As puberty approaches in females, the sense of gender identity is powerfully reinforced and reshaped by society and by physical changes: the development of breasts and pubic hair and the onset of menstruation. In some cultures, girls are told at menarche that they are now women. With menarche comes fertility and the possibility that sexual activity will lead to pregnancy. Although girls can be sexually abused at any age, the possibility of rape is more overt after puberty, and vulnerability to attack becomes part of gender identity. The possibility of pregnancy can be at once a worry and a wish. A young woman may feel that she is not truly a woman until she has had heterosexual intercourse or until she has borne a child. Girls who feel sexual attraction for other girls face a crisis in gender identity because society increasingly expects them to date, form relationships, and engage in sexual activity with males. Medical problems that interfere with any of these functions threaten core gender identity.

Infertility

A common definition of infertility is 12 months of appropriately timed unprotected intercourse that does not result in conception. However, a shorter time (6 months) is often used in women older than 35 years because the nature of fertility at this age makes it desirable to initiate diagnosis and treatment as soon as possible. The World Health Organization has reported that between 8% and 12% of couples, or approximately 50–80 million people worldwide, experience some type of fertility problem during their reproductive lives (World Health Organization Programme of Maternal and Child Health and Family Planning Unit 1991). A more recent study found an overall prevalence of infertility of 9% across countries (Boivin et al. 2007). In the United States, it has been estimated that 7.4% of married couples, or 2.1 million married women of childbearing age, have a fertility problem (Chandra et al. 2005). Although the popular impression is that the prevalence of infertility has risen over the past few decades, the rate of infertility has remained relatively stable since 1965 (Keye 1999). Rather, the use and availability of medical services, as well as willingness to disclose and public awareness of infertility treatment options, have increased (Burns and Covington 1999; Keye 1999).

As much as 40% of the time, infertility may be attributable to multiple causes (i.e., a combination of multiple male and female factors), and up to 10% of the time, the

etiology remains completely unexplained. Historically, infertility that could not be explained on an organic basis was thought to be “psychogenic,” related to ambivalence about becoming a parent, unconscious repudiation of femininity and motherhood, unconscious fears and conflict about sex, and wishes to remain dependent. However, these themes were based on psychoanalytic case reports and have been shown to be present in women with no trouble conceiving (Apfel and Keylor 2002). Thus, the focus of research on the relationship between mental health and fertility has shifted toward exploration of the biological, psychological, and social factors that mediate psychiatric illness or psychological distress in couples with infertility. This research suggests that the relationship between fertility and mental health is complex. Practitioners must take into account the stresses of infertility itself, with the associated investigations and treatment, as well as how psychiatric morbidity may influence fertility and the outcomes of fertility treatments (Williams et al. 2007).

Scope of Psychiatric Illness Affecting Couples With Infertility

Infertility is experienced as stressful, with 50% of women and 15% of men undergoing infertility diagnosis or treatment ranking it the most stressful event of their lives (Freeman et al. 1985). Although some studies show that women with infertility are distressed but do not meet criteria for a major psychiatric disorder, some studies reveal rates of major depressive disorder in infertile women that reach 50%, with anxiety disorders reaching 40% (Chen et al. 2004; Lukse and Vacc 1999; Ramezanzadeh et al. 2004). In a survey of 980 members of an infertility support group, 1 in 5 women reported suicidal feelings (despite the fact that approximately 50% had conceived by the time of the survey) (Kerr et al. 1999). Also, there are sex differences in the scope of psychiatric illness, with men reporting more symptoms of anxiety and depression than men in the general population (but far less than their female counterparts) (Volgsten et al. 2008). Although there is evidence to suggest that women become more depressed with every failed cycle of assisted reproductive technology treatment, successful conception may reduce depression scores (Verhaak et al. 2005, 2007).

Factors Mediating Psychiatric Illness in Couples With Infertility

Biological factors related to infertility that may impact mental health include the cause and duration of infertility, as well as the effects of fertility treatment. There is evidence that the difference in psychological profile between fertile and infertile couples increases with time. Ramezanzadeh et al. (2004) found scores on the Beck Depression Inventory

increasing up to 9 years of infertility and that there is more distress when the cause is unexplained. Interestingly, men show greater distress and guilt when the infertility is attributable to male-factor etiology, but women are equally distressed regardless of the cause (Volgsten et al. 2010). Although the reasons for this sex difference have not been investigated, this may be a reflection of the association of fertility with virility, the social expectation on women for conception and delivery of a baby, and the pervasive shame associated with infertility.

Fertility treatments themselves may have adverse effects on mental health. Interventions can be time-consuming, embarrassing, and invasive. The psychological effects, particularly mood alterations, of fertility-enhancing drugs are underappreciated. Careful attention should be paid to the potential contribution of recent changes in drug regimens to recent-onset psychiatric symptoms such as depression, anxiety, mania, and psychosis (Choi et al. 2005). Progesterone is often used for luteal phase abnormalities of the endometrium and can cause depression, insomnia, and somnolence. Clomiphene induces follicle-stimulating hormone (FSH) and has been associated with anxiety, insomnia, and psychosis (related to ongoing treatment or upon discontinuation of treatment) (Burns 2007).

Both intrauterine insemination (IUI) and in vitro fertilization (IVF) are associated with multiple gestations, which often cause maternal and fetal problems. Maternal complications include significant increases in cardiac morbidity, hematological morbidity, amniotic fluid embolus, pre-eclampsia, obstetric intervention, hysterectomy, and blood transfusion (Walker et al. 2004). Preterm birth is very common in multiple gestations and may be associated with cerebral palsy and other long-term infant sequelae that may cause psychological stress to the whole family (Walker et al. 2004).

Psychological factors play an important role. Becoming a parent is a lifelong fantasy and is experienced as a developmental need for many women. Women experience anger, a sense of loss of control, and reduced self-esteem. Self-blame increases risk of depressive illness (Morrow et al. 1995). Guilt may manifest with respect to being the cause of the infertility (e.g., older age because of choice to establish a career, prior sexually transmitted infection) or from upsetting spouses and disappointing families. Important social factors include gender roles, marital expectations, and familial and societal attitudes (Dyer et al. 2004; Matsubayashi et al. 2004).

Effect of Psychiatric Illness on Fertility

The current understanding is that psychiatric illness may impact fertility directly through mechanisms related to chronic stress, altered immune responses, and hormonal

changes, as well as indirectly through changes in behavior such as smoking, alcohol, poor nutrition, and lack of exercise. Eating disorders (anorexia nervosa, bulimia nervosa, obesity) are all associated with infertility. Restrictive or purging eating behaviors are often undisclosed and result in subfecundity and poor pregnancy outcomes (Stewart and Robinson 2001a). It is also important to consider the impact of psychotropic medications on fertility. For example, selective serotonin reuptake inhibitors (SSRIs) have been shown to be associated with a small but increased risk of early miscarriage, valproic acid is associated with polycystic ovarian syndrome (see Chapter 22, "Endocrine and Metabolic Disorders"), and many antipsychotic medications are associated with anovulation due to hyperprolactinemia (Joffe 2007).

Psychosocial Assessment in Infertility Patients

Although it is not common practice to refer all couples with infertility for a mental health assessment, the grueling nature of infertility diagnosis and treatment is becoming more widely appreciated. Normally intimate and private behaviors are asked about, subjected to strict timing, and brought into the clinical arena. Careful inquiry should be made regarding any psychiatric side effects of fertility-enhancing drugs, particularly alterations in mood.

Some have suggested that current levels of distress and coping strategies should be assessed in couples before initiating infertility treatment to provide the opportunity to learn and practice new adaptive behaviors that could enhance their ability to cope with infertility and the associated medical investigations and procedures. Counseling is sometimes recommended in couples considering donor eggs or sperm or surrogacy. The goal of mental health evaluation is to identify and treat any comorbid psychiatric disorders, to prepare the couple for infertility treatments, to raise emotional and ethical treatment issues that the couple may not have considered, and to offer support and coping strategies. Individual and group interventions are often helpful in providing mutual support, information, and coping techniques (Wischmann 2008).

Contraception

Contraceptive information and care are widely available in the Western world. Nevertheless, half of the pregnancies in North America each year are unintended, and one-third of births in the United States are classified as unwanted or mistimed. Contraceptive choices and use are affected by knowledge and misinformation, by women's comfort with their own sexuality and genitalia, by the preferences of sexual partners, by social custom, and by access to physicians

for hormonal methods. Many women are ill-informed about contraception (Picardo et al. 2003).

Psychodynamics and psychiatric conditions can interfere with a woman's use of a contraceptive technique. Pregnancy may be sought, consciously or unconsciously, as a proof of fertility and womanhood. Contraception, because it requires planning, requires acknowledgment of future sexual activity. For example, because of views about sex outside of marriage or cultural sanctions, some unmarried women may only engage in sexual intercourse when "swept away" by a romantic situation (and are thus unprepared to prevent pregnancy). Some women may feel uncomfortable about touching their own genitalia, as some contraceptive methods require. Many women have limited knowledge about their own anatomy, are too anxious to absorb the information in a hurried office or clinic visit, and are too embarrassed to ask for information to be repeated (Sanders et al. 2003). In a review of 16 studies that examined reasons for unprotected intercourse in adult women, Ayoola et al. (2007) found that reasons for unprotected intercourse included perceived inconvenience; unexpected/unplanned sex; ambivalence about pregnancy; problems using, acquiring, or storing the method; lack of knowledge or misinformation (e.g., low perceived risk of getting pregnant, lack of understanding of how to use/acquire method, belief that contraception reduces pleasure or makes sex unnatural); and unwanted side effects from oral contraception. Other problems included access to contraception (e.g., problems getting appointment, cost, preferred method not available), lack of continuity in care providers, and lack of privacy at contraceptive clinics. Alcohol abuse, particularly binge drinking (the rates of which are rising in young women), may also be a contributing factor.

Unplanned pregnancy is by no means always the result of the factors described above. Contraceptive methods do fail. Forced or unwanted sex is also a reason for unprotected intercourse, and gender and relationship power differentials play a major role in the use of contraception. Some women are sexually assaulted, bullied, or cajoled into unprotected sexual intercourse (Rickert et al. 2002). Ayoola et al. (2007) found that interpersonal reasons for unprotected sex were often partner-related (partner did not want to use contraception, fear of negative reaction from partner) or attributable to the influence of social custom. In a U.S. study of women at risk for sexually transmitted infections, a male partner's unwillingness to use condoms increased the odds of intercourse without barrier contraception by 4.1 (95% confidence interval [CI] = 2.3 to 6.9) (Peipert et al. 2007). In a large sample of New Zealand women, those who experienced interpersonal violence were more likely to have a partner who had either refused to use condoms or tried to prevent the woman from using contra-

ception (Fanslow et al. 2008). Despite these facts, it is women who are often blamed, both in societal and in medical contexts, for becoming pregnant at the wrong time or with the wrong partner. The resultant sense of shame and powerlessness can contribute to psychiatric symptoms and, paradoxically, can leave them more vulnerable to future unplanned pregnancies.

New Developments in Contraception

Newer developments in contraception have important psychosocial implications. For example, emergency contraception consists of higher doses of oral contraceptives taken after unprotected intercourse. Although most effective the earlier it is taken, it can be effective in preventing pregnancy within 3 days, and possibly up to 5 days, after unprotected intercourse. Emergency contraception can be obtained at family planning clinics, hospital emergency departments, or pharmacies. A recent study of women's preferences about obtaining emergency contraception found that women were more likely to use services perceived as sympathetic, nonjudgmental, and protective of privacy (Seston et al. 2007). Women who are young, especially those who are poor or from certain cultural groups, may be uninformed, embarrassed, unaware of their level of risk for pregnancy, worried about side effects of emergency contraception, and concerned about negative responses from others (Shoveller et al. 2007). In England, Australia, Canada, and some other countries, emergency contraception is available without a prescription. The U.S. Food and Drug Administration (FDA) recently notified the manufacturer of the emergency hormonal contraceptive pill Plan B (a 0.75 mg norgestrel) that it may market Plan B without a prescription to women 17 years or older (U.S. Food and Drug Administration 2009). A Cochrane Database systematic review of advance provision of emergency contraception found that it did not lead to increased rates of sexually transmitted infections (odds ratio [OR] = 0.99; 95% CI = 0.73 to 1.34), increased frequency of unprotected intercourse, or changes in contraceptive methods (Polis et al. 2007).

Another important consideration with respect to newer developments in contraception involves the use of hormonal contraceptives on a continuous rather than intermittent basis (e.g., hormonal implants, transdermal contraceptive patches, daily contraceptive pills). These methods have been developed to reduce the likelihood of contraceptive failure due to inconsistent use of the oral contraceptive pill or barrier contraceptive methods. They can also be used to treat dysmenorrhea and menorrhagia. However, continuous hormonal contraception does cause amenorrhea. This may have psychosocial implications for women who hold beliefs about menstruation as necessary for cleansing and confirmation of femininity (Glasier et al. 2003). Hor-

monal implants may also cause a decrease in bone density that is reversible when the implant is removed.

Management

Inquiries about sexual behavior and protection from unwanted consequences should be part of every medical, including psychiatric, history and treatment. Patients may be so accustomed to their birth control pills or injections that they fail to report them when asked what medications they are taking. Clinicians must ask about these contraceptives specifically in order to assess not only the adequacy of the contraceptive method but also the potential for drug–drug interactions. The major pathway of metabolism for both the estrogen and progesterone components of hormonal contraception is through the liver by cytochrome P450 (CYP) 3A4 (Oesterheld et al. 2008). Medications that induce CYP3A4, thus reducing the efficacy of hormonal contraception, include phenobarbital, oxcarbazepine, carbamazepine, topiramate (at dosages >200 mg/day), modafinil, and St. John's wort. Oral contraceptives can also inhibit the oxidation of various psychiatric medications via CYP1A2, 2B6, 2C19, and 3A4. Importantly, this can result in increased levels of benzodiazepines and tricyclic antidepressants (TCAs). Levels of valproate and lamotrigine can also be increased by oral contraceptives (likely via inhibition of glucuronidation).

In summary, access to care and adequate information about contraception is essential for all patients. Certain groups, such as women with severe and persistent psychiatric illness, adolescents, and recent immigrants, may have increased vulnerability to some of the factors cited above and have been shown to use contraceptive methods suboptimally (Gelberg et al. 2002; Magalhaes et al. 2009; Whitaker and Gilliam 2008). Atypical antipsychotic medications do not impair fertility as much as older antipsychotics and may result in unwanted pregnancies in women being treated for psychotic illnesses. Therefore, attention to contraceptive knowledge and use in these groups is of great importance.

Sterilization

Sterilization is the most commonly used method of contraception in the world for women ages 15–49 years who are married or in ongoing heterosexual relationships, with the highest rates in less developed countries (United Nations 2007). It is intended to be a permanent solution to unwanted fertility, although some tubal ligations are reversible. A psychiatrist may be asked to consult when a young nulliparous woman, or a patient with a mental illness, desires to be sterilized. Assessment of capacity to consent to treatment and to give informed consent is essential,

highlighted by state laws enacted in the wake of past involuntary sterilization of individuals with mental illness. It may be appropriate for guardians to consent to sterilization procedures for severely cognitively impaired or developmentally delayed adult women who are unable to cope with the hygienic aspects of menstruation, are victimized by male predators, become pregnant, and are entirely unable to cope with the stresses of birth and parenting. However, mental illnesses cannot be equated with incapacity to make treatment decisions. Women may have psychotic symptoms, or a history of them, that interfere with capacity, but they also may make well-informed decisions not to have children, or more children, precisely because they recognize that their illness would interfere with their parenting. When there is uncertainty, a longitudinal assessment is appropriate. For example, the psychiatrist may ask the patient to return in a few months. If she is mature, not acutely psychotic, and persistent in her desire for sterilization, she may be as appropriate a candidate for the procedure as a woman without diagnosed psychiatric illness.

The occurrence of postsurgical regret ranges from 5% to 20%. A systematic review of 19 studies found that age was a significant risk factor for postsurgical regret, with women who were sterilized when younger than age 30 more than twice as likely to experience regret as women older than 30 years (Curtis et al. 2006). Other risk factors include marital conflict over the procedure and subsequent changes in marital partnerships (Jamieson et al. 2002). Death of a child has been associated with poststerilization regret, and a survey of women in India identified having few or no male children as a risk factor for regret (Machado et al. 2005; Malhotra et al. 2007). Sexual satisfaction does not appear to be affected (Peterson 2008). The provision of clear information about the nature, effectiveness, risks, and benefits of the procedure is a crucial factor in patient satisfaction.

Hysterectomy

Hysterectomy is the surgical removal of the uterus. It is one of the most common surgical procedures performed on North American women, with rates of approximately 5.3 per 1,000 women-years in the United States (Wu et al. 2007) (see also the “Pelvic Surgery” section in Chapter 30, “Surgery”). In North America, hysterectomy rates are between two and five times higher than in European countries, but small area rate variations are widespread in most countries. These variations appear to depend on women's socioeconomic class, race/ethnicity, education level, religion, physician practice, reimbursement schedules, and availability of new technologies (Stewart et al. 2002).

Hysterectomy may be total or subtotal (where the cervix is left intact) and also may be combined with removal of the

fallopian tubes and ovaries (bilateral salpingo-oophorectomy [BSO]). Although vaginal hysterectomy is associated with lower mortality and shorter length of stay, abdominal hysterectomy remains the most common hysterectomy procedure. A small proportion of hysterectomies are performed to treat malignancies or catastrophic hemorrhage, but the vast majority are elective procedures performed primarily to improve quality of life in women with abnormal uterine bleeding, fibroids, uterine prolapse, chronic pelvic pain, or endometriosis. The mean age of women undergoing hysterectomy is the mid-40s, or an average of 6–7 years before the mean age of natural menopause, when some of these problems (abnormal uterine bleeding, fibroids) spontaneously resolve. However, hysterectomy is the treatment of choice for certain gynecological conditions. The predicted advantage must be carefully weighed against the risks of surgery and other treatment alternatives, such as hormonal therapy and endometrial ablation (Lefebvre et al. 2002).

Information Needs and Decision-Making Preferences

Well-informed women who have been involved in decision making about hysterectomy have the best outcomes (Stewart et al. 2002). Various studies and expert panels have concluded that women and their family physicians should be provided with an adequate level of knowledge to make a fully informed decision as to whether hysterectomy, less invasive procedures, medical management, or watchful waiting is the best option (Stewart et al. 2002; Uskul et al. 2003; Vigod and Stewart 2002). Similarly, the options for retention or removal of the cervix and ovaries and route of hysterectomy (vaginal vs. abdominal) should be discussed.

Women's decision making regarding discretionary hysterectomy (i.e., not for treatment of malignancy) is influenced by their age, socioeconomic status, education, desire for fertility, sexual orientation, ethnicity, and severity of their symptoms. The influence of family, friends, and partners as well as health care professionals also plays a major role (Graham et al. 2008). Women who require hysterectomy for the treatment of malignancies are understandably focused more on the cancer, its overall treatment, and its prognosis.

Variations With Ethnic, Socioeconomic, and Sexual Diversity

Several articles have explored ethnic differences and indications for hysterectomy (Bower et al. 2009; Farquhar and Steiner 2002; Lewis et al. 2000). African American women undergo hysterectomy at a younger age for most diagnostic categories, including leiomyomas, genital prolapse, and endometriosis. They are also more likely to have an abdominal hysterectomy, extended hospital stays, and higher in-

hospital mortality (Lewis et al. 2000). Data from the Coronary Artery Risk Development in Young Adults (CARDIA) study in the United States were used to examine differences in hysterectomy rates between black and white women ($N = 1,863$). Black women demonstrated greater odds of hysterectomy compared with white women even after adjustment for age, educational attainment, perceived barriers to accessing medical care, body mass index, polycystic ovarian syndrome, tubal ligation, depressive symptoms, age at menarche, and geographic location ($OR = 3.70$; $95\% CI = 2.44$ to 5.61) (Bower et al. 2009). Qualitative analyses with Hispanic, African American, and lesbian women (Groff et al. 2000) have explored their capacity to acquire a second opinion about hysterectomy and available alternatives that may be limited by education, ethnicity, economics, and access.

Psychological and Sexual Outcomes

A literature review of psychological and sexual outcomes after hysterectomy located more than 100 studies (Flory et al. 2005). The methodological quality of many of the studies was poor, but the authors concluded that while psychosexual and psychosocial effects are minimal overall, a subgroup of women (10%–20%) do report sexual dysfunction, depressive symptoms, and/or impaired body image.

Risk factors for poor outcome appear to be related to preoperative pain, sexual dysfunction, and psychiatric morbidity. Outcome does not appear to depend on the method of surgical removal of the uterus or the type of hysterectomy that was performed (Flory et al. 2006). Hartmann et al. (2004) reported that women with preoperative pain and depression had less improvement after hysterectomy than women without pain and depression preoperatively. A prospective study of 68 women in Taiwan evaluated the risk of major depressive disorder in women who underwent hysterectomy for nonmalignant conditions. The authors found that although overall psychological symptoms improved postsurgery, risk factors for postoperative major depressive disorder were prior emotional problems, poorer body image, and poorer sexual functioning as well as higher stress 1 month postsurgery (Yen et al. 2008). Women with substantiated diagnoses and clear indications for hysterectomy have better physical and psychological outcomes than do women with less defined symptoms and indicators such as chronic pelvic pain.

Role of the Psychiatrist

There may be a role for psychiatrists in assessing mood, anxiety, understanding, and feelings about sexuality and fertility in vulnerable women undergoing hysterectomy. For the informed, psychologically healthy woman who has failed to respond to other treatment options and who has a significantly impaired quality of life because of a specific

gynecological condition, hysterectomy may offer an improved quality of life. However, for women with premorbid depression, anxiety, or personality disorders, especially if accompanied by ambivalence about sexuality, fertility, or the procedure, hysterectomy may fail to ameliorate, or may even exacerbate, preexisting symptoms. It is important to consider that women undergoing hysterectomy with BSO have to confront the onset of sudden surgical menopause if estrogen therapy is not begun shortly after surgery. Even women whose ovaries were not removed may experience sudden menopause due to impaired blood supply to the ovaries. This sudden hormonal change may result in vasomotor symptoms, sleep loss, and depression, especially in vulnerable women with a history of depression associated with reproductive events (Stewart and Boydell 1993). Therefore, psychiatrists should ascertain the hormonal status of women with sudden mood changes following hysterectomy and consider short-term hormonal treatment as well as antidepressants. Psychiatrists who assess women undergoing hysterectomy should evaluate their understanding of the procedure, attitudes toward fertility and sexuality, and experience and expectations of surgery, as well as psychiatric history. The appropriate treatment, whether psychotherapy, hormones, or psychotropics, will, as always, depend on the individual woman.

Abortion

Spontaneous Abortion

Abortion can be spontaneous (miscarriage) or induced (usually just termed *abortion*). Approximately 15%–20% of recognized pregnancies end in spontaneous abortion, with the majority occurring in the first trimester of pregnancy. Spontaneous abortion generally evokes feelings of failure and loss. A woman's body has failed to perform one of its basic functions; she has failed to produce a child for her partner and parents; she has expelled her own potential child; and she may have conceived an embryo with genetic anomalies (Friedman and Gath 1989). Decades ago, miscarriage was sometimes attributed to the woman's unconscious rejection of motherhood, but this theory has never been validated by empirical research. Spontaneous abortion, like a stillbirth or neonatal death, may precipitate pathological grief, postpartum depression, or posttraumatic stress (Brier 2008; Engelhard et al. 2003). Although the psychological sequelae of miscarriage will be to some extent dependent on individual psychodynamic factors, psychiatric history, and prior experiences with loss, there are elements unique to spontaneous abortion that may play a role. Contrary to the traditional conceptualization of loss, a miscarriage often involves grief about anticipated out-

comes. Women report that the failure of society in general and of friends and family to acknowledge their loss is painful and complicates the grieving process. People often say, "There must have been something wrong with the baby," "This is God's way of correcting mistakes," or "You can just get pregnant again." There are no ceremonies to mark the occasion. Friends and co-workers tend to avoid the subject and to expect the woman to recover within days or weeks, but grief may last for months. Gestational age and the degree to which a woman perceives the fetus as "real" have been shown to be associated with the nature and intensity of grief. The perception of the reality of the pregnancy increases when women have seen the fetus via ultrasonography or when they can feel fetal movement (both more likely with increased gestational age). It is important to note that although women are at higher risk of psychological reactions following miscarriage than men, their male partners can and do experience psychological sequelae, sometimes expressed as overinvolvement with work or sports.

Health care providers may have difficulty addressing the emotional effect of spontaneous abortion. They feel helpless to prevent it, and it is generally not associated with serious medical or obstetric complications. Psychiatrists can help them to understand and tolerate how their patients are feeling and to appreciate the benefits of simply allowing patients to express those feelings. Health care providers should be aware that emotional recovery, depending on the circumstances, can take months, and they need to know when and how to make the diagnosis of pathological grief. It is often helpful for them to meet with the patient some weeks after the event to go over the medical findings, if any; the prognosis; and the state of the woman's recovery.

The loss of pregnancy through miscarriage or stillbirth is associated with an increase in anxiety during a subsequent pregnancy (Bergner et al. 2008). Preliminary data suggest that fears related to pregnancy may have a negative impact on pregnancy and delivery outcomes (Fertl et al. 2009). Although patients are frequently counseled to wait 6 months or a year after such a loss, they often conceive as soon as possible, especially if they feel that the fertility clock is ticking. The obstetrician must be prepared to offer them enhanced support. There is evidence to suggest that medical counseling, either alone or combined with psychological counseling, can reduce a woman's distress with respect to grief, self-blame, and worry (Nikcevic et al. 2007).

Induced Abortion

Psychiatric Sequelae

Approximately 1.22 million abortions are performed every year in the United States; at least one in four women in the United States will have an abortion in their lifetime (Ven-

tura et al. 2008). Psychiatrists are seldom consulted about abortion and abortion decisions, and no evidence shows that formal mental health consultation is routinely necessary. The psychiatric ramifications of abortion are a matter of some debate, but the findings are clear once methodological confounds are taken into account. Unbiased reviews of the literature indicate that self-limited feelings of guilt and sadness are common after abortion, although the predominant reaction is one of relief, and new episodes of psychiatric illness are rare (Charles et al. 2008). Although there may be initial increases in distress and anxiety around the time of abortion, adverse effects on self-esteem in the long term are not seen (Bradshaw et al. 2003). In fact, studies have shown that women's quality of life improves in the period from before to after an early abortion (Garg et al. 2001; Westhoff et al. 2003). The best outcomes prevail when women are able to make autonomous, supported choices about their pregnancies. When women seek, but are denied, abortion, the resulting children have significantly poorer outcomes than their siblings or matched control subjects (Kubicka et al. 2002).

Antiabortion groups and writers claim that abortion is associated with a higher risk of serious psychiatric disorders and suicide than is childbirth (Pro-Life Action Ministries, undated; Reardon et al. 2003; Thorp et al. 2003). These publications fail to address the circumstances of and reasons for abortion. Sometimes they confound common self-limited feelings of loss and guilt with diagnosable depression. Women often have abortions because they have been abandoned by the men who impregnated them, because those men threaten to leave if they continue the pregnancy, because the pregnancy is the result of rape or incest, because they are poor and overburdened with other responsibilities, or because they do not have the resources—educational, financial, emotional, or social—to provide adequate parenting. They may simply not want to be a parent. Preexisting serious psychiatric illness makes some women more vulnerable to unwanted pregnancy and less able to parent.

Risk Factors

Not surprisingly, coercion, lack of social support, poverty, rape, incest, and preexisting psychiatric illness are associated with increased risk for psychological difficulties following, but not causally related to, abortion. Women who belong to religious faiths opposed to abortion choose abortion as often as or more often than those who do not. Efforts have been made to reach out to this population, both to enlist them in antiabortion advocacy and to offer them spiritual support (Gay and Lynxwiler 1999; Jeal and West 2003; Ventura et al. 2000). Demonstrators or fear of terrorism at an abortion facility may exacerbate stress, and the attitudes and behaviors of medical personnel during

the abortion procedure have a significant influence on patients' experience (Slade et al. 2001).

The delay of abortion into the second trimester, or later, is most often secondary to denial of pregnancy, difficulties with access, or diagnosis of a serious fetal defect, each of which increases the risk for negative postabortion reactions. The discovery of a fetal defect in a wanted pregnancy or the need to abort because of serious illness in the mother arouses the same sense of failure and loss as a miscarriage, with the added concern that one is carrying a genetic anomaly or is physically unable to bear a child. Consultation may be sought when a woman or family cannot decide, or manifests overwhelming anxiety, when making an abortion decision under these circumstances (Zlotogora 2002). Continuing a pregnancy and relinquishing the child for adoption pose a psychological burden as well (Cushman et al. 1993). There does not appear to be a difference in psychological outcome based on the type of abortion that a woman undergoes (i.e., medical or surgical abortion), although many women prefer the privacy of medical abortion (Ashok et al. 2005).

Minors and Abortion

The effect of abortion on minors, and their ability to make decisions about abortion, is another area of controversy. The vast majority of pregnant minors choose to involve their parents in the abortion decision. No evidence shows that those who think it is not safe or wise to inform their parents derive benefit from being forced to do so. Term pregnancy and delivery pose greater medical and psychological risks for adolescents than does abortion. Arguments that minors are too immature to elect abortion overlook the fact that these same minors, if their pregnancies are not terminated, will soon be mothers with responsibility for infants. In Zabin's classic study of inner-city girls who obtained pregnancy tests at a school clinic, girls who had abortions had better outcomes compared with those who carried their pregnancies to term and even compared with those whose pregnancy test results were negative. This does not imply that the abortion improved these teens' mental health; rather, it may indicate that the inability to confirm whether one is pregnant is associated with other psychosocial problems. Marriage of the pregnant teenager to the father of the baby does not improve outcome and may even worsen it (Zabin et al. 1989).

Chronic Pelvic Pain

Chronic pelvic pain is nonmenstrual pelvic pain of 6 or more months' duration that is severe enough to cause functional disability or require medical or surgical treatment (Howard 2003). It is a relatively common and signifi-

icant disorder of women, with an estimated prevalence of 3.8% in adult women, similar to that of asthma or back pain (Zondervan et al. 1999). Chronic pelvic pain is one of the most common gynecological complaints and accounts for 2%–10% of outpatient gynecological referrals, although most women are managed by their primary care practitioners (Howard 2003). Chronic pelvic pain may lead to disability and suffering, with loss of employment, marital discord and divorce, and overall decline in quality of life (Howard 2003).

Etiology of Chronic Pelvic Pain

Despite the severity and frequency of chronic pelvic pain, its etiology is often difficult to discern. Disorders of the reproductive, gastrointestinal, urological, musculoskeletal, and neurological systems may be associated with chronic pelvic pain. In many cases, however, the pain is related to a combination of physical and psychological factors, such as endometriosis, adhesions, urological problems, irritable bowel syndrome, myofascial pain, depression, anxiety, somatization, and past abusive experiences (Dalpiaz et al. 2008). Endometriosis and pelvic adhesive disease are responsible for most cases of chronic pelvic pain with organic findings, but a significant number of patients have no obvious etiology for their pain at the time of laparoscopy (Gelbaya and El-Halwagy 2001). As with other chronic syndromes, especially those with ambiguous etiology, the biopsychosocial model offers the best way of integrating physical causes of pain with psychological and social factors. One model, the gate-control theory of pain, proposes that peripheral nociceptive signals can be modified by neurotransmitters, such as serotonin and endorphins, that control mood states, and accordingly, the gateway to chronic pain can be opened by a combination of depression and direct tissue irritation. Because interacting psychological and physical factors are likely to be present early in the course of pain, attempts to separate chronic pain into a simple cause–effect relation are usually unrewarding. An alternative theory, the diathesis–stress model, proposes that some patients are at increased risk for chronic pain because of preexisting acquired vulnerability. This might explain why a disproportionate number of patients with chronic pelvic pain report histories of physical and sexual abuse (Gelbaya and El-Halwagy 2001). Recent work on gene–environment interactions may also offer a promising model to explore chronic pelvic pain.

Psychological Factors Associated With Chronic Pelvic Pain

The relation of chronic pelvic pain to psychological state or personality style has received great attention. In general, the concept of psychogenic pain (emotional pain displaced

onto the body) has been superseded. Cognitive-behavioral and psychophysiological theories have moved increasingly toward supporting more complex, multicausal views of chronic pelvic pain. Chronic pelvic pain is likely to be the outcome of several somatic, social, and psychological influences acting together in varying degrees. A systematic review evaluating the literature on factors predisposing women to chronic or recurrent pelvic pain (Latthe et al. 2006) identified psychological variables that appear to be consistently associated with chronic pelvic pain. Both cyclic (i.e., dysmenorrhea) and noncyclic pelvic pain are associated with anxiety, depression, and history of physical and sexual assault. Although very few of these studies were designed in a way to separate psychological predictors of chronic pelvic pain from psychological sequelae, it is clear that chronic pelvic pain is a long-standing condition and women with it are at greater risk of low self-esteem, depression or anxiety, low marital satisfaction and sexual dysfunction, and somatic symptoms (Weijenborg et al. 2007).

Management of Chronic Pelvic Pain

It is well recognized that a multidisciplinary, multifocal approach to chronic pelvic pain, individualized for each woman, is essential (Dalpiaz et al. 2008; Gunter 2003). Recent research suggests that many women become dissatisfied with the care they receive and refrain from seeking help, despite ongoing symptoms (Dalpiaz et al. 2008). This highlights the importance of attention to the therapeutic relationship. Goals of management include improving function, restoring quality of life, and maintaining even small gains in treatment. First-line management includes a combination of physical therapy, nonnarcotic pain management, and psychological support as indicated. Focused psychotherapy may be useful to address issues such as pain management, current conflicts, past sexual and physical abuse, current domestic violence, substance abuse problems, and sexual and marital dysfunction. Phases of treatment include education, skills acquisition, behavior modification, and maintenance. Special techniques may increase the patient's coping ability and sense of control; such techniques include muscle relaxation, deep breathing and imagery, and cognitive-behavioral techniques to identify and address maladaptive thoughts. Because patients with chronic pelvic pain frequently limit their activity to avoid possible pain, activity programs can be initiated to decrease disability behaviors. Additional interventions might include medical therapies (oral analgesics, antidepressants, drugs for dysmotility disorders, management of musculoskeletal pain, ovarian cycle suppression, and antibiotics), biofeedback, and surgical procedures. Unfortunately, the most recent Cochrane Database systematic review on the management of chronic pelvic pain identified only nine

methodologically adequate studies (Stones and Mountfield 2000). Current evidence does not support SSRIs as beneficial in chronic pelvic pain (Cheong and William Stones 2006), but the role of serotonin-norepinephrine reuptake inhibitors (SNRIs) has not been fully explored.

Endometriosis

Endometriosis is defined as the presence of hormonally responsive endometrial tissue outside the uterine cavity. The precise pathogenesis is not clearly established but likely involves retrograde menstruation with seeding of endometrial glands in the dependent part of the pelvis and in or on the ovary, posterior cul-de-sac, broad ligament, uterosacral ligament, rectosigmoidal colon, bladder, and distal ureter. It has been proposed that retrograde menstruation occurs to some degree in all women, but that only those who are unable to clear the menstrual debris because of immune dysfunction will go on to develop endometriosis (Cramer and Missmer 2002). Family history is a risk factor for endometriosis, and current efforts are being made to investigate genetic factors. The mean age of women at diagnosis of endometriosis ranges from 25 to 30 years. This condition is often asymptomatic but is also found in association with dysmenorrhea, dyspareunia, infertility, chronic pelvic or back pain, and rectal discomfort. The pain from the disorder is often cyclic, although it can be constant. The gold standard for diagnosis and staging of endometriosis is laparoscopy; however, the intensity of pain and discomfort does not correlate well with the severity of the disease at laparoscopy (Lu and Ory 1995).

Management

Endometriosis can be treated by watchful waiting, medical or surgical management, or a combination of the latter two options. Current medical regimens to treat this condition with gonadotropin-releasing hormone (GnRH) agonists and other drugs attempt to create states of pseudopregnancy, pseudomenopause, or chronic anovulation. Nonsteroidal anti-inflammatory medication is widely used, but there is little evidence to suggest that it is helpful (Allen et al. 2009). Surgical treatments vary from conservative removal and destruction of endometrial implants by excision, electrocautery, or laser to total abdominal hysterectomy with BSO. Implants have been shown to recur in up to 28% of patients within 18 months and 40% after 9 years of follow-up. However, there is some evidence that perioperative medical management with GnRH agonists may improve outcomes and increase time to recurrence of symptoms (Yeung et al. 2009). Although surgical conservative treatment is widely used to enhance fertility, its efficacy for endometriosis-associated infertility has not yet been shown. Immunomodulators are being studied on the

basis that the peritoneal immune system appears to be impaired in women with endometriosis. Preliminary evidence supports enhancement of fertility when surgery is combined with medical management with immune modulators (Creus et al. 2008).

Role of the Psychiatrist

Because endometriosis is often chronic, and its contribution to chronic pelvic pain is sometimes uncertain, psychiatric opinion may be sought. Women with endometriosis experience a range of problems for which they may not be adequately supported. In fact, some women report that their worst experience is their encounter with health professionals and the way in which their symptoms are trivialized and dismissed (Cox et al. 2003). Depression occurs commonly in cases where endometriosis is accompanied by chronic pain, dyspareunia, or infertility. In addition, GnRH agonists are often used to treat endometriosis, and depressive symptoms may be associated with this treatment. SSRI antidepressants appear to be significantly helpful in the treatment of mood symptoms during the course of GnRH agonists (Warnock et al. 2000). Psychotherapy and antidepressants also may be helpful in addressing other psychological issues and symptoms in women with endometriosis.

Vulvodynia

Vulvodynia is chronic burning, stinging, or pain in the vulva in the absence of objective clinical or laboratory findings. Vulvodynia is divided into two classes: 1) vulvar vestibulitis, which is restricted burning and pain in the vestibular region that is solicited by touch, and 2) dysesthetic vulvodynia, which is burning or pain not limited to the vestibule, which may occur without touch or pressure. A population-based National Institutes of Health study found that approximately 16% of women reported lower genital tract discomfort persisting for 3 months or longer (Edwards 2003), although a more recent national health survey estimated much lower rates for vulvodynia with a current prevalence of 3.8% for chronic vulvar pain for at least 6 months (Arnold et al. 2007). Variability in disease definition may account for these discordant findings.

The etiology of vulvodynia is unknown, and previously suspected agents such as subclinical yeast infections and human papillomavirus have largely been discounted. Many women with vulvodynia also have comorbid disorders, such as interstitial cystitis, headaches, fibromyalgia, and irritable bowel syndrome, as well as clinical depression.

Psychiatrists may be asked to assess the role of psychosexual factors and depression in women with vulvodynia. One recent study of 80 women being treated for vulvodynia reported that more than 50% of the sample showed anxiety

and more than 50% had a depressive disorder (Tribo et al. 2008). A review of the literature in social science databases concluded that distress in women with vulvodynia is related to the woman's sense of sexual identity and impacted by social influences related to expectations of femininity (Cantin-Drouin et al. 2008). This formulation may be helpful in treating women with this disorder. Also, given the efficacy recently shown by dual-action antidepressants (SNRIs) in treating depression and chronic painful conditions, these antidepressants may be a promising treatment for vulvodynia. Although open trials with TCAs and SSRIs, lamotrigine, and gabapentin have shown some promise, no randomized controlled trials with these medications have been published to date (C.S. Brown et al. 2008; G. Harris et al. 2007; Meltzer-Brody et al. 2009; Reed et al. 2006).

Pregnancy

The entire range of psychiatric disorders occurs during pregnancy, and some conditions are unique to pregnancy. Treatment of these disorders is discussed later in this chapter.

Epidemiology of Psychiatric Disorders Occurring During Pregnancy

Depression

The incidence of depression during pregnancy is approximately the same as that for matched populations who are not pregnant. Data from face-to-face interviews in the 2001–2002 National Epidemiological Survey on Alcohol and Related Conditions (NESARC) in the United States found no difference in the 12-month prevalence of major depressive disorder between women with and without pregnancies in the preceding year (8.4% and 8.1%, respectively) (Vesga-Lopez et al. 2008). The signs and symptoms of depression must be carefully distinguished from the sleep, appetite, and energy changes often characteristic of pregnancy and from the signs and symptoms of thyroid dysfunction, anemia, or other diseases of pregnancy. Discontinuation of maintenance medication for women who have had recurrent depressions carries a high risk of relapse. In a prospective observational study of 201 women with a history of major depression, 43% experienced a relapse during pregnancy. Women who discontinued medication had a greater risk of relapse (68% vs. 26%) and more frequent relapses than women who continued antidepressant treatment in pregnancy (L. S. Cohen et al. 2006a).

Bipolar Disorder

There is a growing literature on bipolar disorder during pregnancy indicating that a substantial proportion of women with preexisting bipolar disorder may relapse. In a

recent prospective study of 81 women with bipolar disorder, the overall risk of relapse in pregnancy was 71%. Women who discontinued medication had a twofold increased risk of relapse, had an earlier time to relapse, and spent more time being ill. Abrupt discontinuation led to earlier recurrence than gradual discontinuation (Viguera et al. 2007b). Serious episodes of mania pose a threat to the pregnancy, necessitating especially careful risk-benefit analysis with regard to psychotropic medication.

Anxiety Disorders
