There has been increased attention to the course and impact of anxiety disorders in pregnancy. Maternal symptoms of anxiety during pregnancy may be associated with adverse fetal and developmental outcomes (O'Connor et al. 2002). The course of anxiety disorders during pregnancy may vary with the nature of the anxiety disorder. For example, panic disorder may remit, recur, or remain unchanged during pregnancy. There is little evidence that pregnancy is a high-risk time for new onset of panic disorder. Although an underlying medical etiology is uncommon, new-onset panic symptoms should be investigated because of the consequences of missing a medical etiology (e.g., hyperthyroidism) or medication side effect. Patients with panic disorder who wish to discontinue medication should be tapered off gradually and treated with cognitive-behavioral therapy. More than 10% of female patients with panic disorder report that their first episode occurred postpartum.

Obsessive-compulsive disorder (OCD) may worsen pre- and postpartum, and withdrawal of medication is very likely to result in recurrence. A systematic review of anxiety disorders in the peripartum period revealed five studies indicating that as many as 40% of childbearing OCD outpatients have onset during pregnancy (Ross et al. 2006). Patients with moderate to severe symptoms may require maintenance medication during pregnancy; patients with milder cases can be treated with cognitive-behavioral therapy.

Results from the NESARC survey do not suggest that pregnancy confers increased risk of posttraumatic stress disorder (PTSD) or generalized anxiety disorder (Vesga-Lopez et al. 2008), although PTSD in some women following traumatic deliveries has been reported (Ayers et al. 2008).

Psychotic Disorders

Since almost all women with psychotic disorders have been deinstitutionalized, and most newer antipsychotics do not impair fertility, their rate of fertility approximates that of the general population. Pregnancy does not ameliorate, and may exacerbate, psychotic symptoms (Davies et al. 1995). There is some evidence that women with schizophre-

nia have more obstetric complications such as bleeding in pregnancy and placental abnormalities (Jablensky et al. 2005). Psychotic episodes during pregnancy may be characterized by delusions that the fetus is evil or dangerous, leading the pregnant woman to stab herself in the abdomen or engage in other self-destructive behaviors. Alternatively, psychotic denial of pregnancy can lead to poor antenatal care and/or impair a woman's ability to recognize and react appropriately to the signs and symptoms of labor. Psychoeducation is essential in this population. Antipsychotic medication is a foundation of treatment, although electroconvulsive therapy (ECT) for acute affective psychotic episodes can be effective and is relatively safe for the fetus (Anderson and Reti 2009). Special consideration must be given to the use of restraints for agitated pregnant patients to avoid compression of the vena cava (Solari et al. 2009).

Prenatal assessment and treatment can mitigate wrenching custody disputes after the infant is born. Serious psychiatric illness, if treated, is not always incompatible with successful mothering. The psychiatrist and obstetrician, working together with the patient, family, and social agencies, can plan and make provision for the infant's needs. Psychiatrists may be called on to assist in the assessment of competency to parent an infant. When it is clear that the mother will not be able to care for the child, such as when her other children have been taken into state custody for their protection, the psychiatrist can help her come to terms with the painful separation that will occur.

Alcohol and Substance Abuse

Alcohol and substance abuse arouse heightened concern in a pregnant patient. Standing by while a woman's behavior puts her fetus at risk is a painful situation for prenatal care professionals. The most serious and well-documented result of alcohol abuse during pregnancy is fetal alcohol syndrome. A pregnant woman who drinks the equivalent of 10 beers per day has a one-third risk of delivering a child who has fetal alcohol syndrome and a similar risk of delivering a child who is developmentally delayed but does not have the full syndrome. The perinatal mortality in these circumstances is 17% (Greenfield and Sugarman 2001). More recent studies have not substantiated early fears of an epidemic of "crack babies." It appears that most or all of the negative cognitive and behavioral findings in these children are a result of the environment in which they grow up rather than intrauterine exposure to cocaine (Chiriboga 1998). However, misinformation and rage at pregnant women who abuse substances have led to instances in which women have been imprisoned, either for the protection of the fetus or as punishment for harm to the fetus. Many or most pregnant women who abuse drugs or alcohol will accept treatment if it is practical (e.g., providing

child care) and humane. Evidence indicates that the threat of coercion and punishment leads women to avoid seeking prenatal care altogether, obviating any opportunity to treat them and improve the fetus's intrauterine environment (see also Chapter 17, "Substance-Related Disorders," and Chapter 2, "Legal Issues").

Goals for the treatment of substance-using pregnant women involve motivational enhancement and harm reduction. Clinicians should offer appropriate treatment for the substance use disorder (e.g., methadone maintenance for opioid dependence) and treat comorbid medical or psychiatric disorders. The safety of patient behaviors should be monitored throughout pregnancy and the postpartum period, and child and family services should be involved for risk reduction and facilitation of competent parenting behaviors as needed. The therapeutic relationship is of utmost importance and should be nonjudgmental. Continued motivation enhancement, behavioral skills training, and a multidisciplinary long-term treatment plan will be important, particularly for women returning to environments where they are at high risk of relapse.

Personality Disorders

Women with severe personality disorders may present with risky behaviors that raise concerns about fetal safety. It may also be challenging for prenatal providers to manage some of the interpersonal conflicts in which some of these patients excel. Psychiatrists may be helpful in assessing risk, explaining useful de-escalation strategies, emphasizing consistency in management, and providing ongoing support to staff and the patient.

Situational Anxiety

Some pregnant patients are referred for psychiatric consultation for evaluation of what seems to the primary care clinician to be an inordinate level of anxiety. A careful history often shows that the patient either has been frightened by the experiences of a close family member or has had a traumatic obstetric or general medical care experience herself (Saisto and Halmesmaki 2003). The degree of pain a woman experiences in labor is related to many factors, including her expectations of pain (Chang et al. 2002). When the source of the anxiety is identified, it can be addressed by reviewing the past experience and making plans to avoid the frightening aspects of care in the coming delivery, providing prenatal education about delivery, or using relaxation techniques or hypnosis. Domestic violence is another cause of prenatal anxiety. The World Health Organization (WHO) recently published its findings from a large multinational study of women and abuse. In 15 different countries, the prevalence of reported physical violence in pregnancy ranged from 1% to 28%. Between

one-quarter and one-half of these women experienced direct trauma to the abdomen during pregnancy, and more than 90% of the assailants were the biological father of the fetus (Ellsberg et al. 2008).

Issues Unique to Pregnancy

Denial of Pregnancy

Some women go into full-term labor without having recognized, or their families having recognized, that they are pregnant. Many such patients are not psychotic, but some are women with schizophrenia who are delusional in denying pregnancy (Miller 1990). Older patients may report that they thought pregnancy was impossible at their age and therefore attributed their amenorrhea to menopause and the sensations of fetal movement to digestive problems. Younger patients in this situation are typically passive daughters isolated in very strict families without much knowledge about reproduction. Their preconscious or unconscious fears of the consequences of pregnancy are so terrifying that they keep its signs and symptoms out of awareness (Spielvogel and Hohener 1995). They wear loose-fitting clothing and go about their usual activities. These cases generally come to psychiatric attention only when the new mother kills the infant after birth. Therefore, these young women end up in the penal—rather than the mental health care—system, and there has been relatively little opportunity to work with them and their families to learn more about the dynamics of these situations. One epidemiological study in Germany reported an incidence of up to 1 case of pregnancy denial per 475 births (Wessel et al. 2002). Later, the authors attempted to characterize risk factors for denial of pregnancy in this group, but they concluded that the group was quite varied and were unable to define a “typology” of women at risk. Only 3 out of 65 women had a diagnosis of schizophrenia (Wessel et al. 2007).

Pseudocyesis

At the other end of the spectrum from the patient who does not realize she is pregnant is the patient who is convinced she is pregnant when she is not. This condition, referred to as *pseudocyesis*, is a fascinating example of psychobiological interplay. The patient ceases to have menstrual periods. Her abdomen grows, and her cervix may show signs of pregnancy. Some patients with the delusion that they are pregnant are psychotic, but that is not the case in classical pseudocyesis. Patients with pseudocyesis are a heterogeneous group, and they have no other signs or symptoms of frank psychiatric disorder (Rosch et al. 2002). They declare an expected date of delivery and move the date forward when delivery does not ensue. Their conviction may or may not be swayed by ultrasonographic evi-

dence or physical examination. For unknown reasons, the incidence of this condition is decreasing. Frequent antecedents are pregnancy loss, infertility, isolation, naivety, and a belief that childbearing is a woman's crucial role. These individuals have no interest in psychiatric care, and little is known about how the condition eventually resolves (Whelan and Stewart 1990). It may be important to differentiate pseudocyesis from menstrual irregularity and lactation secondary to hyperprolactinemia in women taking antipsychotic medication. Case reports indicate that the symptoms of hyperprolactinemia may contribute to delusional beliefs about pregnancy in women with schizophrenia (Ahuja et al. 2008).

Hyperemesis

Pernicious vomiting in pregnancy was once thought to be the result of unconscious rejection of the pregnancy. Hyperemesis, which can result in dehydration and electrolyte imbalance and may require hospitalization and intravenous treatment, certainly could induce ambivalence about a pregnancy in a woman who had been very pleased at the prospect of becoming a mother, but no scientific evidence indicates that ambivalence induces the vomiting (O'Brien and Newton 1991). Hyperemesis is no longer considered a psychiatric disorder. Mental health intervention can, however, help the patient and family cope until the condition resolves (Deuchar 1995). In a survey of 808 women with hyperemesis, 83% reported negative psychosocial consequences, including socioeconomic stress (e.g., job loss), attitude changes like fear regarding future pregnancies, and psychiatric symptoms like feelings of depression and anxiety, which for some continued postpartum (Poursharif et al. 2008). There are several case reports of severe hyperemesis gravidarum resulting in Wernicke-Korsakoff encephalopathy. Treatment is usually with standard antiemetics, but mirtazapine may be helpful in treatment-resistant cases (Guclu et al. 2005).

Identification of Psychiatric Illness

Although routine screening for psychiatric illness in all patients is not supported by evidence, psychiatrists may advise obstetricians that an identification of psychiatric illness and appropriate referral and treatment during routine antenatal care will likely decrease the frequency and intensity of noncompliance with antenatal care and of psychiatric emergencies during pregnancy and labor. Patients who might not otherwise recognize that they are in labor, as well as their families, can receive special education so that infants are not delivered into the toilet or in some other less-than-ideal environment. Prenatal education can prepare them for labor and delivery so that they can best cooperate and communicate with medical staff when the time comes.

Postpartum Psychiatric Issues

Perinatal Death

Stillbirth and neonatal death provoke much the same reactions as do losses earlier in pregnancy (as discussed earlier in this chapter), with the added stresses of full-term labor and delivery and the probability that many practical provisions for the expected infant have been made. Clinical practice in dealing with the bereaved and disappointed parents has varied over time. It is probably best to offer parents the opportunity to see or not to see the stillborn infant and to allow them to decide. Many bereaved parents report that their grief is exacerbated by the failure of friends and relatives to acknowledge the loss. For some, naming the baby and having a funeral service, with or without a burial, are helpful rituals. A religious leader of the parents' choice also can help them reconcile their rage at God for depriving them of their child with their need to derive support from their faith.

When the cause of fetal or neonatal death is not clear, an autopsy or other tests may be performed. The results will not be immediately available. The obstetrician, pathologist, geneticist, and psychiatrist may want to meet with the parents some weeks later to convey the results, answer questions, observe the grieving process, and determine whether additional supports are necessary. Stillbirth increases the risk of posttraumatic stress, anxiety, and depression in a subsequent pregnancy, for both men and women (Turton et al. 2006). One study found these sequelae generally resolve within 1 year after the birth of a subsequent healthy child (Turton et al. 2001). Premature birth or the stress of complicated, or even normal, labor can precipitate posttraumatic stress symptoms as well, especially in women with preexisting psychiatric symptoms (particularly anxiety in late pregnancy) and poor social supports (Soderquist et al. 2009; Zaers et al. 2008).

Postpartum Psychiatric Disorders

"Baby Blues"

Within days after birth, 50%–80% of women experience significantly heightened emotional lability. After a few days, the symptoms abate. The phenomenon has been reported in a wide variety of cultures and is not related to demographic variables (Sakumoto et al. 2002). Although the patient may be moved to tears from time to time, none of the other signs or symptoms of depression are present, nor do they develop as an exacerbation of this condition. Some mothers also experience periods of joy or euphoria. This self-limited state may be caused by prolactin or other hormones. If these symptoms are excessive, an alternative diagnosis such as depression or psychosis should be consid-

ered. An interesting hypothesis is that "baby blues" may be related to the effects of oxytocin and other hormones involved in the initiation of mother–infant attachment and maternal behavior (Miller and Rukstalis 1999). Clinicians should offer reassurance. This is especially important because media reports of postpartum depression leading to the murder of children have frightened so many families. About 25% of women with baby blues will not improve within 10 days and will progress to postpartum depression.

Postpartum Depression

Postpartum depression occurs in up to 10%–15% of mothers in North America. Some cases of postpartum depression are simply continuations of antepartum depression. Symptoms can begin anytime from days to months after birth but generally later than "baby blues" and range from 4 weeks to 12 months postpartum. The diagnostic process can be complicated by the similarity of symptoms of the aftermath of delivery and the stresses of caring for a newborn and the signs and symptoms of depression. New mothers are often tired, sleepless, distracted, and preoccupied with infant care rather than the enjoyment of previous pursuits. Their meal schedules and sleep are disrupted. It is useful to ask whether the mother can sleep when the baby sleeps.

Risk factors include previous depression, especially postpartum depression; complications of birth; and poor social supports. Newly immigrant women, who often have poor social supports, are at higher risk (Stewart et al. 2008). There appears to be some cross-cultural variation in the incidence of postpartum depression; this may be related to contrasting patterns of antepartum and postpartum care and social support. In many cultures, the newly delivered woman is traditionally provided with rest, warmth, and enriched nutrition (Kaewsarn et al. 2003). In North America, medical attention decreases drastically after an infant is delivered; few medical and social resources are available to the new family. Some evidence shows that postpartum calls and visits from health care professionals decrease the incidence of postpartum depression (Chabrol et al. 2002). Endocrine factors also play a major role; some women are particularly vulnerable to rapid changes in hormone levels at any time across the life span, and some authors have proposed that there is a reproductive "subtype" of depression (Payne et al. 2009). Estradiol and progesterone are strongly implicated (Bloch et al. 2003). Women with thyroid autoantibodies have an increased risk for postpartum depression, but thyroxine administration does not appear to reduce that risk (B. Harris et al. 2002; Oretti et al. 2003).

Anxiety accompanies pre- and postpartum depression in up to 50% of cases (Ross et al. 2003). In an Australian study of 408 primigravidas, the inclusion of panic disorder and acute adjustment disorder with anxiety doubled the

cases of postpartum psychiatric illness identified. Antecedent anxiety disorders were a more important risk factor for postpartum depression than was antecedent depression (Matthey et al. 2003a).

The thought content of a woman with postpartum depression centers on mothering (e.g., ruminating that she is not a good mother and that her infant is suffering as a result). Sometimes the woman becomes obsessed with thoughts of harm coming to the infant and vividly imagines his or her injury or death. These ruminations are found both in women with OCD and in those with other psychiatric illnesses (e.g., major depressive disorder). There are no reports of women harming their infants solely as a result of obsessional thinking. Most women realize that these thoughts are unreasonable and go to great lengths to avoid harming their infants. However, obsessions must be differentiated from postpartum psychosis, where women are out of touch with reality and are not aware that their thoughts are unreasonable. Reassurance of eventual recovery is crucial to patient care. One of the fears of women with postpartum depression, and their families, is that the depression is the first sign of a condition that will result in self-harm or infanticide. Relatives may be tempted to take over care of the infant of a depressed mother to allow her to rest and recuperate. This can be counterproductive, exacerbating her sense of failure and deprivation. It is preferable for them to help the mother with household tasks, allow her to care for the infant, and reinforce her sense of maternal adequacy.

Although obstetricians have become more aware of and responsive to postpartum depression as a result of the notorious cases in the media and educational initiatives by a variety of professional and advocacy organizations, they may not be in the optimal position to identify it. Women are discharged from the hospital within a day or two after delivery, with a rather cursory office follow-up visit 4–6 weeks later. Obstetric clinicians should be encouraged to increase their contacts with and availability to new mothers. A simple query about depressed mood is often successful in identifying cases (Wisner et al. 2002b). After the birth, the specialist women see most is the pediatrician. There have been attempts, with mixed success, to convince pediatricians to be vigilant for maternal postpartum depression. Several validated scales are available for screening: the Edinburgh Postnatal Depression Scale (Matthey et al. 2003b) is the best known. The efficacy and effectiveness of screening for PPD are controversial (especially if good systems are not available for referral and treatment). Researchers in Hong Kong determined that screening should be delayed for several days after delivery in order to be accurate (Lee et al. 2003), although earlier assessment has been found accurate in North America (Dennis 2003). Screening in an in-

ner-city population in New York uncovered far more cases than were anticipated (Morris-Rush et al. 2003).

Postpartum Psychosis

Postpartum psychosis is characterized by extreme agitation, delirium, confusion, sleeplessness, and hallucinations and/or delusions. Onset can be sudden and usually occurs between days 3 and 14 postpartum, with 90% of episodes occurring within 4 weeks of delivery (Harlow et al. 2007). The overall incidence of postpartum psychosis is estimated at 0.1%–0.2% and appears to have been stable for more than a century and among cultures. A Swedish population-based study found that 40% of women who were hospitalized for psychosis or bipolar disorder during pregnancy were rehospitalized in the postpartum period (Harlow et al. 2007). Only a fraction of these women will go on to attempt suicide or infanticide, but the risk and the stakes are high enough to warrant considering postpartum psychosis as a medical emergency and hospitalizing the patient, at least for a period of observation. Women who have schizophrenic episodes may have more difficulty parenting their children after recovery from the acute episode than do women with other kinds of postpartum psychosis (Riordan et al. 1999).

Many experts believe that most episodes of postpartum psychosis are bipolar disorder (Attia et al. 1999; Chaudron and Pies 2003). The risk of postpartum relapse of bipolar disorder is 30%–50%; these relapses can be acute and severe. If pregnant women with bipolar disorder discontinue medication, there should be a plan for immediate medication resumption at delivery to lower the risk of recurrence (L.S. Cohen et al. 1995).

Trials and media coverage of cases of infanticide disclose major misunderstandings about the state and motivation of the perpetrators. Most often, the mother in these cases has command hallucinations or delusions and/or is suicidal and does not wish to leave the child behind but wants to be reunited with him or her in Heaven. Appleby et al. (1998) reported that the risk of suicide in the first postnatal year is “increased 70-fold” in women hospitalized for a postpartum psychiatric disorder. In some countries, there has been a very proactive stance toward the identification and treatment of women who are at particularly high risk of developing severe mental illness postpartum. For example, in England, the National Institute for Clinical Excellence (NICE) has issued guidelines that all health authorities in England are meant to implement (Department of Health 2007).

Custody

Psychiatric illness in and of itself does not rule out the possibility of adequate mothering. For general evaluation, and

for the legal and medical records, when the question of custody arises, it is useful to perform a regular mental status examination. What are most important, however, are the parenting knowledge, attitudes, and behaviors of the newly delivered patient. Has she been able to arrange adequate accommodations for herself and the infant? How does she plan to feed the infant? Does she know approximately how often a newborn must be fed and its diaper changed? Does she have delusions about the infant?

Observation of mother–infant interaction is key. It is very difficult to predict how a person will behave with an infant in the absence of the infant. The postpartum staff should allow the mother as much observed time with the infant as possible and note how the mother responds to the infant's cries and other needs, whether she can feed the infant and change his or her diapers, and how she relates to the infant overall. New mothers without psychiatric disorders can be tired and overwhelmed; expectations should be realistic.

Custody decisions can be life-or-death decisions. Removing a child from his or her mother, unless a well-disposed and capable relative can take over his or her care, exposes the child to the possibility of a lifetime in transient foster care situations. Allowing a severely ill mother to retain custody exposes the child to possible abuse and neglect. Interactions with child protective services can be problematic. Depending on current resources and recent scandals, child protective services may take a child into custody without giving the mother a chance to show her ability to parent, or they may refuse to intervene with a dangerously psychotic mother because the infant has not yet been harmed. Often, the most appropriate approach, when available, is the provision of home help and/or visiting nurse services, which provide both support and further opportunities for observation of the parenting and the condition of the infant. Having a mental illness does not diminish, and may exacerbate, the grief and rage of a mother whose child is taken away.

Legal aspects of maternal competency are discussed in Chapter 2, "Legal Issues."

Psychotropic Drugs, Psychotherapy, and Electroconvulsive Therapy in Pregnancy and Lactation

No perfect solution exists for treating mental illness during pregnancy and lactation, and a risk–benefit decision must be made in the face of imprecise data. Three types of adverse fetal effects may occur when psychotropics are taken during pregnancy. Teratogenic effects may be incurred from first-trimester exposure, neonatal toxicity and with-

drawal syndromes are related to third-trimester exposure, and behavioral or developmental effects may manifest later in childhood (Marcus et al. 2001; Wisner et al. 2002a).

How depression should be treated during pregnancy is a subject that receives continued scrutiny from the media and challenges both providers and patients. Untreated depression during pregnancy or postpartum is associated with increased morbidity in the mother and her offspring. Potential complications in pregnancy and at delivery include increased risk of poor prenatal care, substance use in pregnancy, preterm birth, and low birth weight (Oberlander et al. 2006; Steer et al. 1992; Suri et al. 2007; Yonkers et al. 2009). Women with depression in pregnancy are at high risk for postpartum depression and for impaired mother–infant interactions that have been associated with poor developmental and emotional outcomes in the offspring (Deave et al. 2008; DiPietro et al. 2006; Punamaki et al. 2006). Unfortunately, evidence indicates that depression is seriously undertreated during pregnancy, with less than 20% of women who experience depression during pregnancy and the postpartum seeking treatment (Marcus 2009).

Although psychotherapy is indicated as acute therapy for mild to moderate depression, it may not be adequate if a woman has severe depression. Also, even in mild to moderate depression, psychotherapy may not improve depression for several weeks to months, leaving the mother and fetus (or even infant) exposed to the effects of untreated depression during that time. Antidepressant medication is an effective treatment of antenatal depression (Dennis and Stewart 2004). However, concerns remain among patients and prescribing physicians about the safety of antidepressant exposure for the fetus/neonate. Previous meta-analyses of data examining potential relationships between antidepressant exposure and neonatal/fetal outcomes have been largely reassuring (Addis et al. 2000; Einarson and Einarson 2005). More recently, however, there has been renewal of the controversy regarding the safety of antidepressant use during pregnancy. Paroxetine has been shown in some, but not all, studies to be associated with heart defects.

Two large prospective databases on antidepressant use in pregnancy were recently published. The Danish database of 493,113 children born between 1996 and 2003 included 1,370 mothers who had had two or more prescriptions of an SSRI filled during the period 28 days before through 112 days after the beginning of gestation (Pedersen et al. 2009). After researchers controlled for maternal age, mental status, and smoking, antidepressant use showed no association with overall fetal major malformations. However, an increase in cardiac septal defects was observed (OR = 1.99; 95% CI = 1.13 to 3.53). Both sertraline and citalopram were associated with an increase in septal

defects, and exposure to more than one type of SSRI was associated with the greatest increase in septal defects (OR=4.7; 95% CI=1.74 to 12.7). The absolute increase in risk for fetal septal defects was low (0.9% for exposure to one SSRI; 2.1% for exposure to more than one SSRI).

The Swedish Medical Birth Registry included 14,821 women who used antidepressant medication in pregnancy from 1995 to 2007 (Reis and Källén 2010). There was an excess of births before gestational week 37 and various pregnancy complications in women using antidepressants. The odds ratios were higher for hypoglycemia, respiratory distress, lower Apgar scores, and jaundice in babies exposed to antidepressants in utero. Atrial septal and ventricular septal defects were more frequent in infants exposed in utero to TCAs (OR=1.84; 95% CI=1.13 to 2.97) and paroxetine (OR=1.66; 95% CI=1.09 to 2.83). Paroxetine use was also associated with fetal hypospadias (OR=2.45; 95% CI=1.12 to 4.64). Although the investigators controlled for maternal age, smoking, and some other drug use, it was not possible to dissociate outcomes from the effects of depression, other comorbidities or exposure, or ascertainment bias.

Reports of small increases in fetal cardiovascular defects have been inconsistently reported for several other antidepressant drugs, leading to questions about possible drug class effects. Short-term adverse neonatal effects and neonatal pulmonary hypertension associated with late third-trimester exposure to SSRIs have been reported (Chambers et al. 2006; Koren and Boucher 2009). In all cases, the small absolute risks associated with antidepressant use in pregnancy must be weighed against the risk of not treating depression.

Hence, the decision about whether to take antidepressant medication in pregnancy is not straightforward. None of the treatment alternatives comes without risk of undesirable outcomes, and there is ongoing scientific uncertainty about risks and benefits of treatment. An added layer of complexity is that a woman is making this decision not only for her own health but also for the health and development of her unborn child. Wisner et al. (2000) presented a clinical decision-making model to aid both clinician and patient in making an optimal clinical decision about treatment for depression in pregnancy. The model guides physicians through the concepts of a diagnostic formulation and presentation of treatment options, including the risks of both untreated depression and antidepressant treatment in pregnancy. The model then guides physicians to help each patient make decisions about treatment based on the patient's values, perceptions of risk, and capacity to consent to treatment. Consideration should also be given to whether a woman has adequate support to make this complex decision.

Classification of Drugs

Current FDA risk assignments of drugs in pregnancy range from A (no risk) through B, C, D, and X (contraindicated). This classification is primarily based on concerns about teratogenicity and neonatal toxicity, because few or no data exist for later child behavior or development. The FDA classification lags behind current data and experience. At present, bupropion, clozapine, and buspirone have a B designation (absence of human risk) with a caveat of limited data. Most SSRI antidepressants, some TCAs (including desipramine), newer antidepressants (such as mirtazapine, nefazodone, and venlafaxine), clonazepam, and most conventional and atypical antipsychotics have received a C designation (human risk should not be eliminated because of inadequate human clinical trials and no or some risk in animals). Lithium, carbamazepine, sodium valproate, most TCAs, and some benzodiazepines (other than clonazepam) have received a D designation, indicating evidence of fetal risk without an absolute contraindication during pregnancy. As a result of concerns about the use of paroxetine (an SSRI) in pregnancy, it has been reclassified as a category "D" medication by the FDA (U.S Food and Drug Administration 2006). Because the FDA is currently revising its method of classifying drug risk in pregnancy, physicians should consult the most recent classification as well as other new literature.

Use of Psychotropic Medication

General principles of using psychotropic medication should guide management of the pregnant women. However, there are additional considerations. Changes in drug metabolism and extracellular fluid volume during pregnancy may require dosage adjustment for several drugs. For example, approximately twice the usual dose of lithium carbonate is required in the second and third trimesters to achieve therapeutic serum levels (Stewart and Robinson 2001b). (See also Chapter 38, "Psychopharmacology," for a discussion of pharmacotherapy during pregnancy.) A longstanding debate has existed, with contradictory data from several studies, on whether diazepam in pregnancy is associated with cleft lip or cleft palate. Some benzodiazepines, such as triazolam, temazepam, and flurazepam, have received an X designation, indicating complete contraindication in pregnancy (Marcus et al. 2001). A consensus statement by the American Psychiatric Association and American College of Obstetrics and Gynecology on the use of antidepressants in pregnancy gives current scientific findings and guidance (Yonkers et al. 2009). Insufficient data are available to ensure safety for most novel antipsychotics; however, high-potency antipsychotics, such as haloperidol,

appear to be relatively safer in pregnancy (Einarson and Boscovic 2009).

Early reports warned of congenital heart disease in infants exposed in utero to lithium carbonate, but subsequent analyses have shown these risks to be only slightly greater than those in the general population (Altshuler et al. 1996). Other mood stabilizers such as carbamazepine and valproic acid are associated with greater teratogenicity than lithium (Stewart and Robinson 2001b). A recent study of antiepileptic drugs found that fetal exposure to valproate (although not carbamazepine or lamotrigine) was related to poorer cognitive development at age 3 years in children of mothers with epilepsy (Meador et al. 2009). For women with unstable bipolar disorder, it is reasonable to continue lithium throughout pregnancy while carefully monitoring serum levels. Divided doses may be safer than once-daily dosing. An ultrasound during the first trimester may be used to identify possible congenital cardiac malformations. Dosage should be reduced after delivery to avoid lithium toxicity in the early postpartum period.

Breast-Feeding and Psychotropic Drugs

The use of psychotropic drugs by breast-feeding women remains controversial. The amount of drug present in breast milk is small but extremely variable over time, even in the same woman. No controlled studies of the effects of psychotropic medication during breast-feeding exist, but several reviews provide further guidance (L.S. Cohen 2007; Yonkers et al. 2004). In general, it appears relatively safe for depressed women to take antidepressants and typical antipsychotics while breast-feeding full-term and healthy babies. Fewer data are available for premature infants or newer antidepressants and atypical antipsychotics. However, a systematic review of the literature on antipsychotics in breast-feeding advises that clozapine is not recommended due to risk of blood abnormalities and that olanzapine may increase the risk of extrapyramidal side effects in the infant (Gentile 2008). Useful reviews of mood stabilizers during lactation include Yonkers et al. (2004) and L.S. Cohen (2007). Lithium has been considered to be contraindicated while breast-feeding due to concerns about neonatal toxicity from passage of lithium into the breast milk (Stewart and Robinson 2001b). However, some experts are revisiting the postpartum use of lithium, given its unparalleled clinical efficacy for certain women who wish to breast-feed. A study measuring lithium levels in 10 breast-fed infants of mothers who were taking lithium found that breast milk levels were low and well tolerated. There were no adverse effects on the infants, but these results should be interpreted with caution (Viguera et al. 2007a). If lithium is used during lactation, both the in-

fant's lithium levels and complete blood count should be monitored.

No adverse effects from the use of carbamazepine, valproate, or lamotrigine have been reported. However, serum concentrations of lamotrigine were 30% of maternal levels in one study, and Yonkers et al. (2004) recommend that such infants be monitored for rash if lamotrigine is used. Decisions about the care of women with a history of bipolar illness must be made on a case-by-case basis given the high risk of recurrence of bipolar disorder in the postpartum period (Viguera et al. 2007b).

Because new information on the use of drugs during pregnancy and lactation is frequently published, the reader is advised to consult the most recent reference in making risk-benefit decisions. The clinician must be cognizant that untreated mental illness in pregnancy and postpartum also has risks to the woman and the developing fetus and newborn child. Decisions should be made in consultation with the woman (and partner, if appropriate) and other health care providers (such as obstetricians and pediatricians), and discussions should be carefully documented in the patient's chart.

Psychotherapy in Pregnancy and Postpartum

Spinelli and Endicott (2003) and O'Hara et al. (2000) found interpersonal psychotherapy to be effective in the treatment of depressed pregnant and postpartum women, respectively. However, a 2007 Cochrane review concluded that there are still insufficient data to make generalized recommendations about the use of psychotherapy in pregnancy (Dennis et al. 2007). Because many women refuse to take medication while pregnant or breast-feeding, psychotherapy is often a viable alternative. However, its efficacy for severe depression is unproven.

Electroconvulsive Therapy

ECT is generally regarded as a safe and effective treatment for severe depression, affective psychosis, and catatonia in pregnancy and the puerperium. ECT is underused and should be considered in emergency situations in which the safety of the mother, fetus, or child is jeopardized; to avoid first-trimester exposure to teratogenic drugs; and in patients who are refractory to psychotropics or who have previously had successful treatment with ECT (Stewart and Robinson 2001b). ECT for acute affective psychotic episodes can be effective and is relatively safe for the fetus (Anderson and Reti 2009; see also Chapter 40, "Electroconvulsive Therapy"). Newer physical treatments for depression, such as vagal nerve stimulation, deep brain stimulation, and transcranial magnetic stimulation, have not been adequately studied in pregnant women.

Premenstrual Psychiatric Symptoms: Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Background

The study of premenstrual symptoms poses unique methodological challenges. Most women in North America, if asked, report premenstrual mood, behavior, and somatic changes. There is a strong cultural belief that the menstrual cycle is associated with such negative changes. However, it is also clear that both women and men attribute unpleasant or problematic feelings and behaviors to the menstrual cycle regardless of whether they are related. The majority of women presenting for care of premenstrual symptoms, when assessed with prospective ratings and careful diagnostic interviews, have symptoms completely unrelated to their menstrual cycles. Nevertheless, premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD) remain popular attributions and diagnoses among women themselves, their families, and physicians. More commonly, women may experience premenstrual worsening of mood and anxiety disorders.

Etiology

Many attempts have been made, over decades, to identify circulating levels of reproductive hormones to account for mood symptoms occurring in concert with reproductive events and cycles. The reality is probably more complex than linear effects of hormone levels on mood. It would seem that some women are particularly sensitive not to specific levels but rather to changes in the levels of reproductive hormones. It has been reported for some time that women who report premenstrual symptoms are more likely to experience postpartum depression and may be predisposed to perimenopausal mood symptoms as well (Payne et al. 2007). Lending biological support to this hypothesis, Huo et al. (2007) reported that the risk of PMDD is associated with genetic variation in the estrogen receptor alpha gene, possibly representing abnormal estrogen signaling during the luteal phase of the menstrual cycle. This may lead to PMDD symptoms via estrogen's effects on serotonin, norepinephrine, gamma-aminobutyric acid (GABA), allopregnanolone, and various endorphins. Further corroborating evidence for treating PMDD as a distinct disorder involves emerging functional neuroimaging findings that women with PMDD may selectively respond to negative stimuli only during the premenstrual phase of their cycle (Protopescu et al. 2008).

Diagnosis

Currently, premenstrual psychiatric symptoms are conceptualized and treated as part of the mood disorder spectrum. Experts, and the framers of DSM, have attempted to distinguish normative mood variations from symptoms worthy of medical attention by publishing research criteria for PMDD. For many years, the study of premenstrual psychiatric symptoms was complicated by the lack of a specific and uniform definition. More than 100 physical, emotional, and cognitive signs and symptoms have been attributed to PMS (Janowsky et al. 2002). PMDD is listed in DSM-IV-TR as an example of a depressive disorder not otherwise specified (NOS) and is described as follows:

In most menstrual cycles during the past year, five (or more) of the following symptoms (e.g., markedly depressed mood, marked anxiety, marked affective lability, decreased interest in activities) were present for most of the time during the last week of the luteal phase, began to remit within a few days after the onset of the follicular phase, and were absent in the week postmenses. The disturbance markedly interferes with work or school or with usual social activities and relationships with others. (American Psychiatric Association 2000, p. 774)

According to DSM-IV TR, approximately 75% of women report mild premenstrual mood changes, and 20%–50% report at least moderate changes. Only 3%–5% of women report severe premenstrual mood symptoms rated prospectively over a 2-month period, fulfilling the proposed DSM IV-TR criteria for PMDD (American Psychiatric Association 2000). Given the tendency to retrospectively overattribute symptoms to the menstrual cycle, prospective daily ratings and careful evaluation for other psychiatric disorders are essential (Landen and Eriksson 2003; Lane and Francis 2003).

Irritability has been conceptualized as a common premenstrual symptom. Born et al. (2008) have validated a 14-item self-report and 5-item observer-rated rating scale for irritability. This scale covers the core elements of irritability—annoyance, anger, tension, hostile behavior, and sensitivity. Specific assessment of irritability may have relevance to both the impact of menstrual cycle-related mood disorders and their management. This may be of particular importance for women who do not meet criteria for DSM-IV mood and anxiety disorders but who present with guilt and shame related to their premenstrual irritability. The possibility of cyclical changes in symptoms and/or treatment response in all diagnostic categories should be considered in all menstruating women or at least in those whose diagnoses or treatment responses are puzzling or unsatisfactory (Landen and Karamchandani 2002).

Psychosocial Effects

Another controversial aspect of PMDD is the severity or effect of the symptoms. The DSM definition specifies a significant negative effect on life function. It has been difficult to specify the distinction between PMS and PMDD in this regard (Smith et al. 2003). Preexisting beliefs about work effect may color the findings in studies that use self-reports (Steiner et al. 2003). A large study of randomly selected members of a health maintenance organization found that women with PMDD reported decreased work productivity as compared with women with milder premenstrual symptoms, but the women with PMDD also reported lower productivity than the others in the follicular phase after the onset of menses, when their PMDD symptoms, according to the definition, should have been absent. This study did not produce significant evidence that premenstrual symptoms, regardless of their level of severity, caused women to stay in bed, reduce their hours at work, or decrease their activities at home or school (Chawla et al. 2002).

Management

No specific empirically supported treatments for PMS are available, but several approaches have proved helpful for both the symptoms and the patients' general health. These include taking vitamins (especially B vitamins), reducing or eliminating caffeine and nicotine, exercising, and using stress reduction techniques. Many women with premenstrual symptoms attempt complementary or alternative approaches (Domoney et al. 2003). In one study, cognitive-behavioral therapy was found to be equally effective as fluoxetine; fluoxetine produced more rapid results, and cognitive-behavioral therapy produced more lasting results (Hunter et al. 2002). Calcium carbonate also has produced promising results in one study (Thys-Jacobs et al. 1998).

Like other disorders in the mood spectrum, PMDD is well treated with SSRIs (Steiner et al. 2006). As of this writing, fluoxetine, sertraline, and paroxetine have received FDA indications for PMDD. For reasons still poorly understood, although SSRIs generally require 2–4 weeks for therapeutic effectiveness in depression, they are reported to be effective for PMDD when used only in the premenstrual phase (Halbreich et al. 2002). Perhaps because of the lack of continued administration, there is no discontinuation syndrome when they are used in this manner. A recent Cochrane Database meta-analysis confirmed effectiveness of either luteal-phase or continuous dosing of the SSRIs fluoxetine, paroxetine, sertraline, fluvoxamine, and citalopram and the highly serotonergic TCA clomipramine (J. Brown et al. 2009). Evidence does indicate that symptoms recur rapidly when luteal-phase treatment is discontinued (Pearlstein et al. 2003).

Exogenous hormones have not been traditionally effective for the treatment of PMDD. However, on the basis of randomized controlled trial evidence, the FDA has recently approved a combination of ethinyl estradiol and drospirenone for the treatment of PMDD (see Pearlstein and Steiner 2008 for summaries of these studies). It is thought that the antiandrogen and antimineralocorticoid properties of drospirenone account for the efficacy of this product (as compared to traditional oral contraceptive pills). This indication has been limited to women who desire to take an oral contraceptive to prevent pregnancy, likely because the potential for adverse effects (e.g., deep vein thrombosis, pulmonary embolism) exceeds that of the SSRIs.

Perimenopause and Menopause

The average age at menopause in North American and European women is 51 years, although the entire period of transition may extend over several years. By definition, menopause is said to have occurred after 12 months of amenorrhea, and perimenopause is that period of time leading up to menopause but before 12 consecutive months of amenorrhea. A National Institutes of Health Stages of Reproductive Aging Workshop recommended dividing perimenopause into early and late stages (Soules et al. 2001). During the perimenopause, the ovarian follicles gradually decline with age, estradiol and inhibin production by the ovary decreases, and FSH and luteinizing hormone levels rise (through loss of feedback inhibition). These changes are orchestrated through the hypothalamic-pituitary-ovarian axis, and cyclic variability often occurs throughout the transitional period. The perimenopause may be asymptomatic, but 70%–90% of women will experience some vasomotor symptoms consisting of hot flashes and night sweats. In addition, some women will experience palpitations, dizziness, fatigue, headaches, insomnia, joint pains, and paresthesias. Women also may complain of lack of concentration and loss of memory during the transitional period, but because men also complain of these symptoms, distinguishing them from normal aging is difficult. For a review incorporating the findings of the U.S. Women's Health Initiative (WHI) study with respect to the pathophysiology and management of vasomotor and vaginal symptoms during the menopausal transition, see Grady (2006).

The association of psychiatric symptoms with the perimenopause has traditionally been controversial. However, in a U.S. longitudinal prospective cohort study of premenopausal women with no lifetime diagnosis of major depressive disorder (MDD), women entering perimenopause had 1.8 times increased odds of developing depression compared to women who remained premenopausal (after ad-

justment for age and history of negative life events) (L.S. Cohen et al. 2006b). A 10-year follow-up of a population-based cohort of premenopausal women without depression or hot flashes at baseline found that 40% reported both symptoms during the study interval and that depressed mood was more likely to precede hot flashes (relative risk = 2.1, 95% CI = 1.5 to 2.9) (Freeman et al. 2009). Whether psychiatric symptoms are caused by hormonal changes, sociocultural factors, or psychological factors remains uncertain. Biological factors include estrogen shifts, whereas sociocultural theories focus on the importance of role changes in parenting, marriage, sex, and work. In addition, attitudes toward aging and female roles vary by culture. A consistent finding is that women with lower socioeconomic class and education report more perimenopausal symptoms. Psychological theories focus on stress during the perimenopausal years as a result of diminished personal and family health, socioeconomic status, family and work changes, other losses, retirement, illness, and death (Avis 2003). In addition, one study has shown that a lifetime history of major depression may be associated with an early decline in ovarian function and earlier menopause (Harlow et al. 2003). Women seeking treatment for physical symptoms in menopause clinics report a high prevalence of depression, irritability, mood lability, anxiety, lack of concentration, short-term memory loss, and decreased libido (Stewart and Boydell 1993). Other investigators have shown that prior depression is a risk factor for depression at perimenopause and that poor physical health, social circumstances, divorce, widowhood, and interpersonal stress are closely correlated with depression in menopausal women (Hunter 1990; Kaufert et al. 1992; Stewart and Boydell 1993). Women with bipolar disorder may be at increased risk for perimenopausal depression, although not necessarily mania (Marsh et al. 2008).

The incidence of depression in women mirrors estrogen shifts across the life cycle, at puberty, premenopause, postpartum, and perimenopause (Stahl 2001). This has led to studies to determine whether estrogen therapy in perimenopause can alleviate symptoms of clinical depression. Two small randomized controlled trials found that estradiol was a well-tolerated and effective treatment for perimenopausal depression (Schmidt et al. 2000; Soares et al. 2001), but this finding has not been replicated to date.

Although estrogen appears to have a salutary effect on depression in some perimenopausal women, in contrast, progesterone and progestins are known to cause dizziness, drowsiness, and sedation in many women and may be associated with negative moods (Bjorn et al. 2000). Progestins are primarily used in women with an intact uterus to prevent an increase in endometrial cancer caused by unopposed estrogen therapy.

Studies also have been conducted on the role of estrogen as an augmentation agent with antidepressants. In a pilot study, 17 women who had a partial response to antidepressants received augmentation with 0.625 mg conjugated estrogen or placebo in a double-blind design. Women receiving estrogen augmentation had significantly greater reductions in Hamilton Depression Rating Scale scores than women who received placebo (Morgan et al. 2005). Further studies of estrogen and selective estrogen receptor modulators as psychotropic augmentation agents are needed.

Moreover, the role of estrogen in psychiatric disorders is not limited to depression. Work by Kulkarni et al. (2001), Seeman (2002), and others has shown a worsening in pre-existing schizophrenic illness and other psychoses associated with decreases in estradiol during perimenopause and beyond. Interestingly, some patients appear to respond to estrogen to augment antipsychotic drugs.

Of concern, however, are results from the WHI study indicating that estrogen-progesterone therapy is associated with an increased risk of breast cancer, cardiovascular disease (Writing Group for the Women's Health Initiative Investigators 2002), cognitive dysfunction, and dementia (Rapp et al. 2003; Shumaker et al. 2003). The estrogen-only arm of the WHI was also prematurely terminated in 2004 when estrogen monotherapy was found to be associated with increased rates of stroke, dementia, and mild cognitive impairment (but not breast cancer) (Women's Health Initiative Steering Committee 2004).

Emerging evidence may affect current use, but at present, estrogen is useful to control severe vasomotor symptoms and vaginal dryness, with current FDA guidelines recommending the smallest dosage for the shortest time possible. Systematic reviews and meta-analyses of nonhormonal therapies for menopausal hot flashes concluded that there is evidence for SSRIs, SNRIs, clonidine, and gabapentin, although the efficacy of these treatments is less than that of estrogen. Results were mixed with respect to the efficacy of isoflavone extracts (Toulis et al. 2009).

In conclusion, the many estrogen effects on brain function are complex. The role of estrogen in treating mood, cognition, and psychosis, and as a psychotropic augmentation agent, requires further adequately powered randomized controlled trials. Personal, social, and physical factors always should be considered in assessing the individual woman, and psychotherapy may be helpful in navigating the many transitions at midlife.

Urinary Incontinence

Urinary incontinence, the involuntary loss of urine, affects up to 23% of adults (Roe et al. 1999), with a prevalence in women that is twice that in men (Melville et al. 2002).

Urinary incontinence affects the physical, psychological, social, and economic well-being of individuals and their families and imposes a considerable economic burden on health and social services. Despite increasingly available and effective treatments for urinary incontinence, many women do not seek help. A Canadian population-based survey found that only 32% of women with urinary incontinence sought help from a physician, while 40% reported a significant impact of urinary incontinence on their quality of life (Vigod and Stewart 2007). Many people are reluctant to seek help because they are embarrassed or ashamed or believe that this problem is a part of normal aging

Etiology and Classification

The etiology of urinary incontinence is multifactorial and may be caused by impairment of the lower urinary tract or the nervous system or by various external factors. There are several subtypes of incontinence, but the most common are 1) stress incontinence (the involuntary loss of urine due to an increase in intra-abdominal pressure, such as coughing, laughing, or exercise); 2) urge incontinence (the involuntary loss of urine preceded by a strong urge to void whether or not the bladder is full); and 3) mixed incontinence (Melville et al. 2002).

Psychosocial Effects

Urinary incontinence may affect quality of life, sexual function, and mood. Studies have found that incontinence has a major negative effect on quality of life (Melville et al. 2002). A population-based cross-sectional study of nearly 6,000 American women between the ages of 50 and 69 years found that 16% reported mild, moderate, or severe incontinence. After adjustment for medical morbidity, functional status, and demographic variables, women with severe and mild to moderate incontinence were 80% and 40%, respectively, more likely to have depression than were continent women (Nygaard et al. 2003).

These findings were confirmed in a Canadian population-based cross-sectional study of 69,003 women, which found that the 12-month prevalence of major depression was 15.5% in women with urinary incontinence, compared to 9.9% in women without urinary incontinence. In this study, women with comorbid depression and urinary incontinence reported substantially worse quality of life than women with either condition alone (Vigod and Stewart 2006). In another population-based study, the severity of urinary incontinence was related to the risk of depressive illness (Melville et al. 2005).

A systematic review of the literature on sexual function in women with urinary incontinence (Shaw 2002) found that most studies were of poor quality. They concluded that further research in which standard definitions and

measures of sexual impairment are used is needed to establish reliable information and prevalence estimates. The Female Sexual Function Index (FSFI) has been used for this purpose in more recent studies. Although results are not always consistent, urinary incontinence appears to negatively affect all domains of sexual function, including desire, arousal, and orgasm (Aslan et al. 2005; B.L. Cohen et al. 2008; Salonia et al. 2004).

Role of the Psychiatrist

Given the high prevalence of incontinence, particularly in middle-aged and older women, and women's frequent reluctance to disclose their symptoms, psychiatrists may wish to tactfully ask about urinary problems, as well as comorbid psychiatric conditions and adjustment problems.

TCAs and duloxetine (a dual-action SNRI) are useful treatments for stress urinary incontinence, particularly in women who have concurrent depression (Mariappan et al. 2007). However, although duloxetine is approved in Europe for urinary incontinence, it has not been approved in North America for this indication. Other treatments that have been used for urinary incontinence include behavioral training (with or without biofeedback), pelvic floor exercises, other drug therapies, intrapelvic devices such as pessaries, and surgical procedures (Rogers 2008).

Psychosomatic Obstetrics/ Gynecology and Men

A woman's significant other may be female or male, but published studies of relationships' effects on obstetric and gynecological events have been performed on heterosexual couples. Virtually every study of the psychosocial aspects of an obstetric and gynecological event or treatment indicates that the attitude of the male partner is a (or the) major determinant of outcome. Women turn to their significant others for reaffirmation of their worthiness if infertile, for reaffirmation of their femininity after hysterectomy, and for help deciding whether to take psychotropic medications while pregnant and whether to breast-feed or bottle-feed. Failure to achieve consensus on such decisions can cause serious long-term repercussions, as when a child is born with problems after (although not necessarily because of) the use of psychotropic medication during the mother's pregnancy, and the child's father blames the mother.

Fathers, brothers, sons, male partners, and husbands can be deeply affected by the obstetric and gynecological experiences of the women they care about, but they often feel uncomfortable, ignored, and excluded when their female loved ones are receiving care (Abboud and Liamputong 2003; Buist et al. 2003). As mentioned in the section

on infertility, men and women may manifest their feelings differently. Women are more likely to show emotion and to want to talk to friends and relatives. Men are more likely to keep their emotions to themselves and to withdraw into work or other activities. Women can mistake this behavior for a failure to care. Men can feel that their presence only makes their loved ones cry. Sometimes, one of the most useful interventions a psychiatric consultant can perform is to facilitate communication within the family.

Conclusion

Obstetricians and gynecologists are busy practitioners, challenged to deal with both specialized technological developments and primary care and burdened by the likelihood of lawsuits. Despite the intense emotional aspects of much of their clinical work, obstetricians and gynecologists have relatively little training or time for psychiatric problems. The scope of psychosomatic medicine in the area of obstetrics and gynecology includes psychopathological aspects of normal reproductive events, psychiatric aspects of obstetric and gynecological diseases and treatments, and psychiatric conditions specific to women's reproductive health. Gender-based medicine, which intersects psychosomatic obstetrics and gynecology at many points, is an exciting and promising area of research and clinical practice. Myriad opportunities exist for providing practical assistance to obstetricians and gynecologists and the women who are their patients, for educating fellow psychiatrists about developments in obstetrics and gynecology, and for conducting basic and clinical research.

Pediatrics

Brenda Bursch, Ph.D.

Margaret Stuber, M.D.

IN THIS CHAPTER, WE PROVIDE a brief overview of the major issues in psychiatric or psychological consultation to pediatrics. (For pediatric topics discussed elsewhere in this book, see Chapter 13, “Deception Syndromes: Factitious Disorders and Malingering”; Chapter 14, “Eating Disorders”; Chapter 29, “Dermatology”; and Chapter 30, “Surgery.”) Many of the issues addressed in pediatrics are similar to those seen with adults. However, because the relative importance of development and of the family is sufficiently different in pediatrics as opposed to working with adults, these issues should be considered at the start of any evaluation, and they infuse every intervention and recommendation.

General Principles in Evaluation and Management

Children’s Developmental Understanding of Illness and Their Bodies

Children’s conceptions of their bodies vary widely and are obviously influenced by experiences with illness. However, in general, children appear to follow a developmental path of understanding their bodies that roughly corresponds to Piaget’s stages of cognitive development. *Sensorimotor children* (birth to approximately 2 years) are largely preverbal and do not have the capacity to create narratives to explain their experiences. Their perception of their bodies and of illness is therefore primarily built on sensory experiences and does not involve any formal reasoning. *Preoperational children* (approximately 2–7 years) also understand through perception, but they are able to use words and some very basic concepts of cause and effect. They tend to be most

aware of parts of the body that they can directly sense, such as bones and heart (which they can feel) and blood (which they have seen come out of their bodies). However, they do not have a clear sense of cause and effect and are therefore inclined to see events that are temporally related as causally related. They also have no real sense of organs but conceptualize blood and food as going into or coming out of their bodies as though the body were itself the container. This leads to many humorous but confusing assumptions and misunderstandings. *Concrete operational children* (approximately 7–11 years) are able to apply logic to their perceptions in a more integrative manner. However, the logic is quite literal or concrete and allows for only one cause for an effect. They tend to be eager to learn factual information about the body and illness at this age but will have difficulty with any concepts that require abstract reasoning. *Formal operational children* (≥ 11 years) are able to use a level of abstract reasoning that allows discussion of systems rather than simple organs and can incorporate multiple causation of illness. It should not be assumed, however, that all adolescents approach the understanding of illness and their bodies at this level of cognition. In fact, most adults function at this level of thought only in areas of their own expertise, if at all.

As with all areas of cognition, education and experience make a difference. Children who have a medical problem (or who have a friend or family member with a medical history) may know more about the body and its function than do other children. However, children also will often be able to repeat what has been said to them without any real understanding of what it means. It is always important to assess children’s level of understanding by asking them to explain in their own words or give their own ver-

sion of why something is happening. This can alert you and the treating team to misunderstandings or fears that could influence adherence to the treatment plan.

Family Systems

No pediatric patient can be considered in isolation from his or her family. Parents are the legal decision makers for the child and thus are involved in all aspects of his or her care. Parents are also the ones to whom children look to understand the world. It is partially from their reactions to the illness and the treatment that the child determines how dangerous this is and how to respond (McLeod et al. 2007). Thus, parental fear, helplessness, anger, or withdrawal is important to address.

Psychiatric Issues

Psychological Responses to Illness

Overview

Psychological distress in response to serious pediatric illness has been a focus of many disease-specific and noncategorical studies over the years. Often symptoms of depression, anxiety, and behavior problems are grouped together. For example, a review of empirical studies of pediatric heart transplant recipients found that 20%–24% of these children experienced significant problems of psychological distress (Todaro et al. 2000). A study of children with epilepsy that used the State-Trait Anxiety Inventory and the Children's Depression Inventory (Oguz et al. 2002) found that the epileptic children reported significantly more depressed and anxious symptoms than did a control group. Even in children undergoing a surgical procedure as minor as a tonsillectomy, 17% of 89 children followed up prospectively had temporary symptoms consistent with a depressive episode (Papakostas et al. 2003). In some cases, the effects can be longer lasting, as was found in a study of 5,736 childhood cancer survivors, studied as young adults, who reported significantly more symptoms of depression than did their control siblings (Zebrack et al. 2002).

An area of increasing clinical focus is illness- or treatment-related trauma symptoms. For example, Kean et al. (2006) found that adolescents with asthma, especially those who have experienced a life-threatening event, as well as their parents, have high levels of posttraumatic stress symptoms (20% and 29% meeting posttraumatic stress disorder [PTSD] criteria, respectively). Rennick et al. (2002, 2004) found that children who were younger, were more severely ill, and experienced more invasive procedures had significantly more medical fears, a lower sense of health control, and chronic posttraumatic stress symptoms for 6 months after hospital discharge; they also

found that exposure to high numbers of invasive procedures was the most important predictor of posttraumatic stress symptoms at 6 weeks after hospital discharge. The symptoms assessed in many of these cases would not necessarily meet criteria for a DSM diagnosis. However, these symptoms do appear to be associated with decrease in function. For example, the type of depression that is seen in association with chronic pain of various etiologies has been found to be strongly associated with functional disability (Kashikar-Zuck et al. 2001).

Social support appears to be a key element in psychological adjustment to illness. Social support was found to correlate negatively with problem behavior in adolescents with human immunodeficiency virus (HIV) over a period of 3 years (Battles and Wiener 2002). In a study of 160 pediatric rheumatology patients, children with higher classmate support had lower levels of depression (von Weiss et al. 2002). Depressed parents of chronically ill children have been found to have depressed children (Williamson et al. 2002). Social support has medical implications as well. For example, families that are less caring or are in more conflict are associated with poorer metabolic control of children with juvenile-onset diabetes (Schiffrin 2001). Studies have shown that serious pediatric illness or treatment may also lead to chronic and acute symptoms of emotional distress in the parents, which may interfere with their ability to provide support for the children. This has been found with pediatric cancer patients (Kazak et al. 1997) and pediatric transplant recipients (Young et al. 2003).

In some cases, psychological distress and behavior problems can be directly caused by physical manifestations of the illness or the treatment. For example, mood disorders and anxiety are relatively common manifestations of involvement of the central nervous system (CNS) in pediatric systemic lupus erythematosus (Sibbitt et al. 2002). Depression, anxiety, aggression, and school problems are observed as side effects of tacrolimus, given to prevent rejection of a transplanted kidney (Kemper et al. 2003). Use of steroids for inflammatory conditions, such as rheumatoid arthritis, can have significant effect on mood (Klein-Gitelman and Pachman 1998). Treatment of behavioral distress, depression, or anxiety in juvenile-onset diabetes mellitus must always consider the agitation that is symptomatic of hypoglycemia or the confusion associated with hyperglycemia (Goodnick et al. 1995).

Screening and Prevention

Because psychological adjustment problems appear to be relatively common, it is recommended that children who are chronically ill, acutely ill, or injured be screened by pediatricians or other professionals for depression, anxiety, and behavioral disturbance (Borowsky et al. 2003). Preven-

tive programs are indicated for some pediatric inpatient services in which anxiety and depression are common. For example, in chronic painful treatment situations, such as pediatric burns, in which significant emotional distress is the norm, anxiety treatment programs are best built in along with pain management programs (Sheridan et al. 1997; Stoddard and Saxe 2001). Some evidence indicates that this may help prevent development of PTSD (see Saxe et al. 1998; Stoddard and Saxe 2001). In treatments with high mortality, such as bone marrow transplantation, in which different phases of treatment appear to have varying levels of depression or anxiety associated with them (Robb and Ebberts 2003), consistent psychosocial support should be available from the start. Kazak et al. (2006) have proposed a model for assessing and treating pediatric medical traumatic stress.

Treatment Considerations

Treatment studies targeting the psychiatric symptoms of medically ill children are rare. Consequently, treatment for anxiety that persists after normal adjustment and comfort issues are addressed is similar to that provided in general psychiatric practice: cognitive-behavioral therapy (In-Albon and Schneider 2007; Kendall 1994; Ollendick and King 1998; Walkup et al. 2008) and the use of selective serotonin reuptake inhibitors (SSRIs) (Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001; Walkup et al. 2008). Individual behavioral techniques, such as exposure and systematic desensitization, can be effective for patients with simple phobias such as needle phobia or food aversion. More extensive cognitive-behavioral treatment packages that address anxiety across many dimensions (including somatic, cognitive, and behavior problems) are indicated for children with more complex anxiety disorders (Piacentini and Bergman 2001). Treatment with a combination of cognitive-behavioral therapy and an SSRI has been shown to be more effective than a single strategy approach (Walkup et al. 2008).

Because hospitalized and chronically ill children often experience many of the symptoms seen in depression, making a decision as to whether a pediatric patient should receive treatment for depression can be difficult. A depressed or irritable mood, diminished interest or pleasure in activities, significant weight loss or change in appetite, insomnia or hypersomnia, psychomotor agitation or retardation, and fatigue or loss of energy may be secondary to the medical condition or to prolonged separation from friends and family. Although medication may be indicated, often supportive and cognitive-behavioral interventions can lead to significant improvements for such symptoms (Rey and Birmaher 2009). Less common, and more concerning, are feelings of worthlessness or inappropriate guilt, diminished

ability to think or concentrate, or thoughts of suicide (Goldston et al. 1994). A careful assessment is necessary and should include suicidal fantasies or actions, concepts of what the child thinks would happen if suicide were attempted or achieved, previous experiences with suicidal behavior, circumstances at the time of the suicidal behavior, motivations for suicide, concepts and experiences of death, family situations, and environmental situations (Pfeffer 1986). Adolescents with suicidal intent and plan, family history of suicide, a comorbid psychiatric disorder, intractable pain, persistent insomnia, lack of social support, inadequate coping skills, a recent improvement in depressive symptoms, or impulsivity are at particular risk for suicide. Antidepressant medication should be started carefully in such cases. For some adolescents, the idea of suicide is an important source of control in the face of an unknown and uncontrollable illness course. Addressing a lack of perceived control, isolation, and distressing physical symptoms should be a high priority.

Pediatricians are often familiar with the use of stimulants and some antidepressants in their practice (Efron et al. 2003), but literature is limited on the use of these medications in medically ill children. The strongest research effort in child psychiatry on effective medication treatments for depression and anxiety has been with SSRIs. In multicenter trials, both fluvoxamine and sertraline have been shown to be superior to placebo in treating separation anxiety disorder, social anxiety disorder, or generalized anxiety disorder in children and adolescents (Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001; Walkup et al. 2008). Additionally, fluoxetine has been found to be effective for childhood obsessive-compulsive disorder (Liebowitz et al. 2002) and depression (Bridge et al. 2007). Antidepressants have been shown to increase the short-term risk of suicidal thinking and behavior in children and adolescents, requiring one to balance this potential risk with clinical indication (Bridge et al. 2007; Hammad et al. 2006; Mosholder and Willy 2006). When youths start taking an antidepressant, they should be closely monitored by clinicians and family members for clinical worsening, suicidal ideation, or unusual behavior changes (Birmaher et al. 2007). Meta-analysis has concluded that both fluoxetine and citalopram offer the most favorable risk-benefit profiles for the treatment of depression in children (Wallace et al. 2006). Strong evidence does not exist to support the use of tricyclic antidepressants (TCAs) or benzodiazepines as a first-line treatment for child anxiety disorders (Riddle et al. 1999). Despite a lack of supporting data, low doses of benzodiazepines are frequently prescribed by pediatricians for acute anxiety or agitation in the hospital because they can have a more immediate effect than SSRIs. Therefore, it is important to note that some anxious chil-

dren have agitated reactions to benzodiazepines. Psychiatric consultants can offer alternatives, including antipsychotics, when immediate response is necessary.

Adherence

The term *adherence* is generally used to describe the extent to which a patient's health behavior is consistent with medical recommendations. Defined as such, adherence would include not only the taking of medications and attendance at clinical appointments but also diet, exercise, and other lifestyle issues such as smoking and use of sunscreen (Lemanek et al. 2001). Adherence is measured according to blood levels, pill counts, and self-report, all of which are problematic (Du Pasquier-Fediaevsky and Tubiana-Rufi 1999; Shemesh et al. 2004). With such a wide definition and different assessment strategies, the estimates vary as to the number of pediatric patients who adhere to medical regimens for chronic conditions (Rapoff 1999; Steele and Grauer 2003). Despite these problems, there is general agreement that nonadherence with medication regimens is a serious problem in pediatric patients with both acute and chronic conditions, resulting in significant clinical morbidity (Bauman et al. 2002; DiMatteo et al. 2002; Phipps and DeCuir-Whalley 1990; Serrano-Ikkos et al. 1998).

Many variables have been cited as potential predictors of nonadherence. Older age of the child and male sex are correlated with increased nonadherence, as is longer time receiving treatment, child self-responsibility for medication, and lack of appropriate family support in most studies across a variety of illnesses (Griffin and Elkin 2001; Kahana et al. 2008b; Lurie et al. 2000; Rapoff et al. 2002; Strunk et al. 2002). The patient's health beliefs about barriers to care, severity of the illness, and susceptibility to problems have been found to be related to nonadherence in some studies (Soliday and Hoeksel 2000), whereas other studies have found that parental health beliefs did not predict adherence (Steele et al. 2001). Some investigations have suggested that cultural beliefs may be equally or more important (Snodgrass et al. 2001; Tucker et al. 2002). Although lack of knowledge would seem to be an important predictor, this has proven more difficult to measure than might be expected (Ho et al. 2003; McQuaid et al. 2003). Although one study found that mild anxiety was associated with better adherence (Strunk et al. 2002), others suggested that psychological distress was associated with nonadherence (Kahana et al. 2008b; Simoni et al. 1997).

Interventions to increase adherence have fallen under the general categories of educational (written and verbal instructions), organizational (simplification of regimens, improved access, increased supervision), and behavioral (reminders, incentives, and self-monitoring). A recent meta-analysis of 12 intervention studies to increase medication

adherence in pediatric otitis media and streptococcal pharyngitis found that multiple-strategy interventions appear to be more effective than single-strategy approaches, and education alone was not sufficient (Wu and Roberts 2008). Likewise, a meta-analysis of 70 psychological intervention studies for chronically ill youths (including children with asthma: 32 studies; diabetes: 16 studies; cystic fibrosis: 10 studies; juvenile rheumatoid arthritis: 2 studies; obesity: 2 studies; and 1 study each for hemodialysis, hemophilia, HIV, inflammatory bowel disease, phenylketonuria, seizure disorders, sickle cell disease, and tuberculosis) found medium effect sizes for behavioral and multiple-strategy interventions and a small effect size for education alone (Kahana et al. 2008a). Consistent with the larger health behavior literature, education appears to be necessary for adherence but is not always sufficient. One study found that treating liver transplant recipients for PTSD improved adherence to medication (Shemesh et al. 2000).

Death, Dying, and Bereavement

One of the most difficult issues for anyone to cope with is the death of a child (Field et al. 2003). Because of the tremendous advances in medicine over the past 20 years and the seeming unfairness of death in childhood, pediatricians and families often resist making the transition from an emphasis on cure to a focus on comfort care. The psychiatric consultant is often called when disagreement occurs within the team or between the team and the child and/or family about whether this point has been reached or about how this transition is to be approached. Sometimes these differences are the result of cultural or philosophical differences. Physicians who believe that life is to be pursued at all costs may have trouble understanding the feelings of nurses who feel that the child is being needlessly subjected to painful interventions. Families who are deeply religious and remain hopeful for a miracle may lead the medical team to request a psychiatric consult to address the family's "denial." Family members who wish to protect the child may feel that it is best to withhold information about disease prognosis or other potentially upsetting information. A dying child or adolescent might wish to be sedated to feel comfortable, whereas the family may want him or her to remain alert, or vice versa. The psychiatric consultant can serve as the interpreter and facilitate these often highly emotionally charged discussions to allow the individuals to understand one another well enough to plan together for the care of the child.

Although depression, withdrawal, and anxiety may be expected, a variety of emotional responses may be seen in terminally ill children and should be anticipated in conversations with parents. Children and adolescents may manifest their confusion and loss by negative, oppositional, ag-

gressive, or emotional acting out, as well as with apathy and withdrawal from family and friends. They may frighten the medical staff or family as they talk about death or carry on conversations with someone who has died or with God. They may seem to know when they are going to die or “take a trip.” What may initially appear to be confusion or delirium may actually be an attempt to communicate through a metaphor (Callanan and Kelley 1992). The approach of the consultant should be to allow such conversations to occur and to support the staff and parents to tolerate these attempts of the child to cope with the process of dying. Play therapy or art therapy may be particularly helpful for younger children and for older children who prefer these modalities. In some cases, children will choose to specifically address unfinished business, such as saying good-bye, making amends, being absolved of perceived transgressions, planning their memorial service, or deciding who gets particular belongings (Gyulay 1989). One study of parents of children who died of cancer found that parents rated medical care of their child higher when physicians clearly told them what to expect at the end of life, communicated in a sensitive and caring manner, and appropriately communicated with the child (Mack et al. 2005). Another study found that parents of children who died of severe malignant disease were more likely to have regrets if they had not discussed death with their child (almost a third of the parents interviewed), with no parents who discussed it having regrets about those discussions (Kreicbergs et al. 2004).

Environmental interventions can relieve many physical discomforts. Interventions to improve communication and understanding can relieve many emotional discomforts and fears. If such interventions are not sufficient to resolve distressing symptoms, medications should be considered. It is important to recognize that children and parents vary in their preferences for sedation or symptoms. It is important to understand these preferences when choosing medications. For a more thorough review of emotional and physical symptom management, see the chapter by Stuber and Bursch (2009) and the book by Behrman et al. (2004). For a more thorough review on the topic of talking to children about death, refer to the article by Stuber and Mesrkhani (2001).

Finally, consultants should be aware of community hospice services and be able to advocate for this approach to optimizing quality of life when indicated. Careful preparation and support are necessary if a family is to take a child home for the dying process. Parents typically need emotional and technical support as well as respite. Siblings will need age-appropriate information and emotional support. While it is often best for the child to be allowed to die at home, some families do not feel they can cope well with this plan. It is also important to consider

that many palliative-care treatment approaches can be used for symptom management well before a transition to hospice care is indicated or decided.

Psychiatric Disorders

Delirium

Pediatric delirium (see Chapter 5, “Delirium”) has received little research attention (Turkel et al. 2003) and is less often diagnosed in pediatrics than on the adult units (Manos and Wu 1997), especially among the younger pediatric patients (Schieveld et al. 2007). Critically ill children can develop delirium, with a hyperactive, hypoactive, mixed, or veiled presentation (Karnik et al. 2007; Schieveld et al. 2007). As in adults, it sometimes may present with what is interpreted to be psychotic symptoms (Webster and Holroyd 2000). The consultation request also may be put in terms of a request for an assessment of unexplained lethargy, depression, or confusion.

In adults, delirium has been found to be the strongest predictor of length of stay in the hospital, after studies have controlled for severity of illness, age, gender, race, and medication (Ely et al. 2001). A recent evaluation of the widely used Delirium Rating Scale found that it does appear to be applicable to children, with scores comparable to those of adults. However, the score or diagnosis of delirium in a child may not have the same implications that it has in adults. The scores for children, unlike those for adults, did not predict length of hospital stay or mortality (Turkel et al. 2003). Similarly, the Glasgow Coma Scale appears to be less effective in predicting prognosis for children than for adults (Lieh-Lai et al. 1992).

Common causes of delirium include infections, metabolic disturbances, and toxicity of medications. These can often be determined with a careful chart review. Other potentially severe or life-threatening causes of confusion include stroke (Kothare et al. 1998), confusional migraine (Shaabat 1996), neuropsychiatric symptoms of systemic lupus erythematosus (Turkel et al. 2001), or inflammatory encephalopathy (Vasconcellos et al. 1999). Less common causes of acute confusional state in children would be multiple sclerosis (Gadoth 2003) or thiamine deficiency (Hahn et al. 1998). Magnetic resonance imaging (MRI) and single photon emission computed tomography have been found to be useful in differentiation of inflammatory encephalopathy (Hahn et al. 1998) and systemic lupus erythematosus (Turkel et al. 2001), respectively.

Even after correction or treatment of the underlying etiology, the symptoms of delirium can last 1–2 weeks (Manos and Wu 1997). Therefore, symptomatic treatment is essential. Support and orienting cues can be very helpful

in reducing the fear and confusion. These include the presence of familiar objects, photographs, and people who can reassure and orient the child, as well as age-appropriate clocks, calendars, or signs. Education can help the parents understand what is happening, reduce their distress, and help them to provide support for the child rather than irritation or fear.

Given the current lack of association between pediatric delirium and adverse outcomes, pharmacological intervention is indicated only if the child is distressed by the delirium or is becoming dangerous because of his or her lack of cooperation with care. Because the research into pharmacological approaches to pediatric delirium is almost nonexistent, the general guidelines are pragmatic and are based on the adult literature and the pediatric anesthesia literature. Treatment with haloperidol or risperidone is effective (Schieveld et al. 2007). Preliminary research suggests that there may be benefit from the use of risperidone for pediatric patients with hypoactive or mixed delirium and haloperidol for patients with hyperactive delirium (Karnik et al. 2007). Avoiding or weaning off benzodiazepines, which appear to compound the confusion with sedation (Breitbart et al. 1996), often should be recommended.

Factitious Disorders

Illness Falsification

The difference between factitious disorder and malingering relates to the primary motivation for the behavior. *Factitious disorder* is defined as the intentional production or feigning (falsification) of physical or psychological signs or symptoms to assume the sick role. *Malingering* is the intentional falsification of physical or psychological signs or symptoms to achieve external gain or to avoid unwanted responsibilities or outcomes.

Little research has been conducted on the topic of illness falsification in children and adolescents. More is known about illness falsification in adults and in child victims of adults (see Chapter 13, "Deception Syndromes: Factitious Disorders and Malingering"). The literature suggests that adult factitious disorder may have origins in childhood for some individuals (Libow 2002) and that some children and adolescents who falsify illness in themselves may have had earlier experiences as a victim of illness falsification or as a recipient of caregiver reinforcement for illness falsification. The child victim experience, including feelings of powerlessness, chronic lack of control, and disappointment in the medical care system, is a possible dynamic in the future development of illness falsification.

Libow (2000) conducted the only literature review to date for cases of child and adolescent patients who falsified illness. She identified 42 published cases in which patients

had a mean age of 13.9 (range: 8–18 years). Most patients were female (71%), with the gender imbalance greater among older children. Patients engaged in false symptom reporting and induction, including active injections, bruising, and ingestions. The most commonly falsified or induced conditions were fevers, ketoacidosis, purpura, and infections. The average duration of the falsifications before detection was about 16 months. Many admitted to their deceptions when confronted, and some had positive outcomes at follow-up. The children were described as bland, depressed, and fascinated with health care.

Child Victims of Illness Falsification

Illness falsification can include exaggeration, fabrication, simulation, and induction. *Exaggeration* is embellishment of a true symptom or problem. *Fabrications* are false statements made by the abuser about the victim's medical history or symptoms. *Simulation* can include the alteration of records, medical test procedures, or symptoms to incorrectly suggest a problem. *Induction* is directly causing a problem or worsening a preexisting problem. Child victims of illness falsification (called *Munchausen syndrome by proxy* when the abuser's behavior is due to factitious disorder not otherwise specified [NOS]) experience significant psychological problems during childhood, including feelings of helplessness, self-doubt, and poor self-esteem; self-destructive ideation; eating disorders; behavioral growth problems; nightmares; and school concentration problems (Bools et al. 1993; Libow 1995; Porter et al. 1994). Adult survivors describe emotional difficulties, including suicidal feelings, anxiety, depression, low self-esteem, intense rage reactions, and PTSD symptoms (Libow 1995).

Ayoub (2002) presented longitudinal data on a sample of 40 children found by courts to be victims of illness falsification. The findings indicated that child victims frequently develop serious psychiatric symptoms that vary depending on the child's developmental age, the length and intensity of the child's exposure, and the current degree of protection and support. She found that PTSD and oppositional disorders are significant sequelae, as are patterns of reality distortion, poor self-esteem, and attachment difficulties. Although these children can superficially appear socially skilled and well adjusted, they often struggle with basic relationships. Lying is common, as is manipulative illness behavior and sadistic behavior toward other children. Many remain trauma-reactive and experience cyclical anger, depression, and oppositionality. Children who fared best were separated from their biological parents and remained in a single protected placement or had an abuser who admitted to the abuse and worked over a period of years toward reunification (Ayoub 2002).

Feeding Disorders

Food Refusal, Selectivity, and Phobias

Feeding problems and eating disturbances in toddlers and young school-age children (see also Chapter 14, "Eating Disorders") occur in 25%–40% of the population (Mayes et al. 1993). Most are transient and can be easily addressed with parent training, education about nutrition or normal child development, child–caregiver interaction advice, and suggestions for food preparation and presentation. However, severe eating disturbances requiring more aggressive treatment occur in 3%–10% of young children and are most common in children with other physical or developmental problems (Ahearn et al. 2001; Kerwin 1999). These children are at risk for aspiration, malnutrition, invasive medical procedures, hospitalizations, limitations in normal functioning and development, liver failure, and death.

Some physical factors that can impair normal eating include anatomical abnormalities, sensory perceptual impairments, oral motor dysfunction, and chronic medical problems (such as reflux, short-gut syndrome, inflammatory bowel disease, hepatic or pancreatic disease, or cancer). Other contributing factors can include the pairing of eating with an aversive experience (posttraumatic feeding disorders), inadvertent caregiver reinforcement of progressively more selective food choices, or a lack of normal early feeding experiences.

Munk and Repp (1994) developed methods for assessing feeding problems in individuals with cognitive and physical disabilities that allow categorization of individual feeding patterns based on responses to repeated presentations of food. Complete food refusal or food selectivity can occur with or without an associated phobia and can be assessed by observing for fear and anxiety behaviors on food presentation (Kerwin 1999).

Food aversion and oral motor dysfunction can be treated by a skilled mental health clinician, speech pathologist, or occupational therapist. Effective behavioral interventions include contingency management with positive reinforcement for appropriate feeding and ignoring or guiding inappropriate responses. Desensitization techniques can be effectively used to address phobias or altered sensory processing. Although no research has directly examined the use of psychotropic medication in treating food refusal, selectivity, or phobias, it may be valuable to consider for use with children with associated anxiety disorders.

Failure to Thrive

Children whose current weight or rate of weight gain is significantly below that of other children of similar age and sex are diagnosed by pediatricians with failure to thrive

(FTT). It is helpful to think of FTT as a presenting symptom with varied and potentially multiple causes (Wren and Tarbell 1998). Parents might have a poor understanding of feeding techniques or might improperly prepare formula, or the mother may have an inadequate supply of breast milk. Biological contributors to FTT include defects in food assimilation, excessive loss of ingested calories, increased energy requirements, and prenatal insults; environmental contributors include economic or emotional deprivation.

Research examining the role of the child–parent attachment indicates that feeding problems and growth deficiencies can occur within the context of organized and secure attachments; however, insecure attachment relationships may intensify feeding problems and lead to more severe malnutrition (Chatoor et al. 1998). In one study of FTT children (who had no identifiable biological contributors), 80% of the mothers reported that they had a history of being victims of physical abuse (Weston et al. 1993).

Classic teaching has been that etiology can be determined by the child's ability to gain weight in the hospital, with a psychosocial etiology presumed if the child gains weight under these conditions. However, it is important to note that conclusions about likely FTT contributors cannot always be made on the basis of the child's ability to gain weight in the hospital. For example, some FTT children who have an inadequate caregiver will still lose weight in the hospital simply because they are separated from the caregiver. Former FTT children have been found to be smaller, less cognitively able, and more behaviorally disturbed than those children without a history of FTT, especially if their mothers are poorly educated (Drewett et al. 1999; Dykman et al. 2001).

The goal of treatment is to provide the medical, psychiatric, social, and environmental resources needed to promote satisfactory growth. Psychosocial treatment interventions need to be targeted at the likely contributors. Children with feeding skills deficits or maladaptive behavior related to food are likely to benefit from behavioral interventions. Primary caregivers with a history of abuse or with current psychopathology might require specific psychiatric assessment and treatment. Interventions targeting the child–parent relationship, sometimes including in-home intervention, might be effective for selected families (Black et al. 1995; Steward 2001). Interventions targeting the social–economic burdens of the family can be critical. In some cases of inadequate parenting, foster care is required while the parent receives needed parent training and psychiatric care. In such cases, the return to home should be closely monitored and based on the parents' demonstrated ability and resources to care adequately for their child.

Pica

Pica is defined as eating nonnutritious substances on a regular basis over a period of at least 1 month (Wren and Tarbell 1998). It is most frequently found in children with mental retardation or a pervasive developmental disorder. *Pica* also has a high prevalence in children with sickle cell disease, with preliminary studies suggesting that more than 30% are affected (Bond et al. 1994; Ivascu et al. 2001). Mouthing and occasional eating of nonnutritious substances are considered normal in children younger than 3 years. Young children with *pica* are most likely to eat sand, bugs, paint, plaster, paper, or other items within reach. Adolescents are more likely to eat clay, soil, paper, or similar substances. *Pica* can be a conditioned behavior, an indication of distress or environmental neglect, or evidence of a vitamin or mineral deficiency. One study (Singhi et al. 1981) in children with iron deficiency anemia (50 with *pica* and 50 without *pica*, individually matched for age, sex, socioeconomic class, and degree of anemia) found that stress factors significantly associated with *pica* included maternal deprivation, caregiver other than the mother, parental separation, parental neglect, joint family, child beating, and too little parent-child interaction (mother or father). Medical assessment includes screening for ingestion of toxic substances and evaluation for possible nutritional deficits. An evaluation and treatment plan to reduce psychosocial stress are also clearly important. Behavioral interventions have been shown to be effective in targeting the *pica* behavior, including food-versus-nonfood discrimination training, response interruption and positive practice overcorrection, habit reversal, and brief-duration physical restraint (Fisher et al. 1994; Johnson et al. 1994; Paniagua et al. 1986; Winton and Singh 1983; Woods et al. 1996). Psychiatric medications are not generally used to treat *pica* unless it is comorbid with another psychiatric disorder.

Rumination

Rumination syndrome is the effortless regurgitation into the mouth of recently ingested food followed by rechewing and reswallowing or expulsion (Clouse et al. 1999; Malcolm et al. 1997). Associated behavioral signs can include aversive posturing or gaze avoidance (C. Berkowitz 1999). Rumination can be conditioned after an illness, a sign of general distress, or a form of self-stimulation or self-soothing that appears to be associated with pleasure. It is most commonly seen in infants and the developmentally disabled but also occurs in children and adolescents with normal intelligence (O'Brien et al. 1995; Soykan et al. 1997).

Patients with rumination syndrome can be misdiagnosed as having bulimia nervosa, gastroesophageal reflux disease, or upper gastrointestinal motility disorders (such

as gastroparesis or chronic intestinal pseudo-obstruction). They might undergo extensive, costly, and invasive medical testing before diagnosis. Complications can include weight loss, fatal malnutrition, dental erosions, halitosis, dehydration, school absenteeism, hospitalizations, and iatrogenic problems from the extensive diagnostic testing (O'Brien et al. 1995).

Rumination syndrome is a clinical diagnosis based on symptoms and the absence of structural disease. However, the Rome II diagnostic groups (defining diagnostic criteria for functional gastrointestinal disorders) include only "infant rumination syndrome," and criteria for older children have not been defined (Rasquin-Weber et al. 1999). Evaluation for gastroesophageal reflux disease is warranted if the rumination is accompanied by apnea, reactive airway disease, hematemesis, or food refusal.

In cases of rumination because of environmental neglect, the primary caregiver-child relationship and possible psychiatric disturbance in the primary caregiver should be evaluated and addressed. Operant behavioral methods can be used for conditioned rumination. Postmeal chewing gum has been used successfully to treat rumination in adolescents (Weakley et al. 1997). Habit reversal using diaphragmatic breathing as the competing response also can be effective in older children and adolescents (Chial et al. 2003; Kerwin 1999; Wagaman et al. 1998). Rumination in the presence of other psychosocial problems or psychiatric disorders in the child or primary caregiver may require additional therapeutic interventions. Later experiences of stress, loss, or isolation can trigger a relapse, requiring the reinstitution of the previously effective intervention (C. Berkowitz 1999).

Autism Spectrum Disorders

Given the prevalence of and comorbidities associated with autistic spectrum disorders, along with the additional coping challenges faced by children with autistic spectrum disorders, one would expect to regularly encounter pediatric inpatients with autistic spectrum disorders or autistic spectrum disorder traits. Autistic spectrum disorders such as autism or Asperger's disorder are neurodevelopmental disorders characterized by impairment in communication (verbal and/or nonverbal) and social interactions. Autistic spectrum disorders occur in all racial, ethnic, and socioeconomic groups but are four times more likely to occur in males than in females. In 2006, the Centers for Disease Control and Prevention (CDC) reported that among 8-year-old children in the United States, about 1 in 110 has an autistic spectrum disorder (Centers for Disease Control and Prevention 2009). Autistic spectrum disorders occur more often than expected among those who have fragile X syndrome, tuberous sclerosis, congenital rubella syn-

drome, and untreated phenylketonuria, as well as among those who were prenatally exposed to thalidomide.

A study published by the CDC in 2003 found that 62% of the children with an autistic spectrum disorder had at least one additional disability (most commonly, mental retardation) or epilepsy (Centers for Disease Control and Prevention 2007). Associated features of autistic spectrum disorders place affected individuals at higher risk for injuries, functional somatic disorders, and other medical problems. Associated features include hyperactivity, short attention span, impulsivity, aggressiveness, self-injury, temper tantrums, perseverative interests, unusual sensory responses, abnormal eating and/or sleeping habits, and seemingly unusual emotional reactions. Common medical presentations might, therefore, include seizures, weight loss or gain, nausea, vomiting, constipation, diarrhea (due to unusual eating habits, abnormal sensory signaling, or underlying gastrointestinal problems), injuries (due to self-injurious behavior, sensory signaling problems, physical altercations, lack of fear, inattentiveness, or clumsiness), pain or other sensory abnormalities, and addictions. Additional reasons for psychiatric consultation might include requests for evaluation and recommendations regarding difficulty coping with hospitalization or illness, nonadherence, capacity to refuse treatment, or pretransplant evaluations.

Individuals with autistic spectrum disorders may have great difficulty identifying and then explaining a symptom or telling the physician what they think is wrong with them. This sometimes requires the clinician to rely more heavily on objective data for diagnosis and monitoring (Smith 2009). Some individuals with autistic spectrum disorders cannot readily identify faces of individuals, potentially making it quite difficult to remember the various medical staff members providing care. Questions asked by clinicians can be difficult to answer if one is interpreting questions literally, if part of the question is implied nonverbally, or if questions are not precise enough (Smith 2007).

If patients have not yet received a diagnosis, it can be extremely helpful to children with autistic spectrum disorders and their parents to learn of their diagnosis and to be educated about the children's specific strengths, weaknesses, and needs. Hospitalized children with autistic spectrum disorders often benefit from being carefully prepared for procedures and daily routines, giving them time to adjust to unexpected changes, minimizing the number of staff involved with their care, and carefully managing distressing sensory stimuli. Extra effort may be required to communicate with a child with an autistic spectrum disorder and to learn how a specific child senses pain or other symptoms. Resources are now being developed for use by parents and medical staff to assist children with autistic spectrum disorders in the medical setting (e.g., see Hudson 2006).

Chronic Somatic Symptoms

Children and adolescents often report persistent physical concerns that are not clearly accounted for by identifiable medical illness (Campo and Fritsch 1994; Garber et al. 1991). In fact, the most common reason for a pediatric psychiatry consultation is for evaluation of unexplained physical symptoms (Simonds 1977; S.J. Tsai et al. 1995). Somatic disorders can be considered the severe end of a continuum that includes functional somatic symptoms in the middle and minor transient symptoms at the other end (Fritz et al. 1997). Examples of symptoms and disorders on this continuum include atypical migraines, cyclic vomiting, chronic nausea, dizziness, fibromyalgia, chronic fatigue, functional abdominal pain, irritable bowel syndrome, myofascial pain, palpitations, conversion paralysis, and nonepileptic seizures (Heruti et al. 2002; Krilov et al. 1998; Li and Balint 2000; Plioplys et al. 2007; Schanberg et al. 1998; Volkmar et al. 1984). Disabling somatic symptoms can occur in the presence or absence of an identifiable etiology and in the presence or absence of other medical or psychiatric disorders.

Traditionally, disability and symptoms in excess of what would be expected given the amount of tissue pathology have been considered psychogenic. In such circumstances, children and families are sometimes informed by well-meaning clinicians that the symptoms have no physiological basis, with the intended or unintended suggestion that the children are fabricating the symptoms. It is sometimes misleading and confusing to families to dichotomize symptoms as organic or nonorganic because all symptoms are associated with neurosensory changes and influenced by psychosocial factors. Maintaining the organic versus nonorganic dichotomy can lead to unnecessary tests and treatments or to an unhelpful lack of empathy. Consequently, it is helpful to remember, and to communicate to families, that experiences of somatic symptoms are the result of an integration of biological processes, psychological and developmental factors, and social context (Bennett 1999; Li and Balint 2000; Mailis-Gagnon et al. 2003; Peyron et al. 2000; Terre and Ghiselli 1997; Zeltzer et al. 1997).

Psychiatric assessment is geared toward identifying psychiatric symptoms, behavioral reinforcements, and psychosocial stressors that could be exacerbating the symptoms. Common comorbid findings include anxiety disorders, alexithymia, depression, unsuspected learning disorders (in high-achieving children), developmental or communication disorders, social problems, physical or emotional trauma, family illness, and family distress (Bursch and Zeltzer 2002; Campo et al. 1999, 2002; Egger et al. 1998; Fritz et al. 1997; Garber et al. 1990; Hodges et al. 1985a, 1985b; Hyman et al. 2002; Lester et al. 2003; Living-

ston 1993; Livingston et al. 1995; Schanberg et al. 1998; Stuart and Noyes 1999; Zuckerman et al. 1987).

The family and treatment team often worry about missing a life-threatening problem or a diagnosis that could be remedied within a traditional biomedical model. This fear is particularly strong when the patient has significant distress about the symptoms. The treatment team must believe that a reasonable evaluation has been completed so that they can clearly communicate to the family that no further evaluation is indicated to understand and treat the problem. A rehabilitation approach can improve independent and normal functioning, enhance coping and self-efficacy, and serve to prevent secondary disabilities (Bursch 2010; Campo and Fritz 2001; Heruti et al. 2002). Functioning, rather than symptoms, should be tracked to determine whether progress is being made. As functioning, coping skills, and self-efficacy improve, symptoms and the distress related to the symptoms often remit.

Specific treatment plans target the biological, psychological, and social factors that are exacerbating or maintaining the symptoms and disability. Treatment techniques designed to target underlying sensory signaling mechanisms and specific symptoms can include cognitive-behavioral strategies (e.g., psychotherapy, hypnosis, biofeedback, or meditation), behavioral techniques, family interventions, physical interventions (e.g., massage, yoga, acupuncture, transcutaneous electrical nerve stimulation [TENS], physical therapy, heat and cold therapies, occupational therapy), sleep hygiene, and pharmacological interventions (Bursch 2008; Eccleston et al. 2009; Fritz et al. 1997; Minuchin et al. 1978; Sanders et al. 1989, 1994). In general, interventions that promote active coping are preferred over those that require passive dependency.

Most of the currently used pharmacological strategies are extrapolated from adult trials without evidence of efficacy in children. Classes of medications to consider include TCAs or anticonvulsants for neuropathic pain or irritable bowel syndrome; SSRIs for symptoms of functional abdominal pain, anxiety, or depression; muscle relaxants for myofascial pain; and low-dose antipsychotics (especially those with low potency) for acute anxiety, multiple somatic symptoms with significant distress, and chronic nausea (Bursch 2006; Campo et al. 2004; Garcia-Campayo and Sanz-Carillo 2002; J.E. Muller et al. 2008; T. Muller et al. 2004; Noyes et al. 1998; Saarto and Wiffen 2007; Volz et al. 2000, 2002; Wiffen et al. 2005a, 2005b). Benzodiazepines sometimes elicit paradoxical reactions in those children who are hypervigilant to their bodies and concerned about losing control. Blocks, trigger point injections, epidurals, and other invasive assessments and treatments that further stimulate the CNS can sometimes exacerbate the problem. Evidence-based treatments should be used whenever available.

Specific Medical Disorders

Oncology

In 2007, approximately 10,400 children in the United States younger than 15 years received a diagnosis of cancer (American Cancer Society 2007). Although cancer is the disease most frequently causing death among U.S. children ages 1–14 years, it is rare. Leukemias and brain or CNS cancers are the two most common cancer types among these children. Because of improved treatment approaches, survival rates have improved dramatically since 1975. However, many children do experience both short- and longer-term treatment side effects.

Psychological Short-Term Effects

Pediatric cancers present several challenges to patients and their families. Despite the numerous stressors, pediatric oncology patients report relatively few depressive symptoms during the time of active treatment. Children with cancer report fewer symptoms of depression than do healthy schoolchildren or children with asthma, and self-esteem concerns and somatic symptoms do not differentiate between depressed and nondepressed children with cancer (Gizynski and Shapiro 1990; Worchel et al. 1988). In fact, pediatric cancer patients report so few symptoms that clinical researchers have hypothesized that these children use an avoidant coping style to deal with their emotional response to cancer (Phipps and Srivastava 1997, 1999) or that their emotional response is shaped by traumatic avoidance (Erickson and Steiner 2000). Interventions that address the contextual issues that are precipitating distress are generally sufficient for the depressive symptoms seen during active treatment (Kazak et al. 2002).

Interventions for Invasive Procedures

One area of intervention that has been extensively researched is preparation for the many invasive procedures children experience during cancer treatment. Cognitive-behavioral techniques, including imagery, relaxation, distraction, modeling, desensitization, and positive reinforcement, are well established as effective (Powers 1999; Uman et al. 2008). This is consistent with the literature that suggests that depressive attributional style and avoidance coping are major predictors of anxiety and depression in pediatric oncology patients (Frank et al. 1997). Although all children have some distress with painful procedures, some appear to be more sensitive to pain and have differential responses to psychological interventions for procedural distress (Chen et al. 2000). In cases of children with severe distress, integration of pharmacological interventions has proven useful (Jay et al. 1991; Kazak et al. 1998). Topical an-

esthetic cream has been used with some success to alleviate the pain of venipuncture or the topical pain of other invasive procedures with pediatric oncology patients (Robieux et al. 1990). In comparisons of conscious sedation and general anesthesia for lumbar punctures, the outcomes were similar, and the conscious sedation was generally preferred and less expensive. However, for some children, the procedure could only be performed under general anesthesia because they were too distressed to cooperate (Ljungman et al. 2001). For conscious sedation, the amnestic effect of midazolam, as well as the ability to administer it nasally, rectally, or orally, has made it popular with anesthesiologists and intensivists. In a double-blind study, midazolam was shown to significantly reduce children's procedural anxiety, discomfort, and pain (Ljungman et al. 2000). For brief general anesthesia, a combination of midazolam and ketamine has been found effective (Parker et al. 1997). Interventions designed to enhance communication with youths with cancer have been developed but not rigorously assessed. Preliminary evidence suggests that some youths with cancer may benefit from informational interventions, support related to procedures, and interventions to facilitate reintegration into school and social activities (Ranmal et al. 2008).

Psychological Late Effects

With increasing survival of childhood cancer patients, the long-term effect of cancer has become a major focus of psycho-oncology research over the past 20 years. Here again, depression does not seem to be a problem (Zebrack et al. 2002). However, a rapidly growing area is investigations of PTSD. A study of 309 childhood cancer survivors (ages 8–20), an average of almost 6 years after cancer treatment, found similar rates of PTSD symptoms in the cancer and comparison groups (219 healthy children) (Kazak et al. 1997). However, in a study of 78 young adult (ages 18–37) survivors of childhood cancer, approximately 20% of the young adult survivors reported symptoms meeting diagnostic criteria for PTSD (Hobbie et al. 2000). Furthermore, PTSD in the young adults appeared predictive of adverse consequences. The young adult survivors who met criteria for PTSD were less likely to be married (none, compared with 23% of the non-PTSD group) and reported more psychological distress and poorer quality of life across all domains. The greatest differences reported were in social functioning, emotional well-being, and role limitations caused by emotional health and pain. Survivors without PTSD did not differ from population norms (Meeske and Stuber 2001). These findings indicate a need to prevent and intervene with children during the time of acute treatment, to prevent long-term consequences in much the same way that medical treatments are being adapted in light of the

late effects of radiation and chemotherapy. Meta-analysis of survivors of childhood acute lymphoblastic leukemia treated solely with chemotherapy (no radiation) has identified neurocognitive sequelae, including deficits in intelligence and academic achievement, processing speed, verbal memory, executive functioning, and fine motor skills (Peterson et al. 2008). Visual-motor skills and visual memory appear to remain intact (Peterson et al. 2008).

Effect on Parents

Parents report significant distress and conflict both during and after their children's cancer treatment (Best et al. 2002; Pai et al. 2007). Although they do not appear to affect child outcomes, psychological interventions have been shown to decrease distress and improve adjustment among parents of youths with cancer (Pai et al. 2006). Specific problem-solving therapy has been found to be effective in helping mothers deal with the stresses of a child's treatment (Sahler et al. 2002), as have brief stress reduction techniques (Streisand et al. 2001). Rates of PTSD in parents of children off treatment appear comparable to those in adult cancer survivors (Manne et al. 1998). In a large study of pediatric cancer survivors' parents, 3% of the survivors' mothers reported severe, and 18.2% reported moderate, symptoms of PTSD, whereas 7% of the survivors' fathers reported severe, and 28.3% reported moderate, PTSD symptoms (Kazak et al. 1997).

Cystic Fibrosis

Cystic fibrosis (CF) affects approximately 30,000 children and adults in the United States and is the most common hereditary disease in white children. A defective gene causes the body to produce a thick, sticky mucus that clogs the lungs and leads to life-threatening lung infections. These secretions also obstruct the pancreas, preventing digestive enzymes from reaching the intestines. CF occurs in approximately 1 of every 3,200 live Caucasian births, with about 1,000 new cases diagnosed each year. More than 80% of patients are diagnosed by the age of 3 years; however, almost 10% are diagnosed at age 18 years or older. The median age of survival is 33.4 years, and nearly 40% of those with CF are adults.

People with CF have a variety of symptoms that vary from person to person but include very salty-tasting skin; persistent coughing; wheezing or shortness of breath; an excessive appetite but poor weight gain; and greasy, bulky stools. Malnutrition can lead to poor growth, delayed puberty, impaired respiratory function, reduced exercise tolerance, and increased risk of infection. CF patients with end-stage pulmonary disease show marked nutritional failure. Evidence shows that improving nutritional status may halt the decline in pulmonary function (Dalzell et al.

1992). Progressive respiratory failure is the most common cause of death.

The treatment of CF depends on the stage of the disease and the organs involved. Clearing mucus from the lungs is part of the daily CF treatment regimen; this entails vigorous clapping on the back and chest to dislodge the mucus from the lungs. Strict adherence to this important treatment has been measured to be only about 40% (Passero et al. 1981). Other types of treatments include antibiotics to treat lung infections and mucus-thinning drugs. A high-energy diet (a high-fat diet with significant amounts of carbohydrate and protein) aiming at 120% of the recommended daily intake for age has been linked to superior nutritional status. However, research has found that dietary adherence is poor, with up to 84% of CF children not reaching dietary goals. Both adherence and health status in children with CF are partially predicted by parental psychosocial variables, including knowledge specific to CF (Anthony et al. 1999; Patterson et al. 1993). More and more individuals with CF have received gene therapy or a lung, liver, and/or bowel transplant.

Many people with CF lead remarkably normal lives and maintain hope with the possibilities of gene therapy and organ transplantation in case of severe deterioration. Although early research suggested that eating disorders may be more prevalent in those with CF, recent work has suggested that this is not true. Similarly, rates of other psychiatric disorders among those with CF do not appear to be greater than the prevalence reported in the general population (Kashani et al. 1988a; Raymond et al. 2000). One study of health values in adolescents with CF found that they are willing to trade very little of their life expectancy or take more than a small risk of death to obtain perfect health (Yi et al. 2003). Although little research has been done on this topic, there are no apparent contraindications to standard assessment and treatment approaches for psychiatric disorders in those with CF. Currently, no clear evidence exists regarding the best psychological interventions to help those with CF and their families manage the disease (Glasscoe and Quittner 2008). Some data suggest that family interventions can be successfully used to improve maternal mental health and treatment adherence among those at high risk (Goldbeck and Babka 2001; Ireys et al. 2001).

Asthma

Asthma is the most common serious pediatric chronic illness, frequently responsible for missed school days and hospitalizations (American Lung Association 2010). Both prevalence and morbidity are rising, despite better pharmacological treatments. Comorbid psychiatric problems and increased levels of stress are cited as possible factors for the increases (Wamboldt and Gavin 1998). Comorbid psychi-

atric disorders may reduce asthma treatment compliance, impair daily functioning, or have a direct effect on autonomic reactions and pulmonary function (Norrish et al. 1977). The literature contains some contradictory findings about the prevalence and type of comorbid psychiatric problems, but it appears that internalizing disorders are more common and that more than one-third of asthmatic children have anxiety disorders. Additionally, those with moderate to severe asthma appear to be at a higher risk for anxiety disorders than those with mild disease. Kean et al. (2006) found that adolescents who have experienced a life-threatening asthma event, and their parents, have high levels of posttraumatic stress symptoms, with 20% and 29% meeting DSM criteria for PTSD, respectively. Although depression has been less consistently identified as a comorbid psychiatric disorder among pediatric asthma patients, the literature suggests that depression, along with other psychosocial problems, may be a risk factor for death in children with asthma. Consequently, the presence of depression in a child with uncontrolled or severe asthma requires serious attention (Bussing et al. 1996; Butz and Alexander 1993; Graham et al. 1967; Kashani et al. 1988b; MacLean et al. 1988; McNichol et al. 1973; Mrazek et al. 1985; Steinhilber et al. 1983; Strunk et al. 1985; Vila et al. 1999).

Twin studies suggest that there may be a genetic relation between atopic disorders and internalizing disorders (Wamboldt et al. 1998). One possible explanation is that panic anxiety acts as an asphyxia alarm system that is triggered by central chemoreceptors monitoring partial pressure of carbon dioxide in the blood (PaCO_2). Children with a genetic vulnerability for panic disorder who also have periodic increased PaCO_2 from asthma exacerbations thus may have panic anxiety triggered by their asthma attacks. Left undiagnosed and untreated, this anxiety can develop into panic disorder. Indeed, recent prospective epidemiological studies indicate that the primary risk factor for development of panic disorder in young adulthood is history of asthma as a child (Goodwin et al. 2003). Other reasons for increased comorbidity include the fact that most asthma medications (e.g., steroids and beta-agonists) are known to cause symptoms that appear psychiatric in nature. An inflammatory allergic response may release cytokines and other mediators that cause fatigue, trouble concentrating, and irritability that could also be interpreted as depression. The physiological response accompanying strong emotions can trigger wheezing in some patients. Recent research indicates not only that stress can lead to increased asthma exacerbations but also that those children with atopic illnesses have a reduced cortisol response to stress (Wamboldt et al. 2003). Stressors thus may have a direct effect on increased inflammation, leading to asthma symptoms or an increase in upper respiratory infections,

which also exacerbate asthma. Depression and anxiety may indirectly influence asthma because distressed asthmatic patients tend to misperceive anxiety symptoms as asthma symptoms, often leading to unnecessary medication use.

Clinicians seeing children with asthma should assess for 1) psychosocial disruption and psychiatric symptoms, especially symptoms of anxiety and depression (including medical trauma); 2) the likelihood of nonadherence; 3) the ability to perceive symptoms; and 4) the presence of vocal cord dysfunction (see following subsection). Asthma can increase family burden, and having depressed primary caregivers increases the risk of poorer treatment adherence. New electronic monitoring of adherence with inhaled medications helps determine how much nonadherence is undermining outcome. Having patients guess their peak flow or rate their symptoms before spirometry or after a methacholine challenge is one way to assess whether these patients are accurate perceivers. Patients who have difficulty with symptom perception (either under- or over-perceiving symptoms) can be trained to use objective assessment methods, such as peak flow meters. Asthma education has been found to be associated with decreases in hospitalizations and emergency department visits, with interactive learning opportunities and more educational sessions leading to a greater effect (Coffman et al. 2008).

Pharmacological and psychological treatments with efficacy to treat anxiety and depression in children are largely applicable to those with asthma. Focused family therapy to improve asthma management skills has been shown to be effective and efficient (Godding et al. 1997; Gustafsson et al. 1986; Lask and Matthew 1979; Panton and Barley 2000). Although some concern has been raised about the concurrent use of TCAs with medicines used in treating asthma, they appear to be safe, and the anticholinergic effects can sometimes be helpful (Wamboldt et al. 1997). Beta-receptor agonists are often used to treat asthma, which makes beta-blockers potentially dangerous. There is no contraindication to use of antipsychotics, and they may be particularly indicated for steroid-induced psychosis. Lithium increases theophylline clearance, requiring that levels of both drugs be monitored (Wamboldt and Gavin 1998). Some children with asthma have difficulty tolerating stimulants. Bupropion has shown efficacy in the treatment of attention-deficit/hyperactivity disorder in young patients in controlled trials (Barrickman et al. 1995; Conners et al. 1996) and does not interact with asthma medications.

Vocal Cord Dysfunction

Vocal cord dysfunction can mimic asthma and commonly occurs comorbidly with asthma. It is a condition of involuntary paradoxical adduction of the vocal cords during the inspiratory phase of the respiratory cycle (Wamboldt

and Gavin 1998). It is often associated with anxiety or chronic stress; however, sexual abuse in this population is not as prevalent as previously believed (Brugman et al. 1994; Gavin et al. 1998). Patients with vocal cord dysfunction frequently present with stridulous breathing, experience tightness in their throats, and feel short of breath. It can be quite anxiety provoking that their symptoms are unrelieved by asthma medications. Clinicians can assess for vocal cord dysfunction by asking patients where they feel short of breath and if they have throat tightness. A flow volume loop can be helpful in showing vocal cord dysfunction, especially on the inspiratory part of the loop. Definitive diagnosis of vocal cord dysfunction is made by visualization of adducted cords during an acute episode via laryngoscopy. Provocation of symptoms during laryngoscopy has been achieved with methacholine, histamine, or exercise challenges. The primary treatment for vocal cord dysfunction is speech therapy or hypnotherapy geared toward increasing awareness and control of breathing and throat muscles (Wamboldt and Gavin 1998).

Childhood Obesity

Genetic factors may account for as much as 70% of the variability in human body weight (Allison et al. 1996; Stunkard et al. 1990). Nevertheless, there has been a disturbing increase during the past 20 years in the prevalence of obesity in children and adolescents in the United States. Children and adolescents are considered obese if they have a body mass index (BMI) of greater than or equal to the 95th percentile for age and sex, and they are considered overweight if their BMI is between the 85th and the 95th percentile (Dietz and Bellizzi 1999). Data from the third National Health and Nutrition Examination Survey, conducted from 1988 to 1994, indicated that approximately 11% of U.S. children were obese. An analysis of 1999–2002 data estimated childhood obesity prevalence at 16% (Hedley et al. 2004). These findings can be compared with the 5% obesity reported in a similar study conducted between 1976 and 1980 (Troiano et al. 1995). This dramatic increase in obesity has been attributed to the proliferation of inexpensive, calorie-rich foods that are quickly and readily available in the United States and the increased number of hours children spend in sedentary activities, such as watching television and playing computer games (Ebbeling et al. 2002). Similar increases in childhood obesity have been documented in Europe and Asia (Chinn and Rona 2001; Chunming 2000) and in developing societies (de Onis and Blossner 2000).

The effect of obesity is both immediate and long-lasting. Children and adolescents with a BMI at or above the 95th percentile for age and sex have been found to have significantly reduced health-related quality of life compared with healthy children and adolescents. In a study of 106

children, ages 5–18 years, the obese subjects were more than five times more likely to have significant impairment of physical functioning and almost six times as likely to have impaired psychosocial health. These findings are similar to those for children with cancer (Schwimmer et al. 2003). A survey of approximately 10,000 women, ages 16–24 years, found that obese adolescents were less likely to complete college than were nonoverweight adolescents with similar educational backgrounds. The obese young adults were much less likely to marry than were nonobese young adults, after the investigators controlled for IQ and parents' education or income level. Those obese women who did marry were more often married to men in a lower socioeconomic class (Gortmaker et al. 1993; Stunkard and Sabal 1995).

The immediate health consequences of childhood obesity are serious and include slipped capital femoral epiphysis, pseudotumor cerebri, asthma, sleep apnea, gallstones, insulin resistance, early puberty, dyslipidemia, and hypertension (for review, see Morgan et al. 2002). Although obese children are likely to become obese adults (Guo et al. 1994), the long-term health risks also include increased likelihood of atherosclerotic cardiovascular disease, gout, and colorectal cancer in men and arthritis and menstrual abnormalities in women, even after adult body mass is taken into account (Mossberg 1989; Must et al. 1999).

Importantly, research has found that with no treatment, the average overweight child can be expected to continue to gain weight over time (Wilfley et al. 2007). A meta-analysis of 61 trials determined that short-term medications, including sibutramine and orlistat, are effective in reducing BMI among overweight children and adolescents (McGovern et al. 2008). Interventions focused on physical activity have a moderate treatment effect on body fat but not BMI (McGovern et al. 2008). Short-term changes in weight status have been detected with combined lifestyle interventions, with preliminary evidence for a longer-term effect (McGovern et al. 2008; Wilfley et al. 2007). Some evidence suggests that behavioral interventions are more effective than cognitive interventions and that there is benefit in increasing the behavioral intervention "dose" and in including parents in the intervention (Gilles et al. 2008).

Among interventions designed to *prevent* pediatric obesity, small effects were detected on target behaviors but not related to BMI (Kamath et al. 2008). Lengthier interventions and interventions with postintervention outcome measurement fared better (Kamath et al. 2008).

Bariatric surgery is viewed as "a last resort option for severely obese adolescents" (Strauss et al. 2001, p. 503). Nevertheless, the bariatric surgery rate among adolescents (per 100,000 population) in the United States increased from 0.7 in 2000 to 2.3 in 2003 (W.S. Tsai et al. 2007). Meta-analysis of surgical interventions for adolescents identified

sustained and clinically significant BMI reductions for both laparoscopic adjustable gastric banding (LAGB) and Roux-en-Y gastric bypass (RYGB), the two most commonly used surgical procedures. In LAGB surgery, a silicone band is placed around the upper portion of the stomach, creating a small pouch where food empties from the esophagus to the upper stomach. RYGB surgery also restricts intake through the creation of a small gastric pouch but includes bypass of the proximal small intestine to reduce food absorption. Complications were reported for both procedures, with more severe complications among the RYGB group (Brolin 2002; Treadwell et al. 2008). Given the likelihood of adolescents to be nonadherent with diet and other instructions, the potential interference with growth, the challenges of obtaining true informed consent from adolescents, and the lack of information on long-term consequences of these procedures, surgical interventions should be reserved for those who have not responded to more conventional interventions and have significant complications of their obesity (Treadwell et al. 2008; Yanovski 2001) (see also Chapter 30, "Surgery").

Sickle Cell Anemia

The sickle cell gene for hemoglobin S is the most common inherited blood condition in the United States, with an estimated 72,000 people affected. Symptoms do not usually appear until late in the first year of life and may include fever; swelling of the hands and feet; pain in the chest, abdomen, limbs, and joints; nosebleeds; and frequent upper respiratory infections. Pain is the most common complaint after infancy, as are the added problems of anemia, fatigue, irritability, and jaundice. Children and adolescents may experience delayed puberty, severe joint pain, progressive anemia, leg sores, gum disease, long-term damage to major organs, stroke, and acute chest syndrome. A compromised spleen can cause increased susceptibility to infections. Current treatments for sickle cell disease are prolonging and improving quality of life. Although most people with sickle cell anemia were not previously expected to survive childhood, most now live into adulthood with about half living beyond 50 years (Platt et al. 1994). Representing an important advance in treatment, preliminary data support the efficacy of hydroxyurea in adolescents to decrease severe painful episodes, hospitalizations, number of blood transfusions, and episodes of acute chest syndrome (Brawley et al. 2008).

Sickle cell crises are acute pain episodes that are usually followed by periods of remission and a relatively normal life. Some patients have few crises, others need to be frequently hospitalized, and some have clusters of severe attacks with long intermittent remissions. Crises become less frequent with age for some. The risk for a crisis is increased by any-

thing that boosts the body's oxygen requirement (including illness, physical stress, or being at high altitudes). The first day of the crisis is usually the worst, with sharp, intense, and throbbing pain in the arms, legs, and back. Shortness of breath, bone pain, and abdominal pain are also common. The liver can become enlarged, causing pain, nausea, low-grade fever, and jaundice. Males may experience priapism. Acute chest syndrome can be life threatening.

Stroke is a common cause of death for sickle cell patients older than 3 years (Kinney et al. 1999; Ohene-Frempong 1991; Ohene-Frempong et al. 1998). Although transfusions may be preventive, 8%–11% of those affected experience strokes. One study comparing sickle cell children with and without a history of stroke found relative deficits on measures of attention and executive functioning. Rodgers et al. (1984) provided positron emission tomography evidence of altered frontal lobe metabolism. Another study examined social information processing, social skills, and adjustment difficulties in children with sickle cell disease and learning and behavior problems, with or without CNS pathology on MRI. Children with CNS pathology had more errors on tasks of facial and vocal emotional decoding than did the control children (Boni et al. 2001). Some cognitive rehabilitation intervention development progress has been made to address cognitive deficits among children with sickle cell disease who have had a stroke (King et al. 2008).

Although children and adolescents with sickle cell disease do not appear to have a greater risk for psychiatric disorders than those in the same-race outpatient clinic control group, children attending outpatient medical clinics are at a higher risk for mental disorders than are nonmedical populations (Cepeda et al. 1997; Yang et al. 1994). Most well-designed studies report a prevalence rate of 25%–30% for psychiatric disorders among pediatric sickle cell patients, with internalizing disorders being most prevalent (Cepeda et al. 1997), similar to other pediatric outpatients (Costello and Shugart 1992; Costello et al. 1988). Psychosocial factors have accounted for more variability than biomedical ones in both depressive symptoms and anxiety, with social assertion, self-esteem, use of social support, and family factors accounting for a significant amount of the variability in adaptation (Burlew et al. 2000; Telfair 1994). Two studies suggest that pica (not often assessed) has a relatively high prevalence (up to 30%) in children with sickle cell disease (Bond et al. 1994; Ivascu et al. 2001).

Psychiatric assessment should look for 1) psychosocial disruption or psychiatric symptoms, especially related to pica, anxiety, and depression; 2) school or social problems that could reflect subtle neurocognitive problems; and 3) chronic pain problems. Pharmacological and psychological treatments with efficacy to treat psychiatric disorders in children are applicable to those with sickle cell anemia.

Problems with academic or social functioning might be assessed via neurocognitive testing and addressed within the school system with an Individualized Educational Program (IEP). Pain in sickle cell patients is most commonly medically managed pharmacologically with nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and adjuvant medications (American Pain Society 1999). Chronic and acute pediatric pain also can be reduced with behavioral, psychological, or physical interventions (American Pain Society 1999). Behavioral interventions might include relaxation, deep breathing, biofeedback, behavioral modification, or exercise. Psychological interventions might include cognitive therapies, hypnotherapy, imagery, distraction, or social support. Physical interventions might include hydration, heat, massage, hydrotherapy, ultrasound, acupuncture, TENS, or physical therapy. Successful treatment of anxiety symptoms can reduce pain and pain-related distress. Although there are no contraindications for the use of psychotropic medications with this population, phenothiazines, TCAs, monoamine oxidase inhibitors, and other CNS depressants may potentiate adverse effects of opioids. It is important to note, however, that these agents also may serve to augment pain control efforts successfully and should be considered if needed. (See also Chapter 24, "Hematology.")

Renal Disease

Each year 20,000 children are born with kidney abnormalities, and 4,500 children require dialysis for renal failure. Hemodialysis (at a center or at home) and peritoneal dialysis are used in children. The basic principles of treatment of end-stage renal disease (ESRD) are similar in adults and children (see Chapter 21, "Renal Disease"). However, attention to dialysis adequacy, control of osteodystrophy, nutrition, and correction of anemia are crucial because these factors can influence growth, cognitive development, and school performance (Warady et al. 1999).

Pediatric patients with chronic renal failure have more problems in psychiatric adjustment than do healthy children, with a trend toward more psychological difficulties in those with higher illness severity (Garraalda et al. 1988). However, even less severely physically ill children appear to have increased difficulties in school adjustment and feelings of loneliness (Garraalda et al. 1988). Separation anxiety disorder in particular may be a relatively common disorder (up to 65.4%) among children receiving continuous ambulatory peritoneal dialysis (Fukunishi and Kudo 1995). This may be due to the forced dependence on parents for daily renal care. The burden for families caring for children with ESRD can be significant, especially when it involves dialysis. Disruption of family life, marital strain, and a tendency for more mental health problems in the parents also appear to be related to the severity of the child's renal illness

and its associated care burdens (Reynolds et al. 1988). Children with ESRD (with or without transplant) have been shown to have lower-than-expected IQs and achievement scores. Lower achievement test scores were predicted by younger age at the time of renal disease diagnosis, increased time on dialysis, and caregiver's lower achievement (Brouhard et al. 2000; Fennell et al. 1984; Qvist et al. 2002). Overall, former pediatric ESRD adults appear to have a long-term favorable adjustment, with lower self-esteem related to early onset of the disease and to educational and social dysfunction (Morton et al. 1994).

According to the latest statistics (April 26, 2010) from the United Network for Organ Sharing (UNOS), 804 children were waiting for a kidney transplant in the United States, including 2 younger than 1 year, 150 in the 1- to 5-year-old age group, 142 in the 6- to 10-year-old group, and 508 in the 11- to 17-year-old group. Most transplanted kidneys come from cadavers. However, family members or unrelated individuals who are a good match may be able to donate one of their kidneys and live healthy lives with the kidney that remains. Pediatric kidney transplantation is associated with improved physical health, emotional health, and family functioning; however, poor peer relationships, school maladjustment, and other adjustment problems (as well as adherence problems) can remain after transplant (Fukunishi and Kudo 1995; Reynolds et al. 1991). Living with a transplant is a lifelong process requiring daily medications and monitoring for rejection. Medication nonadherence rates for pediatric renal transplant patients can be as high as 64% (Ettenger et al. 1991). Adverse consequences of nonadherence include medical complications and hospitalizations, higher health care costs and family stress, and increased risks for loss of the organ (Arbus et al. 1993; Bittar et al. 1992; Fukunishi and Honda 1995; Salvatierra et al. 1997; Swanson et al. 1992).

Those conducting mental health evaluations of children with renal disease should consider the effect of possible cognitive deficits, adaptation difficulties, and family strain on social and academic functioning, as well as adherence. The level of family stress and distress, as with all pediatric patients, is essential to evaluate and address as part of a larger treatment approach. Recommendations related to the use of psychotropic medication must be extrapolated from adult studies (see Chapter 21, "Renal Disease") because these data are not available for children.

Diabetes

Juvenile-onset diabetes mellitus affects 1.7 of every 1,000 school-age children in the United States (Centers for Disease Control and Prevention 2010). Type 1 diabetes mellitus is caused by autoimmune destruction of insulin-producing pancreatic beta cells and must be treated with

exogenous insulin. Type 2 diabetes mellitus is the result of resistance to insulin rather than deficiency, can often be treated with diet or hypoglycemic agents, and is generally later in onset than type 1. There are genetic predispositions to both type 1 and type 2 diabetes mellitus (Drash 1993). Obesity and atypical antipsychotic medications appear to contribute to the development of type 2. Both can contribute to mortality and may cause significant morbidity, including retinopathy, nephropathy, peripheral neuropathy, and cardiovascular disease. Injected insulin also may precipitate potentially life-threatening episodes of hypoglycemia (DCCT Research Group 1993, 1994). A meta-analysis conducted by Gaudieri et al. (2008) with 1,393 children with type 1 diabetes and 751 control children determined that type 1 diabetes was associated with slightly lower overall cognitive abilities across a range of domains. Overall, learning and memory were similar for both groups. However, increased impairment was evident among those with early-onset disease. Verbal and visual learning and memory skills, along with attention and executive functioning skills, were more impaired among children with early-onset diabetes compared with those with late-onset diabetes.

The complexity of the management of type 1 diabetes mellitus leads to frequent problems with adherence to medical instructions. Patients on Humalog (or regular) and NPH (neutral protamine Hagedorn) regimens must inject themselves with insulin and test their blood glucose levels at least three times a day to maintain "tight" control, decreasing the incidence or delaying the onset of complications. Patients on Lantus must take an injection every day and another every time they eat more than 15 grams of carbohydrates (e.g., an apple). Even with an insulin pump, blood glucose must be tested at least four times a day. Diet and exercise must be regulated because both have significant effect on the need for exogenous insulin.

The physiological changes of puberty can lead to increased insulin resistance. In addition, the importance of peer acceptance and the withdrawal of parental supervision with the normal developmental focus on identity and autonomy lead to significant adherence problems during adolescence (Hauser et al. 1990). Poor control of diabetes has been repeatedly confirmed with HbA_{1c} (glycosylated hemoglobin), which allows one to get an estimate of glycemic control over the past 3 months. The medical consequences of such poor control were documented in a study of 78 adolescents with type 1 diabetes, ages 11–18 years, followed up for 8 years. Their mean HbA_{1c} peaked in late adolescence. Serious diabetic complications were seen in 38% of the females and 25% of the males (Bryden et al. 2001).

Psychiatric comorbidity in diabetic individuals is also a major issue for psychiatric consultants to pediatrics. Some

moodiness and feelings of isolation and of loss or grief, as well as mild anxiety about the future, are to be expected as normal responses to diabetes. However, assessment for possible intervention is indicated if patients have aggression, school absences, hopelessness, or nonadherence to the insulin regimen (Jacobson 1996). In a study of 92 pediatric patients, ages 8–13 years, followed up over 9 years, 42% developed at least one psychiatric disorder, and 26% developed two or more disorders. Of these, the most common were depression in 26% and anxiety in 20%, with various behavior disorders in 16%. Children who were at higher risk for developing psychiatric comorbidity were those in the first year after diagnosis and those with preexisting anxiety or mothers with psychopathology (Kovacs et al. 1997). Eating disorders are also relatively common. A study of 91 adolescent girls, ages 12–18 years, followed up for 5 years found highly or moderately disordered eating in 29% at baseline and in 33% at follow-up (Rydall et al. 1997).

Treatment of comorbid psychiatric disorders with medications requires careful monitoring because most antidepressant, mood stabilizer, and atypical antipsychotic medications may stimulate appetite or affect glucose tolerance, inducing hypoglycemia or hyperglycemia. Beta-blockers should be avoided because they mask the early warning signs of hypoglycemia, eliminating the window of opportunity for patients to address the problem themselves before requiring the assistance of others (Goodnick et al. 1995).

Effective behavioral interventions for children with diabetes and their parents include identifying readiness for change and improving self-efficacy, the belief that one can maintain behavior change despite regular challenges (Anderson et al. 1996, 1999). In 110 young adults (ages 18–35 years) with type 1 diabetes mellitus, self-efficacy was more predictive of self-care and metabolic control than was self-esteem. After factoring in previous adherence, self-efficacy continues to be predictive of self-care and HbA_{1c} (Johnston-Brooks et al. 2002). A growing area of research is the application of motivational interviewing to improve health self-management among adolescents with diabetes mellitus (Berg-Smith et al. 1999; Dunn et al. 2001; Williams et al. 1998).

Cardiac Disease

Congenital Heart Defects and Disease

Congenital heart defects and disease include patent ductus arteriosus, atrial septal defects, and ventricular septal defects. About 40,000 children are born with a heart defect each year, and most can benefit from surgery. It appears that heart defects are multidetermined by factors that include genetics as well as exposure during pregnancy by the

mother to certain viruses (such as rubella or German measles) or drugs (such as alcohol, anticonvulsants, or lithium). Acquired heart diseases that develop during childhood include Kawasaki disease, rheumatic fever, and infective endocarditis.

Van Horn et al. (2001) studied concerns expressed by mothers of children with congenital heart disease during hospitalization and again 2–4 weeks after discharge. During hospitalization, mothers were most concerned about medical prognosis. Mothers' concerns, anxiety, and depressed mood decreased after discharge. At follow-up, mothers' perceptions of medical severity were related to distress about psychosocial issues. Overall, it appears that children with heart disease psychiatrically resemble a healthy population without elevations in anxiety, depression, or behavior problems (Connolly et al. 2002; DeMaso et al. 2000; Visconti et al. 2002). However, similar to the case in healthy or other chronically ill children, demographic and socioeconomic factors, medical severity, and family distress appear to be related to symptoms of depression, anxiety, behavior problems, and cognitive effects (Alden et al. 1998; Karsdorp et al. 2007; Visconti et al. 2002; Yildiz et al. 2001). A meta-analysis by Karsdorp et al. (2007) found that older youths with congenital heart disease had a slightly increased risk of externalizing behavior problems and a greater increased risk of internalizing symptoms than did younger children with congenital heart disease. Additionally, they found that youths with severe congenital heart disease had lower cognitive functioning, across age groups, when compared with youths with mild disease. DeMaso et al. (2000) studied pediatric patients with recurrent cardiac arrhythmias who underwent radiofrequency catheter ablation of ectopic myocardial foci. Although these patients resembled a psychiatrically healthy population before the procedure, they experienced reductions in their "fear of their heart problem" and increases in "the things that they enjoy" after the ablation (DeMaso et al. 2000, p. 134). Those who experienced a curative ablation had better functioning than did those who did not experience improvement.

Heart Transplant Recipients

Serrano-Ikkos et al. (1999) compared the psychosocial outcome of pediatric heart and heart–lung transplant recipients with that of children and adolescents who underwent conventional cardiac surgery. Preoperatively, rates of psychiatric disorders (including anxiety and phobic states, depression, and adjustment reaction) were relatively the same in all groups (26%–28.5%). The prevalence of psychiatric disorder was unchanged after transplant in the transplant groups but decreased in the conventional cardiac surgery group. DeMaso et al. (1995) similarly found that most of

the pediatric heart transplant patients studied (78.3%) had good psychological functioning after their heart transplantation. It was further noted that patients with psychological difficulties before and after transplantation had more hospitalizations after transplantation. Finally, Uzark et al. (1992) found that pediatric heart transplant recipients did not differ from peers on measures of self-concept and anxiety but showed less social competence and more behavior problems than a normative population. Behavior problems were frequently suggestive of depression and related to greater family stress and diminished family resources for managing stress. Relaxation and imagery techniques have been used successfully for routine endomyocardial biopsies after heart transplantation (Bullock and Shaddy 1993). A review of the literature related to cognition found that children and adolescents generally function normally on measures of cognitive functioning posttransplant, but a complicated transplant course (caused by infections or rejections) may increase risk for cognitive difficulties (Todar et al. 2000). Serrano-Ikkos et al. (1998) found medication adherence to be relatively high, with 91% adherence confirmed by cyclosporine levels; however, adherence to medical diary keeping was lower, at about 70%. Variables associated with poor adherence to medication were heart-lung as opposed to heart transplantation, one-parent or blended families, and family adjustment.

Chest Pain

Chest pain as a presenting symptom in a previously healthy child is not as ominous a symptom as in an adult because it is rarely a sign of underlying cardiac disease (Driscoll et al. 1976; Tunaoglu et al. 1995). Idiopathic chest pain is the most common diagnosis made, followed by functional pain (associated with anxiety) and musculoskeletal pain (Selbst 1985). Laboratory tests are not typically helpful in establishing the etiology of chest pain. This topic is more fully discussed in the subsection "Chronic Somatic Symptoms" earlier in this chapter.

Psychotropic Medications

The American Heart Association (Gutgesell et al. 1999) has published recommendations for the use of psychotropic medications in children. Briefly, this document concludes that stimulants cause increases in heart rate and blood pressure that are typically considered clinically insignificant. (Although very rare incidences of sudden death have been reported since these guidelines were published, in 2006 the U.S. Food and Drug Administration Pediatric Psychopharmacology Advisory Panel concluded that there is no increased risk for sudden death in healthy patients taking stimulants for attention-deficit/hyperactivity disorder.) TCA treatment in pediatric patients is associated with

cardiovascular changes that are likely of minor clinical significance (Wilens et al. 1996). The electrocardiographic effects of TCA administration include an increase in heart rate (by 20%–25%), PR interval (by 5%–10%), QRS duration (by 7%–25%), and QT interval (by 3%–10%). Malignant arrhythmias have not been documented except for the ventricular fibrillation observed in one pediatric patient with a family history of sudden death. To date, deaths in children taking TCAs have not been conclusively linked to the medication and have not been reported to be more frequent than expected in the population base. SSRIs have minimal cardiovascular effects. Clonidine has been associated with two deaths (in patients who also received methylphenidate), but the mechanism for these deaths is unknown and may have been sudden cessation of treatment. Adverse effects have occurred when the P450 system was inhibited, leading to elevated levels of medications that prolong the QT interval and produce ventricular tachycardia. Most notable have been deaths related to nonsedating histamine-blocking agents, now off the market. Other medications that inhibit or are metabolized by the cytochrome P450 system include antidepressants, calcium channel blockers, histamine blockers, gastrointestinal motility agents, and steroids. Antiarrhythmic drugs of class IA and class III prolong the QT interval, and therefore use of psychotropic medications with these drugs is not recommended. In addition to their effect on cardiac conduction, antipsychotic medications have a negative inotropic effect, reducing cardiac output and lowering blood pressure (Fayek et al. 2001).

American Heart Association recommendations include taking a careful history, obtaining an electrocardiogram (ECG) at baseline before TCA or phenothiazine therapy is begun (primarily to detect unsuspected instances of long-QT syndrome) and another when steady state is achieved, careful monitoring of all prescribed medications along with heart rate and blood pressure, and avoiding use of psychotropic medications with medications that are metabolized by or inhibit the P450 enzyme system (Gutgesell et al. 1999). The clinician should obtain a history of syncope, near syncope, or palpitations; family history of deafness (which can be associated with a congenital long-QT syndrome), sudden unexpected cardiac death, syncope, or tachydysrhythmias; and a medication history to document all medications that may have direct or indirect effects on the cytochrome P450 system or ECG intervals. Some cardiologists argue that ECG screening in children with no symptoms of cardiovascular disease is less efficient and helpful than simply asking about patient and family history of syncope or sudden death. However, no data are available to clearly settle this question. The American Academy of Child and Adolescent Psychiatry does not specifically address this issue in its policy statement related to

prescribing. Nevertheless, the recommendation to conduct ECG screens was recently reiterated (Francis 2002; Labelarte et al. 2003).

Fetal Alcohol Syndrome and Alcohol-Related Neurological Disorder

Prenatal alcohol exposure represents one of the leading preventable causes of congenital neurological impairment, affecting as many as 1 in 100 children born in the United States yearly (May and Gossage 2001), with severe lifelong consequences for affected individuals. Fetal alcohol syndrome (FAS) is defined by a characteristic pattern of facial anomalies, growth retardation, and CNS dysfunction in one or more of the following areas: decreased cranial size at birth, structural brain abnormalities, and neurological hard or soft signs (Stratton et al. 1996). However, alcohol exposure to the fetus can result in neurocognitive changes even when none of the characteristic facial anomalies are present (Streissguth and O'Malley 2000).

The facial characteristics most frequently described in individuals with FAS include short palpebral fissures and abnormalities in the premaxillary zone, including a thin upper lip and flattened philtrum (Astley and Clarren 2001; Stratton et al. 1996). Neurocognitive changes include structural changes in the brain (Roebuck et al. 1998); verbal learning and memory problems; attention deficits; problems in executive functioning characterized by difficulties in planning, organizing, and sequencing behavior; and problems in abstract and practical reasoning and concept formation (Adnams et al. 2001; McGee et al. 2008), complex nonverbal problem solving (Goodman et al. 1999), flexible thinking (Schonfeld et al. 2001), and behavioral inhibition (Mattson et al. 1999). These changes appear to last into adulthood (Streissguth and O'Malley 2000). Children with FAS have been found to have lower levels of adaptive functioning related to social interaction and communication, personal living skills, and community living skills (Jirikowic et al. 2008). They also rated higher on maladaptive behavior scales (Jirikowic et al. 2008) and had motor delays (Kalberg et al. 2006). Secondary disabilities include high levels of psychiatric illness, school failure, social problems, alcohol and other drug abuse, impulsivity, history of trauma or abuse, delinquency, and trouble with the law, placing them at higher risk for suicidality (Baldwin 2007). No safe level of prenatal alcohol consumption has been established, making abstinence the best policy for those who are hoping to conceive. Because many women are often not aware of when they conceived and may continue to drink alcohol at least until pregnancy recognition, preconception counseling is suggested for all women of childbearing age who consume alcohol.

Physical Medicine and Rehabilitation

Jesse R. Fann, M.D., M.P.H.

Richard Kennedy, M.D.

Charles H. Bombardier, Ph.D.

PHYSICAL MEDICINE AND rehabilitation, or *rehabilitation medicine*, is concerned with helping people reach the fullest physical, psychological, social, vocational, and educational potential consistent with their physiological or anatomical impairment, environmental limitations, and desires and life plans (DeLisa et al. 1998). The patients encountered in the rehabilitation setting are highly diverse, and their problems include those listed in Table 35–1. As can be seen, the medical and surgical issues range from acute to chronic and can involve nearly any organ system. Rehabilitation can take place in outpatient, inpatient, and extended-care programs and includes both prevention and treatment of disorders. Striving for maximum independence is central to the goal of maximizing quality of life.

Rehabilitation is generally a multi- or interdisciplinary effort. Rehabilitation medicine physicians (physiatrists) usually lead the team of other specialized professionals, including physical therapists, occupational therapists, speech pathologists, clinical and neuropsychologists, vocational rehabilitation counselors, recreation therapists, social workers, and nurses. Rehabilitation programs often have a dedicated psychologist on staff whose job is to conduct psychological and neuropsychological assessments; provide counseling to patients and families; oversee behav-

ioral programs; and generally assist staff in the management of cognitive, behavioral, affective, and social aspects of rehabilitation.

Psychiatrists have an increasing role in the care of patients in the rehabilitation setting. As advances in medical care have increased survival in many medical and traumatic conditions that previously were fatal—the so-called epidemic of survival—opportunities and challenges have emerged that did not previously exist in the rehabilitation of thousands of individuals each year. Data from the 2007 National Health Interview Survey suggest that 12% of the U.S. population has a limitation in usual activities because of one or more chronic health conditions (Adams et al. 2008). For the first time, *Healthy People 2010: Understanding and Improving Health* (U.S. Department of Health and Human Services 2001), the national agenda for improving the health of Americans, included a chapter on “Disability and Secondary Conditions,” acknowledging that disability is a critical risk factor for many other health-related conditions.

The World Health Organization has shifted its framework for classifying functioning, health, and health-related states from an emphasis on “consequences of disease” found in the previous *International Classification of Impairments, Disabilities and Handicaps* (World Health Organi-

zation 1980) to an emphasis on “components of health” in the current *International Classification of Functioning, Disability and Health* (ICF; World Health Organization 2001). The ICF conceptually differentiates health and health-related components of the disabling process at the levels of 1) *body structures* (anatomical parts of the body, such as organs, limbs, and their components) and *functions* (physiological functions of body systems, including psychological functions) and 2) *activities* (execution of a task or an action by an individual) and *participation* (involvement in a life situation). The ICF defines *impairments* as problems in body function or structure, such as a significant deviation or loss, and focuses on *activity limitations* rather than disabilities and *participation limitations* rather than handicaps. A further change has been the inclusion of a section on *envi-*

ronmental factors as part of the classification, with the recognition of the important role of environment in either facilitating functioning or creating barriers for people with disabilities. Environmental factors interact with a health condition to restore functioning or create a disability, depending on whether the environmental factor is a facilitator or barrier. Figure 35–1 illustrates the interactive and dynamic dimensions of this model. The ICF puts the burden of all diseases and health conditions, including mental illness, on an equal footing. Psychosocial factors can cause impairment and limit activities and participation in many ways, thus affording opportunities for multifaceted psychosocial interventions in the rehabilitation setting.

In this chapter, we focus on the psychiatric issues encountered in the treatment of traumatic brain injury (TBI) and spinal cord injury (SCI), two common and highly complex rehabilitation problems with aspects that may require psychiatric intervention. Although many of the other disorders encountered in the rehabilitation setting are covered in other chapters of this text, many of the principles discussed in this chapter also apply to them.

Traumatic Brain Injury

Epidemiology

TBI is a significant problem from both an individual and a public health perspective. An estimated 1.7 million Americans sustain TBI each year; of these, approximately 275,000 are hospitalized and survive, 1.365 million are treated and released from an emergency department, and 52,000 die (Faul et al. 2010). These figures likely underestimate the incidence of TBI as a result of underreporting of milder injuries. According to data from hospitalized individuals, at least 5.3 million persons in the United States, or about 2% of the population, live with disabilities resulting from TBI (Thurman et al. 1999). Although about 75% of TBIs are mild in severity, many of these individuals experience long-term somatic and psychiatric problems that may lead to disability (Brown et al. 1994; Guerrero et al. 2000). TBI is often referred to as the *invisible epidemic* because TBI-related disabilities are not readily visible to the general public.

With improved medical care, TBI mortality and hospitalizations have declined 20% and 50%, respectively, since 1980 (Thurman et al. 1999), leading to more long-term morbidity and disability. Decreases in TBI mortality also have been seen in military injuries because of advances in body armor (Okie 2005). The peak incidence of TBI is in 0- to 4-year-old and 15- to 19-year-old persons (mostly from falls and motor vehicle accidents, respectively), with a secondary peak among those 65 years and older (mostly from falls).

FIGURE 35-1. Interactions between components of health as defined in the *International Classification of Functioning, Disability and Health*.

Early studies differentiated between military and civilian injuries, with injuries to military personnel outside of combat zones more closely resembling the latter than the former. TBI sustained during combat was noted to be predominantly posterior injuries to the occipital and parietal lobes, whereas civilian TBI was noted to be predominantly anterior injuries to the frontal and temporal lobes. The incidence of penetrating TBI among military groups also was higher than that among civilian groups. These findings have not held up in recent conflicts. Blast injuries are now the predominant cause of injury among personnel in combat zones (Warden et al. 2006), which present with a more diffuse form of TBI (Ritenour and Baskin 2008) that some experts categorize as being distinct from both penetrating and nonpenetrating injuries in civilians (Arciniegas and McAllister 2008). However, penetrating injuries are still more common in military than in civilian settings (Galarneau et al. 2008). The demographics of those injured in current military operations are thought to reflect the overall demographics of those deployed, with most of those injured younger than 30 years (Hoge et al. 2008; Vasterling et al. 2006).

Because TBI affects a predominantly younger population, the effects of disability are much greater than for illnesses occurring later in life. Approximately one in four adults with TBI is unable to return to work 1 year after injury (Centers for Disease Control and Prevention 1999), and approximately 43% of the individuals hospitalized for

TBI have long-term disability (Selassie et al. 2008). In the United States in 2000, direct and indirect costs of TBI totaled an estimated \$60 billion (Finkelstein et al. 2006). Figures show that the total acute care and rehabilitation costs of TBI are \$9–\$10 billion per year (National Institutes of Health Consensus Development Panel on Rehabilitation of Persons With Traumatic Brain Injury 1999), and about \$13.5 billion is necessary for continuing care of those who experienced TBI in previous years (J.F. Kraus and McArthur 1999). About 65% of TBI-related costs are accrued among survivors. Statistics from 1985 estimate that TBI-related work loss and disability cost approximately \$20.6 billion (Max et al. 1991); this figure would be much higher today because of the rapid increase in the number of individuals with TBI surviving their injury but requiring supportive care (J.F. Kraus and McArthur 1999). Similar results have been reported among the military for recent conflicts, with the estimated total cost of \$600–\$900 million in the first year after diagnosis of TBI (Tanielian and Jaycox 2008). Long-term disability has primarily been attributed to psychiatric disorders and to behavior problems such as irritability (Sander et al. 1997; Whelan-Goodinson et al. 2008). Finally, self-reported TBI appears to be more frequent among psychiatric inpatients compared with the general population, with rates of approximately 66% in studies examining the issue (Burg et al. 1996, 2000). Thus, many psychiatrists will be involved in some level in the care of individuals with TBI.

Severity Classification

Original severity classifications for TBI focused on the Glasgow Coma Scale (GCS) (Jennett and Bond 1975) because of its widespread use. A TBI with a low postresuscitation GCS score of 3–8 is considered severe, 9–12 is moderate, and 13–15 is mild. However, although the GCS is useful for predicting mortality after TBI, it has less utility in predicting level of disability and neurobehavioral outcome, particularly at the upper end of the scale. It is recognized that individuals with GCS scores of 13–15 are quite heterogeneous in terms of levels of impairment and outcome (Dikmen et al. 2001; Saatman et al. 2008; Williams et al. 1990). Durations of coma and of posttraumatic amnesia are also used to describe TBI severity. These variables are difficult to determine in the civilian and combat setting, making TBI ascertainment and severity classification problematic.

The American Congress of Rehabilitation Medicine has put forth a definition of mild TBI that is widely used, requiring at least one of the following: 1) loss of consciousness (LOC) of 30 minutes or less, with an initial GCS score of 13–15; 2) posttraumatic amnesia of 24 hours or less; 3) presence of any alteration of mental state at the time of the injury (e.g., feeling dazed, disoriented, or confused); or 4) a focal neurological deficit (Kay et al. 1993). Patients with a GCS score of 13–15 who have imaging evidence of intracranial pathology have outcomes more similar to those of moderate TBI and are often classified as “complicated mild” injuries (see Williams et al. 1990).

Functional Pathophysiology

There has been considerable progress in understanding the pathophysiological mechanisms of TBI in recent years. The physical forces in TBI initiate mechanical and chemical changes that lead to neurological dysfunction. These are divided into *primary damage*, which occurs at the moment of injury, and *secondary damage*, which is initiated at injury but evolves over time. The latter is subdivided into direct injury, occurring within the neuron itself, and indirect injury, occurring outside the neuron but affecting its function.

Primary damage consists of injuries such as skull fractures, brain contusions and lacerations, and intracranial hemorrhage (McIntosh et al. 1996). Because these occur at the time of injury, the key treatment is prevention. Diffuse axonal injury is the predominant mechanism of injury in most cases of TBI (Meythaler et al. 2001), with shearing forces resulting in temporary or permanent disruption of axonal function. Diffuse axonal injury can evolve over a period of 24–72 hours after injury (Povlishock et al. 1983), making it potentially responsive to pharmacological intervention; however, no currently used therapeutic modality is known to influence its progression (Doppenberg and Bullock 1997).

Direct secondary injury occurs via neurochemical changes evolving over time after the mechanical disruption of neuronal pathways (McIntosh et al. 1996). The acute phase of this process has been well described, with a global increase in cerebral metabolism after injury (Bergsneider et al. 2001; Yoshino et al. 1991). This is accompanied by a period of excessive activity of neurotransmitters, including acetylcholine, glutamate, dopamine, norepinephrine, and various growth factors (Hayes et al. 1992; McIntosh et al. 1996). This may lead to abnormal activation of receptors, causing changes in intracellular signaling that lead to long-lasting modifications of cell function (Hamm et al. 2000). In addition, excessive transmitter activity may have direct neurotoxic effects, leading to apoptosis and permanent dysfunction. A key event in the early phase of injury is excessive influx of calcium (Gennarelli and Graham 1998), which may lead to gene activation, triggering preprogrammed cell death and enzyme activation, leading to damage to the cellular cytoskeleton and free radical generation.

The neurochemical changes in the subacute phase of TBI have been less intensively investigated, but current evidence indicates that this phase is associated with a dramatic reversal of acute processes. Cerebral metabolism and function of many neurotransmitters, including glutamate, acetylcholine, dopamine, and norepinephrine, become depressed (Hamm et al. 2000; Hayes and Dixon 1994); given the prominence of these neurotransmitters in psychiatric disorders, these alterations would potentially account for cognitive and neurobehavioral deficits in TBI. Research in animal models of TBI has successfully identified pharmacotherapies to reduce behavioral and histological complications (Marklund et al. 2006). However, clinical investigations of such agents have been disappointing (Wang et al. 2006). Interventions explored include anticholinergics, cholinomimetics, anti-inflammatory agents, calcium channel blockers, free radical scavengers, glutamate antagonists, and hypothermia (Beauchamp et al. 2008; Kokiko and Hamm 2007).

Psychiatric Disorders in Traumatic Brain Injury

Although useful data have been collected regarding the epidemiology of psychiatric disorders after TBI, the numbers of studies and subjects for each disorder remain small. Other limitations of many studies include selection bias (examining only hospitalized subjects or those referred for psychiatric evaluation), varying assessment periods, use of unstructured psychiatric interviews, and limited assessment of premorbid psychiatric history (Van Reekum et al. 2000). Such factors lead to wide variation in the estimates of incidence and prevalence of psychiatric disorders after TBI. Other complex disturbances seen after TBI are not ad-

equately captured by current diagnostic systems such as DSM-IV-TR (American Psychiatric Association 2000). Some symptoms, such as fatigue or impulsivity, may cause significant impairment but may not fit into a specific diagnosis. Also, individuals with TBI may lack insight into, and not report, their deficits. Psychiatrists may give greater weight to the reports of family and treating clinicians for this reason. However, family ratings may be influenced by other factors, including caregiver personality characteristics (McKinlay and Brooks 1984). Similarly, the clinician's emotional response to the patient may interfere with accurate assessment of deficits (Heilbronner et al. 1989). In addition to these general concerns, there may be differences in the presentation and phenomenology of specific disorders in the context of TBI.

The development of psychiatric disorders involves a complex interplay between premorbid biological and psychological factors, postinjury biological changes, and psychosocial and environmental factors. The role of many risk factors has yet to be well elucidated, and many are specific to a given disorder. A review by Rao and Lyketsos (2002) compiled risk factors for the development of psychiatric sequelae in general (Table 35-2). These are divided into highly significant risk factors (sufficient evidence exists for their role in psychiatric disorders) and less significant risk factors (evidence is still controversial). In a large unselected primary care population, Fann et al. (2004) found psychiatric history to be a highly significant risk factor for psychiatric illness in the 3 years following TBI. Their data suggested that moderate to severe TBI may be associated with higher initial risk for psychiatric problems, whereas mild TBI and prior psychiatric illness may increase the risk for more persistent psychiatric problems. The authors hypothesized that psychiatric symptoms that arise immediately after TBI may be etiologically related to the neurophysiological effects of the injury, consistent with the early relation between TBI severity and psychiatric risk, whereas other factors, such as psychological vulnerability, self-awareness of deficits, social influences, and secondary gain, may play roles over time, particularly in individuals with prior psychiatric illness and prior injury.

The role of TBI in the etiology of psychiatric disorders after TBI may have significant implications for prognosis and treatment, as well as medicolegal ramifications (Van Reekum et al. 2001). Although several psychiatric disorders are common after TBI, establishing a causal link between these remains difficult. Both Van Reekum et al. (2000, 2001) and Rogers and Read (2007) noted that some evidence for causality exists, in that studies (particularly in experimental animals) have shown that TBI disrupts neuronal systems involved in mood and behavior. However, other lines of evidence are inconclusive. The following sug-

TABLE 35-2. Risk factors for psychiatric illness after traumatic brain injury

Highly significant risk factors

- Preinjury psychiatric history
- Preinjury social impairments
- Increased age
- Alcohol abuse
- Arteriosclerosis

Less significant risk factors

- More severe injury
- Poor neuropsychological functioning
- Marital discord
- Financial instability
- Poor interpersonal relationships
- Low preinjury level of education
- Compensation claims
- Female gender
- Short time since injury
- Lesion location (especially left prefrontal)

Source. Adapted from Rao and Lyketsos 2002.

gestive findings point to other possible associations: 1) the psychiatric disorder increases the risk for TBI (Fann et al. 2002); 2) the risk for both TBI and the psychiatric disorder is due to a common third factor, such as substance abuse; and 3) a postinjury condition, such as pain or change in family status, contributes to the psychiatric disorder. Evidence for a biological gradient, in which more severe injuries are associated with higher risk for psychiatric disorders, is mixed. There is also a lack of specificity: TBI has been postulated to cause a variety of psychiatric disorders and conditions rather than a single specific syndrome. Assigning TBI as the definitive cause of psychiatric disturbances in most instances is not possible under current evidence.

Depression

Several studies have used structured interviews to examine rates of depression. Fann et al. (1995) used the National Institute of Mental Health Diagnostic Interview Schedule (DIS) to assess 50 consecutive outpatients presenting to a rehabilitation clinic for evaluation of TBI. Of these, 26% received the diagnosis of major depression, and another 28% had had major depression with onset after injury that had since resolved. Hibbard et al. (1998) administered the Structured Clinical Interview for DSM-IV (SCID) to 100 patients with TBI who were randomly selected from a larger quality-of-life study. Depression was found in 61%, with the onset of depression after injury in 48%. Deb et al.

(1999) examined 164 outpatients previously admitted to the emergency department with a diagnosis of TBI. Assessment based on the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) indicated that the rate of depression was 18%. Ashman et al. (2004) administered the SCID to 188 outpatients 3 months to 4 years after injury as part of a longitudinal follow-up of TBI. Major depression was present in 20% of patients before injury and in 24%–35% of patients during the first year of follow-up. Levin et al. (2005) prospectively followed up 239 consecutive subjects admitted with a diagnosis of mild TBI; of the 129 returning for follow-up at 3 months, 11.6% met criteria for major depression according to the SCID. Among the estimated 20% of Iraq and Afghanistan veterans who sustain a TBI, 7.3% report both TBI and posttraumatic stress disorder (PTSD) or depression, and 5% report all three conditions (Tanielian and Jaycox 2008). Among army soldiers with mild TBI with and without LOC, 23% and 8%, respectively, had major depression, compared with 7% with other injuries and 3% with no injuries (Hoge et al. 2008). Bryant et al. (2010) reported on 1,084 randomly selected admissions to four Australian trauma centers. Using the Mini International Neuropsychiatric Interview (MINI; Sheehan et al. 1998), 16% of patients were diagnosed with major depression at 12 months, with 11.6% being new onset after TBI. Bombardier et al. (2010) examined 559 consecutive admissions to a single trauma center with complicated mild to severe TBI. Assessments with the nine-item Patient Health Questionnaire (PHQ-9; Kroenke et al. 2001) at 1- to 2-month intervals identified 53.1% of patients with major depression during the 12-month follow-up period. Point prevalence ranged between 31% at 1 month and 21% at 6 months. Fann et al. (2005) found that the PHQ-9 was highly correlated with the SCID diagnosis of depression and other measures of depressive symptoms. Use of the criteria of at least five PHQ-9 symptoms being present for at least several days over the past 2 weeks, with at least one symptom being depressed mood or anhedonia, showed excellent operating characteristics with a sensitivity of 93% and a specificity of 89% for major depression.

In a systematic examination of depression after TBI, Federoff et al. (1992) examined 66 consecutive trauma center admissions with the Present State Examination (PSE), a forerunner of the SCAN. Approximately 1 month after injury, 26% had symptoms that met criteria for major depression. Jorge et al. (1993a, 1993b) carried out follow-up examinations on this cohort. At 3 months after injury, 12 of 54 patients (22%) had major depression; at 6 months, 10 of 43 (23%) had major depression; and at 12 months, 8 of 43 (19%) had major depression. Although the prevalence of depression remained fairly stable, some individuals had resolution of depression during the course of the year,

whereas others had onset of depression. Of the 41 patients without depression seen for follow-up, 11 (27%) developed depression during the study: 4 (10%) at 3 months, 4 (10%) at 6 months, and 3 (7%) at 12 months. Jorge et al. (2004) subsequently replicated these results in another cohort of 91 consecutive hospital admissions for TBI, showing 33% of the patients developing major depression during the first year after injury: 17% at initial evaluation, 10% at 3 months, and 6% at 6 months. Dikmen et al. (2004) followed up 283 consecutive hospital admissions with complicated mild to severe TBI with the Center for Epidemiological Studies Depression (CES-D) Scale. At 1 month postinjury, 46% of the subjects had at least mild depression. The rates declined to 35% at 6 months and remained stable at approximately 30% at 1 and 3–5 years postinjury.

Kreutzer et al. (2001) examined the scores of 722 outpatient referrals for neuropsychological evaluation with the Neurobehavioral Functioning Inventory (NFI), which assesses a wide range of functions after TBI. By mapping 37 of the NFI items to DSM-IV-TR (American Psychiatric Association 2000) diagnostic criteria, the authors reported that the prevalence of depression was 42%. A subsequent study (Seel et al. 2003) that used the same methodology in 666 patients at 17 TBI Model Systems centers found a rate of 27%. These studies had large sample sizes, but it remains unclear how the authors' mapping of NFI items corresponds with the diagnosis of depression on the basis of DSM-IV criteria in a clinical interview.

In their cohort, Jorge et al. (1993b) noted no difference between depressed and nondepressed patients with respect to demographic variables, type or severity of TBI, family history of psychiatric disorder, or degree of physical or cognitive impairment. Those with depression were significantly more likely to have a premorbid history of psychiatric disorders, including substance abuse. Subjects with depression had significantly poorer social functioning prior to injury, and poor social functioning was the strongest and most consistent correlate of depression on follow-up. Findings from their later cohort were generally consistent with these observations, except that individuals with depression were not more likely than individuals without depression to have a history of substance abuse (Jorge et al. 2004). In their original study (Federoff et al. 1992), depression at 1 month was strongly associated with lesions in the left dorsolateral frontal and/or left basal ganglia regions on computed tomography (CT) scanning. Right parieto-occipital lesions were associated with depression to a lesser extent. Pure cortical lesions were associated with a decreased probability of depression. However, no relation was found between lesion location and depression in subsequent follow-ups (Jorge et al. 1993a). In their later study (Jorge et al. 2004), major depression

was associated with reduced volume in the left prefrontal cortex at 3-month follow-up. Replication is needed to confirm these correlations.

Fann et al. (2004) found that patients with mild TBI had a higher risk for mood disorders (including depressive and anxiety disorders) than did patients with moderate to severe TBI (e.g., relative risk = 2.7 vs. 1.0 in the first 6 months following TBI) among 939 health maintenance organization enrollees with TBI. This finding is consistent with other reports that more severe TBI is not necessarily associated with a higher risk of depression (Fann et al. 1995; Hibbard et al. 1998). Dikmen et al. (2004) also found no relation between injury severity and risk for major depression but did find that less education, an unstable preinjury work history, and alcohol abuse increased the risk. Levin et al. (2005) noted that increasing age, presence of CT abnormalities, and higher CES-D scores at 1 week were strong predictors of major depression at 3 months. Finally, Bombardier et al. (2010) identified presence of major depression at the time of injury, history of major depression prior to injury, older age, and lifetime history of alcohol dependence as risk factors for major depression after TBI. Half of patients with MDD in the year following TBI were depressed within the first 3 months. These findings suggest that early evaluation for depressive symptoms can be helpful in identifying patients at risk for subsequent depression and that preventive measures may be useful in select subgroups of patients with mild TBI.

Early studies of major depression showed high rates of vegetative symptoms among individuals with TBI that exceeded the reported rate of depression in these patients. These symptoms included psychomotor slowing, reported at 67%–74% (Cavallo et al. 1992; McKinlay et al. 1981); difficulty concentrating, 38%–88% (Cavallo et al. 1992; Oddy et al. 1978b); fatigue, 33%–71% (Cavallo et al. 1992; Oddy et al. 1978b); insomnia, 27%–56% (Fichtenberg et al. 2001); and decreased interest, 21%–55% (Oddy et al. 1978b; Thomsen 1984). Although these investigations did not include a structured psychiatric assessment, the findings raised concern about the validity of using physical symptoms in the diagnosis of depression after TBI. The “inclusive,” “etiological,” “substitutive,” and “exclusive” approaches used in the medically ill have similar advantages and disadvantages in the TBI population. Although no studies have compared these approaches per se in TBI, Jorge et al. (1993a) did use a similar methodology to explore this issue. They found that TBI patients who reported depressed mood had higher rates of both physical and psychological symptoms of depression (as assessed with the PSE) than did those without depressed mood. The group with depressed mood also endorsed more DSM-III-R (American Psychiatric Association 1987) symptoms of major depression than did those with-

out depressed mood. The symptoms of suicidal ideation, inappropriate guilt, anergia, psychomotor agitation, and weight loss or poor appetite occurred with significantly greater frequency in the depressed group. Studies from patients with other forms of brain injury are similarly encouraging for the use of DSM diagnostic criteria. Paradiso et al. (1997) examined patients with acute stroke; the frequency of major depression was 18% by the inclusive strategy and 22% by the substitutive strategy. Dikmen et al. (2004) found that depressed affect and lack of positive affect, as well as somatic symptoms, contributed to elevated scores on the CES-D among subjects with major depression. R.E. Kennedy et al. (2005) compared the NFI depression subscale scores of subjects with and without a diagnosis of major depression according to the SCID. The highest between-group differences were not restricted to vegetative symptoms but included psychological symptoms such as loss of pleasure, being uncomfortable around others, feelings of hopelessness, and lack of confidence. Thus, it appears that the diagnosis of major depression can be accurately made with DSM criteria in brain-injured patients.

The course of major depression is the best described of disorders that develop after TBI. Jorge et al. (1993b) found that the mean duration of depression was 4.7 months. Subjects with anxious depression had a significantly longer duration of symptoms than did those with depression and no anxiety (7.5 months vs. 1.5 months). In their follow-up study, 33% of the patients met criteria for major depression during the year after injury. In half of these patients, the depression developed acutely; in the other half, the depression was of delayed onset. The mean duration of depression was 4.7 months for those who received antidepressants and 5.8 months for those who did not. Bombardier et al. (2010) found that among patients depressed within the first 3 months of injury, the median duration of depression was 4 months, with 27% depressed for only 1 month and 36% depressed for 6 months or more. Collectively, these data show that the onset of depression is not immediately linked to the occurrence of TBI in a significant number of individuals and that the duration of depression varies widely.

Mania

The prevalence of bipolar disorder after TBI is difficult to determine because most reports have been single cases or small case series. Varney et al. (1987) noted that 5% of their sample met the criteria for manic episodes, although it is unclear how many of these cases of mania predated the injury. A prevalence of 2% was reported by Hibbard et al. (1998), with all occurring after TBI; and Jorge et al. (1993c) reported that 9% of their subjects met the criteria for mania at some point during the year after injury. In contrast,

none of the subjects developed bipolar disorder in the study by Fann et al. (1995). Thus, although TBI may increase the risk for developing bipolar disorder, it still appears to be a relatively rare consequence of injury.

Phenomenologically, all forms of bipolar disorder, including bipolar I, bipolar II, and rapid-cycling variants, have been reported (McAllister 1992). The largest study addressing this topic suggested that patients are more likely to present with irritable than with euphoric mood (Shukla et al. 1987). Shukla et al. (1987) observed that mania after TBI was associated with posttraumatic seizures but not with family history of bipolar disorder. Jorge et al. (1993c) noted that mania after TBI was significantly related to basopolar temporal lesions but was not associated with type or severity of TBI, degree of physical or intellectual impairment, family or personal history of psychiatric illness, or posttraumatic epilepsy. They also reported on the course of mania occurring in their subjects. Of the six cases of subjects developing mania after TBI, five occurred within 3 months after injury and one within 6 months after injury. The duration of the manic episode was only 2 months, but elevated or expansive mood persisted for a mean of 5.7 months. These limited data suggest that episodes of bipolar disorder may occur soon after TBI. Its duration is relatively brief, although patients may have sub-syndromal disturbances present after mania resolves.

Anxiety

A continuing topic of interest and controversy has been the development of acute stress disorder and PTSD after TBI. Early opinion was that PTSD could not develop after TBI; investigators argued that LOC or posttraumatic amnesia would prevent patients from having reexperiencing and avoidance because memories were not encoded (Harvey et al. 2003). This hypothesis was supported by the studies of Mayou et al. (1993), Sbordone and Liter (1995), and Warden et al. (1997), each noting that none of their sample who had LOC during injury went on to develop PTSD. However, the first two studies relied on clinical interviews to determine PTSD, and the last used a modified version of the PSE, which assessed only two of the five criterion B (re-experiencing) symptoms. Thus, some experts have raised legitimate concerns that these studies did not adequately assess for PTSD.

Studies with more detailed, structured assessments of PTSD have yielded different results. Hibbard et al. (1998) noted that 19% of their subjects had symptoms that met criteria for PTSD. Mayou et al. (2000) examined consecutive admissions to an emergency department with the PTSD Symptom Scale, another structured interview providing DSM-IV diagnosis. Ten of the 21 subjects (48%) with definite LOC met the criteria for PTSD at 3 months, com-

pared with 9 of 39 (23%) with probable LOC and 179 of 796 (22%) without LOC. At 1-year follow-up, the rates of PTSD were 33%, 14%, and 17%, respectively. Levin et al. (2001) interviewed a sample of 69 patients with mild to moderate TBI drawn from admissions to a major trauma center. Of the patients, 12% received diagnoses of PTSD at 3 months according to the SCID, which was identical to the rate in general trauma control subjects. Ashman et al. (2004) found that 10% of their subjects met criteria for PTSD prior to injury, with 18%–30% meeting criteria during the first year of follow-up. Bombardier et al. (2006) prospectively examined 125 consecutive hospital admissions with complicated mild to severe TBI over 6 months with the PTSD Checklist–Civilian version (PCL-C). Only 5.6% of the subjects met full DSM-IV criteria for PTSD. The highest rates of PTSD symptoms (11.3%) were observed in the first month after injury, with a gradual attenuation of symptoms in the remaining months. This suggests that other studies that use referral samples may overestimate the prevalence of PTSD. Among military personnel, Hoge et al. (2008) found that 44% of those with mild TBI who reported LOC met criteria for PTSD, compared with 27% of those who reported mild TBI with altered mental status but no LOC, 16% of those with injuries other than TBI, and 9% of those with no injury.

Harvey and Bryant (1998) reported on 79 consecutive hospital admissions with mild TBI. According to the Acute Stress Disorder Interview, a structured clinical interview based on DSM-IV symptoms of acute stress disorder, 14% fulfilled diagnostic criteria. Of these subjects, 71 participated in follow-up at 6 months (Bryant and Harvey 1998), undergoing assessment with the PTSD module of the Composite International Diagnostic Interview, and 50 in follow-up at 2 years (Harvey and Bryant 2000). Rates of PTSD were 25% at 6 months and 22% at 2 years. Bryant et al. (2000) also examined 96 subjects drawn from admissions to a brain injury rehabilitation unit with severe TBI. Approximately 27% of the subjects met criteria for PTSD on the basis of the PTSD Interview; however, again, subjects were not consecutive admissions, and these data cannot be used to estimate overall prevalence of PTSD after TBI. In the largest study to date, Broomhall et al. (2009) used the Clinician-Administered PTSD Scale to examine 1,116 subjects consecutively admitted to the hospital with mild TBI. Approximately 4.6% of the subjects met criteria for acute stress disorder, again indicating that the rates of noncombat PTSD may be artificially inflated with referral samples or nonconsecutive admissions. Bryant et al. (2010) reported that 9.7% of their 1,084 patients had PTSD at 12 months, with 7% of these cases being new onset. Several of these studies also examined risk factors for, and the phenomenology of, PTSD. Bryant and Harvey (1998) noted

that 82% of the mild TBI patients who met criteria for acute stress disorder went on to develop PTSD, whereas only 11% of those without acute stress disorder eventually developed PTSD. It is not entirely clear whether memory of the traumatic event is necessary for the development of PTSD. In some cases, those who are “amnesic” for the event will actually have “islands” of traumatic memories that are involved in PTSD. In other cases, patients who do not recall their injury may develop PTSD around traumatic experiences involved in hospitalization, which they do recall. However, patients with mild TBI initially may have low rates of posttraumatic symptoms such as intrusive memories, but these may increase over time to meet criteria for PTSD (Bryant and Harvey 1999). Among those with severe TBI, Bryant et al. (2000) noted that the overwhelming majority of patients with PTSD did not have nightmares or intrusive memories but met reexperiencing criteria on the basis of marked psychological distress in response to reminders of the trauma. This area clearly warrants further investigation to determine the appropriateness of a PTSD diagnosis for such individuals.

It seems rather certain that those who do have memories of traumatic events are at increased risk for developing PTSD and should be monitored accordingly (Hiott and Labbate 2002). This is supported by the study of Gil et al. (2005), which prospectively examined 120 subjects with mild TBI for the development of PTSD. Memory of the traumatic event significantly increased the risk of developing PTSD; 23% of the subjects with memory of the traumatic event received a diagnosis of PTSD at 6 months postinjury, compared with only 6% of those without such memory. The differing rates of diagnosis were largely explained by differences in reexperiencing symptoms between subjects with and without memory of the traumatic event. Such findings are particularly important in light of research suggesting that PTSD occurring after TBI may be less likely to remit spontaneously, with more than 80% of the patients meeting criteria for acute stress disorder having PTSD on reassessment 2 years later (Harvey and Bryant 2000).

Bombardier et al. (2006) noted that being assaulted, feeling terrified or helpless at the time of the injury, and having stimulant (cocaine or amphetamine) intoxication increased the risk for developing PTSD. Lower levels of education also were associated with increased risk for PTSD, although it is unclear if this association would remain after the study controlled for other factors. Gil et al. (2005) found that acute posttraumatic symptoms, presence of depressive or anxiety disorders, and history of psychiatric illness increased the risk for PTSD. Among military personnel, Schneiderman et al. (2008) found that mild TBI approximately doubled the risk of PTSD among

recently returned service members. In contrast, a recent review (Institute of Medicine 2008) found only limited or suggestive evidence of a link between mild TBI and PTSD among Gulf War veterans; the reasons for these discrepant findings are unclear but may relate to differing mechanisms of injury. Finally, Vanderploeg et al. (2009) noted that subsequent mild TBI was associated with a significantly increased risk for persistence of PTSD symptoms among Vietnam War-era veterans compared with those who did not experience TBI.

Overall, the evidence indicates that PTSD is a common occurrence after TBI; however, the precise incidence is less certain, particularly for more severe injuries with posttraumatic amnesia. Individuals with acute stress disorder and other psychiatric disorders appear particularly vulnerable to the development of PTSD and should be monitored accordingly.

Other anxiety disorders also may be fairly common, although the number of investigations into this topic remains quite small. Fann et al. (1995) found that 24% of subjects met the criteria for generalized anxiety disorder (GAD) and 4% had panic disorder after TBI. In the follow-up study by Jorge et al. (1993b), 23 (76.7%) of the patients with major depression also met criteria for comorbid anxiety disorder, compared with 9 (20.4%) of the patients without major depression. Bombardier et al. (2010) reported that patients with TBI who were depressed were 9 times more likely to have a panic or other anxiety disorder compared with those who were not depressed. Hibbard et al. (1998) reported rates of 14% for obsessive-compulsive disorder (OCD), 11% for panic disorder, 7% for phobias, and 8% for GAD after injury. Deb et al. (1999) noted that 9% of their subjects had panic disorder, 3% had GAD, 2% had OCD, and 1% had phobias. Ashman et al. (2004) found that 16% of their subjects met criteria for other anxiety disorders besides PTSD prior to injury, with 19%–27% having other anxiety disorders during the first year of follow-up. Finally, Bryant et al. (2010) reported rates of 11.1% for GAD, 9.7% for agoraphobia, 6.9% for social phobia, 5.9% for panic disorder, and 3.5% for OCD at 12 months postinjury. The paucity of studies precludes any firm statements about risk factors for the development of anxiety disorders other than PTSD.

Psychosis

Relatively few studies have examined psychosis after TBI. Davison and Bagley (1969) reviewed eight studies before 1960, which showed that between 0.7% and 9.8% of the patients with TBI had a schizophrenia-like psychosis (although diagnosis was not based on structured criteria). In a different approach, Wilcox and Nasrallah (1987) performed a retrospective review of 659 hospital admissions

and found a significantly higher rate of prior head trauma in patients with schizophrenia compared with control subjects admitted for depression, mania, or general surgery. However, this study would not allow causal inferences to be made. Malaspina et al. (2001) examined 1,830 individuals who were first-degree relatives of patients with schizophrenia or bipolar disorder. Compared with other first-degree relatives, those individuals with a history of TBI were significantly more likely to develop schizophrenia. This suggested a synergistic relation between schizophrenia and TBI, in which familial factors among schizophrenic patients and their relatives increased the risk of TBI, and TBI further increased the risk of schizophrenia in those with genetic vulnerability.

Only a few studies have examined other forms of psychosis. Violon and DeMol (1987) performed a retrospective review of 530 patients with TBI admitted to a neurosurgical unit, noting that 3% had delusions during follow-up. Koponen et al. (2002) noted that three patients (5%) in their sample met criteria for delusional disorder, and one (2%) met criteria for psychotic disorder not otherwise specified. Fann et al. (2004) also found a higher rate of psychotic disorders among patients with TBI, compared with matched non-TBI control subjects, especially in those with moderate to severe TBI and with prior psychiatric illness.

Risk factors and phenomenology are similarly understudied. Sachdev et al. (2001) compared symptoms of 45 patients with TBI and psychosis with symptoms of 45 patients with TBI but no psychosis. They noted that auditory hallucinations and paranoid delusions were more common than negative symptoms. Fujii and Ahmed (2002) reviewed descriptions of psychosis after TBI in 69 patients from 39 publications, with particular emphasis on studies that used neuroimaging or neurophysiological measures. Delusions, most commonly persecutory, were much more common than hallucinations, and hallucinations were more likely to be observed in delayed-onset psychosis. Negative symptoms seen in schizophrenia were relatively uncommon.

In their review, Davison and Bagley (1969) identified several risk factors for psychosis, including left hemisphere and temporal lobe lesions, closed head injury, and increasing severity of TBI. Others have noted that more extensive brain injury, greater cognitive impairment, male gender, and having TBI in childhood were associated with psychosis (Fujii and Ahmed 2002; Sachdev et al. 2001).

Electroencephalogram abnormalities (especially in the temporal lobe) were common, and the rates of seizure disorders among individuals with psychosis after TBI were much higher than estimates for the rates of seizures after TBI in general (Fujii and Ahmed 2002). Neuroimaging lesions (predominantly in the frontal and temporal lobes) were also frequent. Finally, the severity and duration of

psychosis occurring after TBI may be less than those of idiopathic psychotic disorders, with only about one-third of patients with psychosis after TBI having a chronic course similar to schizophrenia in the studies examining this issue (Hillbom 1960; Violon and DeMol 1987). The onset of psychotic symptoms is typically gradual and delayed, often occurring more than a year after injury (Fann et al. 2004; Fujii and Ahmed 2002; Sachdev et al. 2001).

Anger, Aggression, and Agitation

Many patients with TBI have difficulty modulating emotional reactions and controlling impulses (Rao and Lyketos 2002), often described in the TBI literature as *posttraumatic agitation* (Sandel and Mysiw 1996). However, as noted by Yudofsky et al. (1997), *agitation* is a poorly defined term encompassing behaviors ranging from “constant unwarranted requests” to assaultiveness. Although measures such as the Agitated Behavior Scale (ABS; Corrigan 1989) have been well validated for TBI, they are rarely used in clinical practice (Fugate et al. 1997). Similarly, the Overt Aggression Scale (OAS; Yudofsky et al. 1986) was developed to provide objective measurement of the severity of aggression and, to a lesser extent, agitation. Other authors have expanded the OAS to make it more applicable to the rehabilitation setting by including a greater number of choices for antecedents and outcomes (Overt Aggression Scale-Modified for Neurorehabilitation-Extended [OAS-MNR-E]; Giles and Mohr 2007). Brooke et al. (1992b) used the OAS to measure agitation in 100 patients with severe TBI. Only 11% of the patients had agitation; an additional 35% were classified as “restless” but not severely enough to be labeled “agitated.” Bogner and Corrigan (1995) examined 100 consecutive patients admitted to an inpatient TBI unit. Of these, 42% had agitation (as measured by the ABS) during at least one shift. Episodes of anger or aggression are also common (Auerbach 1989). In their validation study of the OAS-MNR-E, Giles and Mohr (2007) noted 158 episodes of aggression in 34 subjects over a 6-week study period.

Although aggression may be a symptom of many disorders, several features are characteristic of aggression after TBI (Yudofsky et al. 1990). Such behavior is typically *non-reflective*, occurring without any premeditation or planning, and *nonpurposeful*, achieving no particular goals for the individual. It is also *reactive*, triggered by a stimulus, but often a stimulus that would not normally provoke a strong reaction. Aggression after TBI is *periodic*, occurring at intervals with relatively calm behavior in between, and *explosive*, occurring without a prodromal buildup. Finally, it is *ego-dystonic*, creating a great deal of distress for the patient.

The lack of precise definitions of agitation and aggression in the literature makes identification of risk factors

difficult, although some have been reported. Agitation is more likely to occur with frontotemporal injuries (Van der Naalt et al. 1999). Disorientation, comorbid medical illness, and use of anticonvulsant medications are also associated with agitation (Galski et al. 1994). Risk of aggression is increased with a premorbid history of impulsive aggression (Greve et al. 2001), impaired executive-attention function (Wood and Liossi 2006), arrest (Kreutzer et al. 1995), substance abuse (Dunlop et al. 1991), or depression (Jorge et al. 2004). For these risk factors, it is often difficult to ascertain whether the aggression is a direct result of TBI, premorbid character pathology, or both (Kim 2002).

Little is known about the course of agitation or aggression after TBI. However, in their review of the literature, Silver and Yudofsky (1994a) noted that 31%–71% of the individuals had these behaviors in long-term follow-up ranging from 1 to 15 years. Similarly, Baguley et al. (2006) noted that approximately 25% of inpatient rehabilitation patients with TBI showed aggression on the OAS at 6, 24, and 60 months postinjury. Greater depressive symptomatology and younger age at injury were the most significant predictors of later aggression. These authors also reported that 70% of the inpatient rehabilitation patients with TBI had agitation at discharge and at 6 and 24 months postdischarge in a retrospective chart review (Nott et al. 2006). Increased agitation was found to be associated with longer duration of posttraumatic amnesia, increased length of stay, and greater cognitive impairment. Thus, it appears that agitation and aggression may be chronic problems not confined to the early stage of recovery. This would be expected for such behaviors that predate the injury; it is currently unclear whether agitation and aggression directly resulting from TBI follow this chronic course.

Substance Use Disorders

Substance abuse and dependence are of great concern in the TBI population, at the time of injury and afterward. Substance use disorders not only are highly prevalent and often the underlying cause of injury but also adversely affect outcomes, including agitation, length of coma, risk of reinjury, return to work, and ability to reintegrate into the community (Bombardier and Turner 2009; Corrigan and Cole 2008). Alcohol intoxication at the time of injury may influence initial injury severity; however, preinjury alcohol abuse and problems do not necessarily predict poorer postacute cognitive functioning (Turner et al. 2006). Preinjury history of alcohol and substance abuse among individuals with TBI may not differ significantly from that of demographically similar control groups (Ponsford et al. 2007), although this requires further investigation. Literature reviews have shown that in higher-quality studies, 44%–66% of the patients with TBI had a history of significant alcohol-

related problems before injury and that 31%–51% were intoxicated at the time of injury (Bombardier and Turner 2009; Ponsford et al. 2007; Vickery et al. 2008). Those with a history of significant alcohol-related problems before injury are 11 times more likely to have alcohol problems after injury compared with those without alcohol problems before injury (Bombardier et al. 2003). Studies that used informal interviews and screening measures found that 21%–37% reported a history of illicit drug use (Bombardier et al. 2002; Kolakowsky-Hayner et al. 1999; Kreutzer et al. 1991, 1996; Ruff et al. 1990). In one study, 37.7% had a positive toxicology screen at the time of injury for one or more illicit drugs (marijuana 23.7%, cocaine 13.2%, amphetamine 8.8%; Bombardier et al. 2002). Bryant et al. (2010), using structured interviews to diagnose substance abuse, found that 9.9% of patients met criteria at 12 months, with 2.5% having onset after TBI. Substance abuse declines after TBI but remains significant. Longitudinal data indicate that, depending on the criteria used, rates of remission from alcohol problems range from 31% to 56% during the first year after injury (Bombardier et al. 2003). However, the initial decrease in alcohol use may subsequently increase with additional time since injury (Ponsford et al. 2007). Data on postacute heavy drinking and alcohol problems are relatively consistent in that 22%–29% of patients were moderate to heavy drinkers (Bombardier et al. 2002; Kreutzer et al. 1996) or met the criteria for substance abuse or dependence (Hibbard et al. 1998). However, some studies reported much lower rates of substance abuse or dependence—8% by Fann et al. (1995), 4% by Deb et al. (1999), and 10%–14% by Ashman et al. (2004). Research in which less formal measures were used has shown that 14%–43% of individuals reported significant alcohol or drug use after their injury (Kolakowsky-Hayner et al. 2002; Kreutzer et al. 1990, 1991). Timing of assessment and sensitivity of screening measures, as well as whether patients were unselected or from referral populations, may play critical roles in explaining some of these variations. Risk factors for postinjury substance abuse include male gender, history of legal problems related to substance abuse, substance abuse problems among family or friends, postinjury diagnosis of depression, younger age, and less severe injuries (Horner et al. 2005; Jorge et al. 2005; Ponsford et al. 2007; Taylor et al. 2003).

Brain injury rehabilitation may represent a window of opportunity for intervening in substance abuse disorders (Bombardier et al. 1997). More than 75% of TBI patients considered to be “at-risk” drinkers indicated that they were intending to reduce or were contemplating reductions in their alcohol use during inpatient rehabilitation (Bombardier et al. 2002). Of these patients, 17%–20% reported wanting to enter treatment or try Alcoholics Anonymous, and about 70% wanted to try changing on their own. A

simple typology based on lifetime history of alcohol-related consequences combined with recent alcohol consumption and toxicology results can be used to recommend tailored interventions: 1) TBI-specific education and advice, 2) brief motivational interventions, 3) relapse prevention training, or 4) referral to comprehensive substance abuse treatment (Turner et al. 2003). Referral to outside substance abuse treatment programs may be most helpful when staff members at available programs are comfortable with the cognitive and physical disabilities associated with TBI. Small financial incentives can facilitate substance abuse treatment attendance and completion in people with TBI (Corrigan and Bogner 2007). If such specialized programs are not available, efforts can be made to integrate evidence-based substance abuse interventions within rehabilitation programs (Bombardier and Turner 2009; Taylor et al. 2003).

Cognitive Impairment

Much effort has been devoted to characterizing the cognitive deficits that occur after TBI. Some have suggested that deficits can be divided into four time periods (Rao and Lyketsos 2000). The first is the period of LOC that results from the injury. After emerging from unconsciousness, many individuals enter a phase consisting of multiple cognitive and behavioral deficits, which some have described as posttraumatic delirium (Kwentus et al. 1985; Trzepacz 1994). The third period is a rapid recovery of cognitive function, which plateaus over time. This leads to the fourth period of permanent cognitive deficits. TBI is associated with deficits in multiple domains, including impaired memory, language deficits, reduced attention and concentration, slowed information processing, and executive dysfunction (Capruso and Levin 1996).

Although TBI is associated with an acute decrement in cognitive function that typically improves over time, recovery is very individualized, and no universally applicable description of the recovery process exists. Rao and Lyketsos (2000) offered the following general timeline: the first two periods of recovery will last from a few days to a month, the third period will last 6–12 months, and the fourth period will last 12–24 months. Such guidelines are more characteristic of moderate to severe injuries. By definition, individuals with mild TBI will have LOC of less than 30 minutes, with many having none at all (Kay et al. 1993). It is also estimated that about 95% of patients with mild TBI will recover to baseline status within 3–6 months and not enter the fourth phase of permanent deficits (Binder et al. 1997). Even among individuals with moderate to severe TBI, some recovery of cognitive function may occur 2 years or more after injury, although the gains are typically small (Millis et al. 2001). A few patients may experience decline late in the

course of recovery, perhaps caused by depression (Millis et al. 2001). Thus, these time frames must be considered general approximations only.

Descriptions of the period of recovery from TBI vary in the rehabilitation literature. One classical term is *posttraumatic amnesia*, which occurs “from injury until recovery of full consciousness and the return of ongoing memory” (Grant and Alves 1987). This would include the first two periods described earlier and potentially extend into the third. However, characterization of the deficits after TBI as purely amnesic is an oversimplification because multiple cognitive deficits occur (D.I. Katz 1992). Stuss et al. (1999) advocated discarding *posttraumatic amnesia* for the concept of *posttraumatic confusion*, although this has not gained widespread use in the TBI literature. Another common term for the period of recovery after TBI is *posttraumatic agitation*, characterized by “excesses of behavior that include some combination of aggression, akathisia, disinhibition, and/or emotional lability” (Sandel and Mysiw 1996, p. 619). This would correspond closely to the second period described earlier.

Unfortunately, the terminology used in the rehabilitation literature does not correspond exactly to DSM-IV-TR psychiatric diagnoses. Most definitions of posttraumatic amnesia would be consistent with a period of delirium followed by an amnesic phase (Trzepacz and Kennedy 2005). The term *posttraumatic confusion* more closely resembles the diagnosis of delirium yet still omits features such as mood and perceptual disturbances. *Posttraumatic agitation* is defined by some experts as a subtype of delirium (Sandel and Mysiw 1996), yet others have noted that agitation may resolve while the confusional state persists (Van der Naalt et al. 1999). Thompson et al. (2001) examined this issue in detail by concurrently rating inpatients with TBI on the Delirium Rating Scale (Trzepacz et al. 1988), a standardized measure for delirium; the Galveston Orientation and Amnesia Test (GOAT; Levin et al. 1979), a measure of posttraumatic amnesia; and the ABS (Corrigan 1989), a measure of posttraumatic agitation. Of those with a diagnosis of delirium, 22.5% had normal scores on the ABS, and 7.5% had normal scores on the GOAT. Among those without delirium, 7.5% had abnormal scores on the ABS, and 27.5% had abnormal scores on the GOAT. A combination of GOAT and ABS scores classified the delirium diagnosis with 77.5% accuracy. Thus, although the terms *delirium*, *posttraumatic amnesia*, and *posttraumatic agitation* describe conditions that share many common features, they are not synonymous.

The long-term diffuse cognitive deficits seen after TBI would be categorized as dementia due to head trauma or cognitive disorder not otherwise specified under DSM-IV-TR. This would include the fourth period described earlier and potentially the third period when the recovery process

is slow. Rehabilitation experts have expressed concern with use of the term *dementia* in the TBI population (Leon-Carrion 2002). The impairments seen after TBI, unlike those seen in most dementias, tend to be either static or improving over time. Experts also have expressed concern that application of DSM criteria would lead to diagnoses of dementia in the vast majority of individuals with moderate and severe TBI, with potential legal and social ramifications. Clearly, these implications should be further studied and addressed, but the DSM framework provides a useful standardized approach to diagnosis in this population that might otherwise be lacking.

Preliminary studies suggest that delirium after TBI shows phenomenological similarities to other types of delirium (Sherer et al. 2003b), with both hypo- and hyperactive subtypes noted in other patient populations. The hyperactive subtype appears more common and is associated with agitation and high frequency of hallucinations or delusions. Several risk factors for delirium in the medical-surgical population would likely apply to individuals with TBI (Trzepacz and Kennedy 2005), who are at increased risk for several medical illnesses (Kalisky et al. 1985; Shavelle et al. 2001). Risk factors for prolonged posttraumatic amnesia include older age, low initial GCS score, nonreactive pupils, longer coma duration, higher number of lesions detected by neuroimaging, and use of phenytoin (Ellenberg et al. 1996; J. T. Wilson et al. 1994). These would likely be risk factors for delirium as well. Unfortunately, patients who are traditionally considered to have a higher risk for delirium—especially alcoholic patients, elderly patients, those with psychiatric and neurological histories, and those with prior brain injury—are nearly always excluded from posttraumatic amnesia studies (Trzepacz and Kennedy 2005). Finally, more recent studies have highlighted the prognostic significance of delirium after TBI, which is an important predictor of length of rehabilitation stay (Sherer et al. 2005) and later employability and productivity (Nakase-Richardson et al. 2007; Sherer et al. 2008).

For dementia, severity of injury is consistently associated with the degree and duration of cognitive impairments. The extent of impairment is also influenced by pre-morbid intellectual abilities and the time after injury at which the patient is assessed (Dikmen et al. 1995). As with other dementias, the cognitive domains affected will vary from patient to patient (Kreutzer et al. 1993). Patients with TBI also may be at increased risk for developing dementia from other causes, such as Alzheimer's disease (Amaducci et al. 1986; Graves et al. 1990).

Postconcussive Syndrome

The diagnosis of postconcussive syndrome has been a source of wide controversy. It is important to differentiate

postconcussive *symptoms* from postconcussive *syndrome*. The symptoms of postconcussive syndrome are nonspecific and include disturbances such as headache, dizziness, irritability, fatigue, and insomnia. Indeed, several studies have documented high base rates of postconcussive symptoms among subjects without TBI, often at rates similar to those in individuals with mild TBI (Boake et al. 2005; Caviness 1966; Gouvier et al. 1988; McLean et al. 1983; Meares et al. 2008; Tuohimaa 1978). There is disagreement as to the number and types of symptoms required for postconcussive syndrome. Most experts concur that the diagnosis of postconcussive syndrome requires the presence of multiple concurrent symptoms (Brown et al. 1994; Mittenberg and Strauman 2000), although disagreement may remain over which specific symptoms are required. Standardized diagnostic criteria for postconcussive syndrome have been developed; DSM-IV-TR lists provisional criteria for postconcussional disorder (Table 35–3), indicating that the diagnosis may still undergo refinement. The most widely published criteria are those in ICD-10 (World Health Organization 1992), listed in Table 35–4. Differences between the two sets of criteria do exist, but the implications have not been well studied. Boake et al. (2005) found the ICD-10 criteria to be much more inclusive than the DSM-IV criteria, with 64% of individuals hospitalized for mild to moderate TBI meeting criteria for postconcussive syndrome at 3 months using the former but only 11% with the latter. Unfortunately, few studies have used either of these criteria sets (Mittenberg and Strauman 2000). The adoption of such standard definitions will be a necessary step in advancing the study and treatment of postconcussive syndrome.

Because postconcussive symptoms are not specific to TBI, it is important to consider their differential diagnosis. Alexander (1995) and Mittenberg and Strauman (2000) noted that postconcussive syndrome has significant overlap with psychiatric disorders. Both major depression and postconcussive syndrome have symptoms of depressed mood, irritability, sleep disturbance, fatigue, and difficulty with concentration. However, unlike major depression, postconcussive syndrome does not include symptoms of changes in appetite, psychomotor changes, or suicidal ideation. Stein and McAllister (2009) specifically described the overlap between PTSD and postconcussive syndrome. PTSD and postconcussive syndrome have common symptoms of anxious mood, difficulty sleeping, irritability, poor concentration, and difficulty recalling the injury. Postconcussive syndrome is not associated with persistent reexperiencing of the event or with numbing of responsiveness, and PTSD is not associated with the headaches, dizziness, and general memory disturbance that characterize postconcussive syndrome. Symptoms such as head-

TABLE 35-3. DSM-IV-TR research criteria for postconcussional disorder

- A. A history of head trauma that has caused significant cerebral concussion.
- Note:** The manifestations of concussion include loss of consciousness, posttraumatic amnesia, and, less commonly, posttraumatic onset of seizures. The specific method of defining this criterion needs to be established by further research.
- B. Evidence from neuropsychological testing or quantified cognitive assessment of difficulty in attention (concentrating, shifting focus of attention, performing simultaneous cognitive tasks) or memory (learning or recalling information).
- C. Three (or more) of the following occur shortly after the trauma and last at least 3 months:
- (1) becoming fatigued easily
 - (2) disordered sleep
 - (3) headache
 - (4) vertigo or dizziness
 - (5) irritability or aggression on little or no provocation
 - (6) anxiety, depression, or affective lability
 - (7) changes in personality (e.g., social or sexual inappropriateness)
 - (8) apathy or lack of spontaneity
- D. The symptoms in Criteria B and C have their onset following head trauma or else represent a substantial worsening of preexisting symptoms.
- E. The disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning. In school-age children, the impairment may be manifested by a significant worsening in school or academic performance dating from the trauma.
- F. The symptoms do not meet criteria for dementia due to head trauma and are not better accounted for by another mental disorder (e.g., amnesic disorder due to head trauma, personality change due to head trauma).

ache, fatigue, dizziness, blurred vision, memory disturbance, and hypochondriacal preoccupation with health may be part of postconcussive syndrome or of a somatoform disorder. Postconcussive syndrome is not associated with the gastrointestinal symptoms often seen in somatization disorder, and it is also not associated with marked

TABLE 35-4. ICD-10 criteria for postconcussive syndrome

- A. History of head trauma with loss of consciousness precedes symptom onset by maximum of 4 weeks.
- B. Three or more symptom categories
1. Headache, dizziness, malaise, fatigue, noise intolerance
 2. Irritability, depression, anxiety, emotional lability
 3. Subjective concentration, memory, or intellectual difficulties without neuropsychological evidence of marked impairment
 4. Insomnia
 5. Reduced alcohol tolerance
 6. Preoccupation with above symptoms and fear of brain damage with hypochondriacal concern and adoption of sick role

motor or sensory deficits or nonepileptic seizures often seen in conversion disorder. Patients with chronic pain also may have symptoms of headaches, fatigue, poor sleep, poor concentration, depressed mood, and dizziness that overlap with postconcussive syndrome. Thus, the presence of psychiatric disorders may lead to high rates of reporting of postconcussive symptoms, regardless of TBI history (Fox et al. 1995; Suhr and Gunstad 2002; Trahan et al. 2001). Careful history taking and diagnosis are needed to avoid mislabeling these patients as having postconcussive syndrome. The clinician also must keep in mind that individuals may have both postconcussive syndrome and a psychiatric disorder, which may blur the boundaries between the two.

Studies have examined risk factors and time course for the development of postconcussive syndrome. However, failure to use standardized diagnostic criteria for postconcussive syndrome in most studies makes generalization difficult. Most studies of postconcussive syndrome have focused on individuals with mild TBI, although postconcussive syndrome can occur with more severe injuries as well. The symptoms of postconcussive syndrome are extremely common after mild TBI, with 80%–100% of patients experiencing one or more symptoms in the immediate postinjury period (Levin et al. 1987a). Several studies have shown that such symptoms resolve completely within 3 months in most patients (Alves et al. 1986; R. W. Evans 1996; Leininger et al. 1990). However, other prospective studies have shown that 20%–66% of patients have persistent symptoms at 3 months (Englander et al. 1992) and that 1%–50% have persistent symptoms at 1 year (Middle-

boe et al. 1992; Rutherford et al. 1979). Alves et al. (1993) followed up the resolution of these symptoms in 587 consecutive adult hospital admissions with mild TBI, with assessments at baseline and at 3, 6, and 12 months. Approximately two-thirds of the patients had symptoms of postconcussive syndrome at discharge, with progressive decline in prevalence during recovery. At 3 months, 40%–60% experienced such symptoms; at 6 months, 25%–45%; and at 12 months, 10%–40%. Most of these subjects reported only one or two postconcussive symptoms and would not qualify for a diagnosis of postconcussive syndrome under DSM or ICD. Subjects with multiple symptoms consistent with a diagnosis of postconcussive syndrome were rare—between 1.9% and 5.8% of those studied. For this and many other studies, the lack of an appropriate control group makes it difficult to determine how many of these symptoms could be attributed to the TBI itself.

Because the symptoms of postconcussive syndrome are nonspecific, some have questioned whether it constitutes a true disorder or syndrome (King 1997, 2003). There also is a long-standing debate as to whether postconcussive syndrome constitutes a neurological or a psychiatric syndrome (King 2003; Mittenberg et al. 1996). Currently, the acute syndrome is thought to be related to neurological factors, whereas chronic symptoms are more likely to persist because of psychological factors (Larrabee 1997; Mittenberg and Strauman 2000). Complaints of poor sleep, difficulty concentrating, and memory disturbances that arise shortly after TBI may be caused by direct neuronal injury (Alexander 1997). Dizziness may be due to central or peripheral vestibular injury, and pain complaints may be due to musculoskeletal or scalp injury (Alexander 1997). It is not known how these putative neurological injuries, which should resolve quickly, transition into chronic postconcussive syndrome. Symptom expectations, in which patients fear that their symptoms will not resolve, may play a role (King 2003; Mittenberg and Strauman 2000; Mittenberg et al. 1996). However, the precise role of psychological factors in persistent postconcussive syndrome is far from clear (Dikmen et al. 1989). Thus, the risk factors for postconcussive syndrome are a mixture of biological and psychological.

The more commonly reported risk factors are female gender (Bazarian et al. 1999; McCauley et al. 2001; McClelland et al. 1994; Meares et al. 2008), older age (Alexander 1997; McCauley et al. 2001), history of TBI (McCauley et al. 2001; Schneiderman et al. 2008), psychosocial stress (Fenton et al. 1993; Moss et al. 1994), and poor social support (Fenton et al. 1993; McCauley et al. 2001). Dikmen et al. (2010) also found that preinjury history of alcohol abuse and psychiatric history were associated with greater endorsement of posttraumatic symptoms. Low socioeco-

nomic status and ongoing litigation also increase risk (Alexander 1997; Binder and Rohling 1996; McCauley et al. 2001). However, for the latter, it should be noted that few individuals involved in litigation have improvement in postconcussive syndrome after settlement (King 2003). Self-reported rates of specific postconcussive symptoms (anxiety, noise sensitivity, and difficulty concentrating) also have been associated with increased risk of long-term postconcussive syndrome (Dischinger et al. 2009). Finally, in examining postconcussive symptoms among individuals without TBI, Gouvier et al. (1992; Santa Maria et al. 2001) noted that females had higher rates of symptom reporting, and rates of reporting increased with levels of psychosocial stress.

A significant association is seen between depression and postconcussive symptoms, including those postconcussive symptoms that do not overlap with depression (Fann et al. 1995; King 2003), and severity of depressive symptoms predicts risk for postconcussive syndrome (McCauley et al. 2001; Meares et al. 2008). McCauley et al. (2001) used portions of the SCID to identify major depression and PTSD as significant moderators of postconcussive syndrome. It appears that psychiatric disorders, particularly depression, may significantly amplify the presentation of postconcussive symptoms. Meares et al. (2008) had similar findings with the Mini International Neuropsychiatric Interview and the ICD-10 criteria for postconcussive syndrome, with major depression, PTSD, and other anxiety disorders increasing the risk for postconcussive symptoms within 2 weeks of injury. They also noted that increasing levels of pain raised the risk for postconcussive syndrome. Schneiderman et al. (2008) found PTSD to be a significant predictor of postconcussive symptoms among combat veterans with mild TBI, even after overlapping symptoms of PTSD and postconcussive syndrome were eliminated. Hoge et al. (2008), in their study of recently returned soldiers, found that the association of mild TBI with postconcussive symptoms was no longer significant after they controlled for major depression and PTSD, suggesting that elevated rates of postconcussive symptoms after mild TBI in this population were mediated to a large degree by the latter two diagnoses. In contrast, Vanderploeg et al. (2009) noted that mild TBI and PTSD had independent contributions to postconcussive symptoms among Vietnam War-era veterans. In the latter study, mild TBI occurred several years after the development of PTSD, whereas in the former, the traumatic event and mild TBI occurred in the same period, so the results cannot be directly compared.

Although the vast majority of the persons with mild TBI experience good recovery (Binder et al. 1997), Ruff (1999) identified a “miserable minority” of 10%–20% of mild TBI patients with poor outcome, and Malec (1999)

noted that 20%–40% of mild TBI patients have residual long-term symptoms or disability. In many cases, such individuals complain of symptoms of postconcussive syndrome, indicating that ongoing postconcussive syndrome may be an important source of disability. Studies of such patients also have found significant deficits on a variety of neuropsychological tests (Bohnen et al. 1992; Guilmette and Rasile 1995; Leininger et al. 1990), although it remains unclear how these difficulties develop during the course of postconcussive syndrome. The severity of postconcussive symptoms is consistently correlated with severity of impairment in information-processing speed, but correlations with other cognitive domains (such as verbal and visuospatial abilities) are equivocal (King 2003). In particular, Larrabee (1999) commented on two of these studies, which consisted of patients experiencing postconcussive symptoms after TBI involving LOC of less than 30 minutes. The effects on neuropsychological testing observed in these patients were equivalent to the effects observed in other studies in patients who had undergone 1–4 weeks of coma (Dikmen et al. 1995). These data suggest that individuals with persistent postconcussive syndrome differ in significant respects from most individuals with TBI, although the reasons for these differences remain unexplained. Investigators also have found that high rates of postconcussive symptoms were better predictors of neuropsychological test performance than was actual history of mild TBI (Hanna-Pladdy et al. 1997; Pinkston et al. 2000). These results cast further doubt on the contention that the cognitive impairment in persistent postconcussive syndrome is due to TBI.

Sleep Disorders

Sleep disturbances are a common component of many neuropsychiatric disorders occurring after TBI, including delirium, major depression, bipolar disorder, anxiety disorders, and postconcussive syndrome. TBI also may have significant effects on sleep architecture that are independent of these illnesses by altering the levels of several neurotransmitters involved in the regulation of sleep. The prevalence of sleep disturbance after TBI is high, with estimates ranging from 30% to 70% (Ouellet et al. 2004). Although insomnia is a frequent focus in the literature, other forms of sleep disturbances, such as fatigue and daytime sleepiness, have been reported. Reports also have found increased rates of obstructive sleep apnea, periodic limb movements, and narcolepsy among individuals after TBI compared with control populations (Castriotta et al. 2007; Lai and Castriotta 1999; Verma et al. 2007; J.B. Webster et al. 2001). In at least some cases, evidence suggested that the sleep disorder predated the TBI, raising the possibility that the sleep disorder increased the risk for TBI rather

than vice versa. Orff et al. (2009) provided a comprehensive review of the literature concerning sleep and TBI. They noted several deficiencies in existing studies, including poor descriptions of comorbid physical and psychological conditions that may contribute to sleep disturbances, inadequate information about TBI severity and injury location, and few long-term studies. More recent studies also indicate that sleep disturbance, particularly insomnia, is more likely with mild TBI than with more severe injuries, although the reasons for this difference are unknown.

Psychological Aspects

In addition to the defined DSM-IV-TR psychiatric disorders, TBI is associated with psychological challenges that may not fit into specific diagnostic categories. Four areas of importance are the neurological injury and resultant cognitive deficits, the psychological meaning of deficits and their effect on the patient, the psychological factors that exist independently of TBI, and the broader social context (Lewis 1991).

Deficits due to neurological impairment may have a direct effect on psychological functioning. Impaired self-awareness is common after TBI, with 76%–97% of TBI patients showing some degree of impairment (Sherer et al. 1998c, 2003a). Many individuals with TBI also have deficits in awareness of their behavioral limitations (Prigatano and Altman 1990), which may be one of their most troubling problems (Ben-Yishay et al. 1985; Prigatano and Fordyce 1986). Awareness of cognitive and emotional changes tends to be worse than awareness of physical dysfunction (Sherer et al. 1998c). There is little agreement on the most appropriate way to measure lack of awareness (Sherer et al. 1998b, 2003a). Comparisons of patient reports with those of family members (D.J. Fordyce and Roueche 1986; Hendryx 1989; McKinlay and Brooks 1984; Prigatano 1996; Prigatano and Altman 1990; Prigatano et al. 1990; Walker et al. 1987) or rehabilitation providers (D.J. Fordyce and Roueche 1986; Gasquione 1992; Gasquione and Gibbons 1994; Heilbronner et al. 1989; Ranseen et al. 1990) may be biased by respondent characteristics. Comparing patient reports with neuropsychological test results can eliminate much of this subjectivity but may not allow the consultant to gauge the accuracy of patient self-reports of real-world functioning (Allen and Ruff 1990; Anderson and Tranel 1989; Heaton and Pendleton 1981). The method of questioning is also important because studies have shown that patients are much less likely to report deficits when asked general questions rather than specific ones (Gasquione 1992; Sherer et al. 1998b).

Impaired awareness has both neurological and psychological dimensions. At one extreme is anosognosia, wherein the person has no awareness of neurological impairments

(Prigatano 1999). At the other extreme is “defensive denial,” which represents the person’s attempt to cope with overwhelming anxiety associated with neurological impairment by minimizing the implications. Apparent impaired awareness also can be the result of moderate to severe memory impairment that prevents the person from consolidating and acting on new information about his or her condition. The neuroanatomical underpinnings of impaired self-awareness are not well documented, but hypoarousal associated with subcortical damage and various types of cortical damage is thought to contribute (Prigatano 1999). Few studies have attempted to separate neurological from psychological causes of decreased awareness (Boake et al. 1995; McGlynn and Schacter 1989). Phenomenologically, decreased awareness might appear the same regardless of cause but has significant treatment implications. Interventions designed to address denial and other forms of decreased awareness resulting from psychological causes may be ineffective when the decreased awareness is due to neurological dysfunction that cannot be reversed.

Finally, most studies of awareness have focused on individuals who overestimate their abilities compared with the reports of others. However, some patients underestimate their abilities; the deficits that these individuals have in awareness have not been well studied (Prigatano and Altman 1990). Although more than a half-dozen instruments have been developed for measurement of awareness in the TBI population, there has been little work on the psychometric properties or factor structures of these instruments (Seel et al. 1997; Sherer et al. 1998b). Research in this area is ongoing, and the most systematically studied scales are the Patient Competency Rating Scale (Prigatano and Fordyce 1986) and the Awareness Questionnaire (Sherer et al. 1998a). Other measures are also being developed and validated. Nimmo-Smith et al. (2005) specifically investigated a bedside examination of anosognosia for hemiplegic deficits with questions related to bilateral arm and leg use to find maximum discrimination between groups that did and did not overestimate their physical abilities. Murrey et al. (2005) reported that the Mayo-Portland Adaptability Inventory had good discrimination between patients with severe TBI having frontal lobe damage and anosognosia and patients with mild TBI having no demonstrable frontal lobe damage. Both the total score and four of the subscale scores (Communications, Emotions, Independent Living Skills, and Relationship) differed between groups, whereas no differences were noted on the Mobility subscale, indicating that the scale was useful for measuring specific deficits of awareness. The available literature suggests that deficits in awareness are common immediately after TBI, with gradual improvement over time (C. Evans et al. 2003).

The patient’s psychological state and the perceived meaning of physical and cognitive deficits may be strongly linked. Patients with depression or anxiety appear to perceive their injury and associated cognitive problems as more severe (Fann et al. 1995, 2000). Many patients with TBI experience grief in reaction to their disability and loss of their “former self.” For many years, rehabilitation researchers have relied on bereavement concepts to explain the adjustment-to-disability process (Stewart and Shields 1985; Vargo 1978). However, long-held assumptions about the symptoms and process of normal bereavement have not withstood empirical testing (Marwit 1996; Stroebe et al. 2001; Wortman and Silver 1989). For example, the 2-month time limit placed on a “normal” grieving process in DSM-IV has been called into question (Parkes and Weiss 1983; Wortman and Silver 1989). Also, contrary to the belief that a person must make a “show” of grief, some support exists for the benefits of focusing on positive emotions (Bonanno and Kaltman 1999). Finally, advances in the understanding of grief following loss of a loved one, with few exceptions (Niemeier et al. 2004), have not yet been applied to the emotional experience of individuals with functional and cognitive losses due to illness or injury.

Psychological defenses and adaptations used by the individual prior to TBI are also important. In many cases, patients will continue to use previously learned defenses. However, in some instances, coping mechanisms used before the injury may no longer be available because of the degree of neurocognitive impairment; this can cause considerable distress for the patient. Evidence indicates that many behavioral traits are exacerbated by TBI rather than developing *de novo* after injury (Prigatano 1991). Such alterations would be diagnosed as personality change due to TBI in DSM-IV-TR.

Finally, as with many other chronic illnesses, TBI has a significant effect on family and social functioning. Individuals with TBI may be unable to return to their former roles as breadwinner, parent, or spouse, placing significant demands on other members of the family system (Kay and Cavallo 1994). In general, neurobehavioral disturbances are the most important source of stress for the family, but this effect can be mediated by good social support (Ergh et al. 2002; Groom et al. 1998). Family members are at significantly increased risk for psychiatric disorders, particularly anxiety and depression, and for increased substance use (Hall et al. 1994; Kreutzer et al. 1994; Livingston et al. 1985). Caregivers may experience problems such as unemployment or financial loss, placing additional stresses on the patient and family (Hall et al. 1994). Sexual dysfunction after TBI places further stress on intimate relationships (Hibbard et al. 2000a), and partners may be uncomfortable with the dual role of caregiver (parentlike) and

sexual partner (spouse) (Gosling and Oddy 1999). Rates of separation and divorce are also elevated for individuals with TBI (G. Webster et al. 1999).

Spinal Cord Injury

Epidemiology

SCI results from trauma to the spinal cord and may cause changes in motor, sensory, or autonomic functioning. SCI is an uncommon but often catastrophic injury with an annual incidence of 30–40 per million and a point prevalence of 183,000–230,000 in the United States (Go et al. 1995). However, a recent unpublished report commissioned by the Christopher Reeve Foundation suggests that the prevalence of SCI may be as high as 1,275,000 (www.christopherreeve.org). Those who sustain SCIs are predominantly males (80%), young (half are ages 16–30), and Caucasian (89%). At the time that they are injured, those sustaining SCI are less likely to be married, twice as likely to be divorced, and slightly less educated than the general population. The most common causes of SCI are motor vehicle crashes (44.5%), falls (18.1%), violence (16.6%), and sports activities (12.7%).

Early survival and overall life expectancy rates for persons with SCI have improved dramatically over the past 30 years. However, life expectancy with SCI remains below that of the general population, especially among those who are ventilator dependent (DeVivo et al. 1999). Leading causes of death are heart disease (19%); external causes such as accidents, suicide, and violence (18%); respiratory illness, especially pneumonia (18%); and septicemia (10%) (DeVivo et al. 1999). Death from suicide is approximately five times more common among people with SCI than in the general population (59.2 per 100,000) and represents about 9% of deaths. Most suicides occur within 5 years of injury (Charlifue and Gerhart 1991).

Severity Classification

Tetraplegia (or quadriplegia) denotes SCI that affects all four limbs, whereas *paraplegia* denotes injuries that affect only the lower extremities. SCI usually is described in terms of the level and the completeness of injury. The level of injury refers to the most caudal segment with normal motor or sensory function. Neurological level of injury may vary on the right and the left side, and segments also may be partially innervated. More than half of all injuries (54%) result in tetraplegia, whereas 46% are classified as resulting in paraplegia. The midcervical region is the most common site of injury. Injury severity is most commonly described according to the American Spinal Injury Association (ASIA) Impairment Scale (Table 35–5). Approximately half

TABLE 35–5. American Spinal Injury Association (ASIA) Impairment Scale

- A. Complete**—No sensory or motor function is preserved in the sacral segments S4/5.
- B. Sensory Incomplete**—Sensory but no motor function is preserved below the neurological level and includes the sacral segments S4/5.
- C. Motor Incomplete**—Motor function is preserved below the neurological level, and more than half of the key muscles below the neurological level have muscle grade less than 3 (active movement against gravity). There must be some sparing of sensory and/or motor function in the sacral segments S4/5.
- D. Motor Incomplete**—Motor function is preserved below the neurological level, and at least half of the key muscles below the neurological level have a muscle grade greater than or equal to 3. There must be some sparing of sensory and/or motor function in the sacral segments S4/5.
- E. Normal**—Sensory and motor functions are normal. Patient may have abnormalities of reflex examination.

of all injuries are considered ASIA-A or “complete.” Of those admitted with an ASIA-A SCI, only about 2% are expected to improve to the point of having functional motor recovery below the level of their injury. In contrast, those admitted with an ASIA-B injury have about a 35% chance of regaining functional motor abilities below the level of their lesion. Those admitted with an ASIA-C injury have a 71% chance of regaining functional motor ability below the level of their injury (Marino et al. 1999).

Acute Management and Management of Secondary Complications

Emergency management of SCI involves immobilizing the spine as well as ensuring an open airway, breathing, and circulation. In many settings, standard practice is to administer a large intravenous bolus of methylprednisolone within 8 hours of injury to minimize secondary injury due to swelling within the spinal canal. Unstable spine fractures may require surgical decompression and stabilization. Various orthoses are used to maintain external spinal stabilization after surgery, typically for 3 months.

Key aspects of postsurgical care include respiratory management and prevention of pneumonia, management of orthostatic hypotension associated with blood pooling in the lower extremities, and prevention of deep venous

thrombosis and pulmonary embolus from venous stasis and hypercoagulability. Neurogenic bladder and bowel management begins with indwelling or intermittent catheterization and establishment of a regular bowel regimen. After injury, heterotopic ossification, the deposition of new bone in and around joints, may cause loss of range of motion. Spinal reflexes are initially depressed during the period of "spinal shock" but then become hyperactive during the first 6 months after injury. Daily range of motion and static muscle stretch are used to reduce spasticity and prevent contractures, along with medication such as baclofen, diazepam, and clonidine. Pain is a common problem; 25% complain of severe pain, and 44% report that pain interferes with daily activities (Staas et al. 1998). SCI-related pain classification remains controversial, but important dimensions include whether the pain is above, at, or below the lesion level and whether the pain is judged to be nociceptive or neuropathic (Bryce et al. 2007). Concurrent TBI is present in about 60% of patients with SCI, although 57% of brain injuries are mild (Macciocchi et al. 2008). Of the patients with recent SCI, 10%–60% may have cognitive impairment (Davidoff et al. 1992). Cognitive deficits may be attributable to a variety of factors, including preinjury learning disabilities, substance abuse, and traumatic or hypoxic brain injury sustained at the time of SCI. Behavior problems such as noncompliance, anger, and agitation may be attributable to premorbid traits or undetected brain injury. A severe complication for people with midthoracic or higher spinal cord injuries is autonomic dysreflexia. Autonomic dysreflexia is often triggered by a noxious stimulus below the level of lesion that leads to sympathetic discharge uninhibited by descending neural control. Immediate steps must be taken to control hypertension and to identify and reverse the triggering stimulus. The most common secondary medical complication during the first year postinjury is pressure ulcers (McKinley et al. 1999).

Acute Rehabilitation

Patients are usually transferred to specialized rehabilitation programs once they are medically stable and can participate in therapies for at least 3 hours per day. Inpatient rehabilitation typically focuses on education, physical training, strengthening, and basic skill building needed to return to maximal functional independence for living in the community. Individuals with paraplegia are usually expected to be able to function and live independently once their rehabilitation is complete (Consortium for Spinal Cord Medicine 1999). Those with low cervical lesions (C7–8) should be independent in most functional tasks. Depending on their neurological level, people with higher cervical lesions require different degrees of assistance for activities of daily living, such as managing bowel and blad-

der, bathing, dressing, eating, and transferring to and from a wheelchair. Whatever his or her level of injury, the person with SCI is expected to be independent in guiding others to care for him or her in areas the person cannot perform on his or her own.

Adjustment to Spinal Cord Injury

Following discharge from acute rehabilitation, 91% of the people with SCI are discharged to a home environment (Eastwood et al. 1999). Estimates of employment rates after SCI have varied from 13% to 69%. One study found that, overall, 27% were employed, with 14% employed within 1 year and 35% employed within 10 years postinjury (Krause et al. 1999). Subjective well-being and quality of life are somewhat controversial, especially with regard to patients with high tetraplegia. The controversy relates to the tendency of health care workers to overestimate depressed mood and underestimate potential quality of life in survivors of SCI (Caplan 1983; Gerhart et al. 1994; Trieschmann 1988). In sharp contrast with what health care workers predict, more than 90% of the people living in the community with high tetraplegia, including those with ventilator dependence, report that they are "glad to be alive" (Gerhart et al. 1994). Nevertheless, people with SCI tend to report lower subjective quality of life compared with nondisabled persons (Barker et al. 2009). It is somewhat surprising that quality of life is generally unrelated to level of injury or injury severity, weakly related to physical impairment, and more strongly related to one's ability to carry out day-to-day tasks and participate in school, work, or other community activities (Barker et al. 2009; Mortenson et al. 2010). These studies suggest that quality of life is related to several modifiable risk factors such as pain, subjective health competence, mood, social participation, and environmental barriers.

Common biased expectations among rehabilitation staff and their misapplication of stage models have interfered with appropriate understanding and intervention to promote psychological adjustment to SCI (Elliott and Frank 1996; Trieschmann 1988). In numerous studies, rehabilitation staff, primarily nurses and therapists, have been found to overestimate depressed mood regularly in SCI patients (Trieschmann 1988). Rehabilitation staff also tend to view signs of depression as a normal, even necessary, stage of grief. An SCI patient wrote that the most depressing part of his rehabilitation program was that staff expected him to be depressed, an expectation dubbed "the requirement of mourning" (Trieschmann 1988). Empirical data contradict popular conceptualizations of grief. Most people who sustain significant losses (including SCI) do not become depressed and do not go through traditional "stages of grief" (Bonanno et al. 2002; Wortman and

Silver 1989). Rather, resilience is the modal response to loss (Bonanno et al. 2002), and acceptance of loss begins early and is more prominent than any other emotional response (Maciejewski et al. 2007). In a study that used the Beck Depression Inventory to measure depressive symptoms weekly during inpatient rehabilitation, about 60% of the SCI patients never scored in the depressed range, 20% endorsed significant depressive symptoms only once, and 20% reported significant depressive symptoms at multiple time points and required treatment with antidepressants (Judd et al. 1989). Viewing persisting depression as a normal or even healing part of the grief process may interfere with appropriate recognition and treatment of major depression. Conversely, staff may judge the absence of depression to be pathological, a sign of denial or poor adjustment and an indication that the staff should confront the patient more forcefully with the implications of his or her impairments.

In the absence of empirically supported approaches to manage grief and poor adjustment, the consultant is advised to “do no harm” by eschewing confrontational approaches that may only damage relatively healthy defenses or increase patient resistance. We recommend tolerance of adjustment patterns that are not interfering with rehabilitation. We also attempt to educate staff and family members about countertherapeutic myths of coping with loss, such as the belief that it is necessary to “work through” the loss, that patients should reach a state of “acceptance,” and that the absence of grief is pathological (Wortman and Silver 1989).

Psychiatric Disorders in Spinal Cord Injury

Depression

Major depressive disorder is probably the most common psychiatric disorder after SCI (Banerjee et al. 2009; Fullerton et al. 1981; Migliorini et al. 2008). According to studies that used DSM criteria, the prevalence of major depression ranged from 9.8% to 37.5%, with most estimates falling between 15% and 23% (Bombardier et al. 2004). Some studies suggest that depression may be more common soon after injury but may remit after several months (Kishi et al. 1994, 1995). In unselected cases, mood tends to improve over the first year after injury (Richards 1986). However, other studies suggest that a subgroup of about 30% of patients develop significant depressive and anxiety symptoms soon after injury and remain highly depressed and anxious through at least 2 years after injury (Craig et al. 1994).

Depression is a significant and disabling problem for persons with SCI. Depression is associated with longer lengths of hospital stay and fewer functional improvements (Malec and Neimeyer 1983) as well as less functional

independence and mobility at discharge (Umlauf and Frank 1983). Depression is associated with the occurrence of pressure sores and urinary tract infections (Herrick et al. 1994), poorer self-appraised health (Bombardier et al. 2004), less leisure activity (Elliott and Shewchuck 1995), poorer community mobility and social integration, and fewer meaningful social pursuits (Fuhrer et al. 1993; MacDonald et al. 1987). Persons with SCI and significant depression spend more days in bed and fewer days outside the home, require greater use of paid personal care, and incur greater medical expenses (Tate et al. 1994). Symptoms consistent with depression, such as documented expressions of despondency, hopelessness, shame, and apathy, are the variables most predictive of suicide 1–9 years after SCI (Charlifue and Gerhart 1991). Probable major depression predicts all-cause mortality after SCI (Krause et al. 2008).

Anxiety

Relatively few studies have examined PTSD or other anxiety disorders in this population. Rates of current PTSD range from 14% to 22% in patients with SCI (P. Kennedy and Evans 2001; Radnitz et al. 1998). Rates of PTSD appear to vary as a function of level of injury, with lower rates found among those with tetraplegia (2%) compared with those with paraplegia (22%; Radnitz et al. 1998). This variability has been attributed to diminished experience of psychophysiological arousal, which may occur in higher-level injuries (P. Kennedy and Duff 2001). Current PTSD appears to be no more prevalent in persons with SCI than in other trauma survivors. People with SCI who are war theater veterans, have prior exposure to violence, or have limited social support may be at higher risk for PTSD (P. Kennedy and Duff 2001). Elevated levels of general anxiety also have been found in people with SCI (Craig et al. 1994; P. Kennedy and Rogers 2000), particularly in a subgroup of patients with chronic comorbid depression. Anxiety and depression are associated with lower quality of life (Budh and Osteråker 2007).

PTSD symptoms are also common in families of persons with SCI. Boyer et al. (1998) found that 25% of pediatric SCI survivors reported significant current PTSD symptoms, but 41% of mothers and 36% of fathers also endorsed significant PTSD symptoms on self-report measures.

Substance Use Disorders

High rates of alcohol and drug abuse problems are found among trauma patients generally and SCI patients specifically (Bombardier and Turner 2009). Preinjury alcohol problems are common (35%–49%; Bombardier and Rimele 1998; Heinemann et al. 1988). Rates of alcohol intoxication at the time of injury range from 36% to 40% (Heine-

mann et al. 1988; Kiwerski and Krasuski 1992). After SCI, substance abuse appears to decline but remains somewhat higher than in the general population and, importantly, may be more harmful because of its association with poorer health maintenance behaviors (Krause 1992), including pressure ulcers (Tate et al. 2004). Acute SCI rehabilitation is a potential “teachable moment” for patients with a history of alcohol abuse or dependence to initiate changes in their drinking behavior (Bombardier and Rimmele 1998). Most do not have severe dependence and, depending on the person’s history, may benefit from advice, brief motivational interventions, relapse prevention skills, or referral to specialist treatment (Turner et al. 2003).

Sexual Dysfunction

SCI affects erectile functioning, ejaculation, and emission in males and lubrication in females as a function of level (upper motor neuron vs. lower motor neuron) and completeness of injury (Table 35–6). Approximately 70% of men with SCI recover some degree of erectile function (Sipski and Alexander 1997). Reflex erection ability is dependent on the parasympathetic reflex arc in the sacral segments (S2 to S4) and can be brought on by direct stimulation of the penis or other erogenous areas. Psychogenic erection is dependent on the integrity of the hypogastric plexus, which includes both the T11–L2 segments and the sacral plexus, and can be elicited by sexual thoughts or feelings (Sipski and Alexander 1997).

Laboratory research confirms that women with complete upper motor lesions affecting the sacral segments are likely to have vaginal lubrication from reflexive but not psychogenic mechanisms (Sipski et al. 1995). Women with incomplete upper motor lesions affecting the sacral segments retain the capacity for reflex lubrication but will have psychogenic lubrication only if they have intact pinprick sensation in the T11–L2 dermatomes. Women with incomplete lower motor lesions affecting the sacral segments are expected to achieve psychogenic lubrication in 25% of cases and no reflex lubrication.

By contrast, achieving orgasm is less well studied but appears to be relatively independent of level and complete-

ness of injury. Among males with SCI, 38%–47% report achieving orgasm, which may be experienced as similar to or different from preinjury experiences. In a laboratory study, about 50% of the women with SCI reported experiencing orgasm, with longer stimulation, greater sexual knowledge, and higher sexual drive associated with higher rates of orgasm (Sipski et al. 1995). Sexual desire, activity, and pleasure tend to decrease after SCI for both women and men, but most remain interested in sexual activity. Erogenous zones and preferences for type of sexual activity may change.

Numerous treatments are available for sexual dysfunction related to SCI (Consortium for Spinal Cord Medicine 2010; see also Chapter 16, “Sexual Dysfunction”). First-line treatment for erectile dysfunction is with sildenafil and other phosphodiesterase type 5 (PDE-5) inhibitors (Lombardi et al. 2009). Large increases in successful intercourse rates can be achieved with the use of PDE-5 inhibitors. Ejaculation and orgasm rates also improve. All PDE-5 inhibitors appear safe with the caveat that most studies have been short term. Second-line treatments include vacuum erection devices, pharmacological penile injections, and penile implants. Ejaculatory dysfunction and related infertility are treated with vibratory or electroejaculation procedures in conjunction with intrauterine insemination, in vitro fertilization, or intracytoplasmic sperm injection, depending on sperm quality and motility (Amador et al. 2000). Decreased lubrication in females can be managed by water-based lubricants. Regarding sexual enjoyment, patients can benefit from many standard counseling strategies adapted for people with SCI, such as enhancing communication skills, teaching sensate focus exercises, addressing performance anxiety, and generally dispelling common counterproductive beliefs about sexual relationships (Consortium for Spinal Cord Medicine 2010; Zilbergeld 1978). It is important to broach the subjects of sexuality and fertility while the person is undergoing acute rehabilitation, but studies indicate that during this time many patients rate other rehabilitation concerns as more important and may prefer to discuss sexual concerns in more detail after the acute rehabilitation phase (Hanson and Franklin 1976).

TABLE 35–6. Male sexual functioning by level and type of lesion

Male sexual functioning	Psychogenic erection (%)	Reflex erection (%)	Anterograde ejaculation (%)
Upper motor neuron—complete	0	70–93	4
Upper motor neuron—incomplete	19	80	32
Lower motor neuron—complete	26–50	0	18
Lower motor neuron—incomplete		67–95	70

The PLISSIT sexual counseling model is a useful framework when offering sexually related counseling to patients in a rehabilitation setting (Consortium for Spinal Cord Medicine 2010). First, one asks for **P**ermission to discuss sexuality during acute rehabilitation with all patients. If permitted, the clinician should provide **L**imited **I**nformation, generally educational in nature, about sexual functioning. The clinician should give **S**pecific **S**uggestions about how to manage sexuality or fertility problems and refer the patient to a sexual counseling specialist for **I**ntensive **T**herapy when indicated.

Personality and Psychological Testing

Personality assessment among persons with SCI has received justifiable criticism. Critics allege that clinicians are guilty of a negative bias, of overreliance on measures designed only to detect pathology, and of attribution of behavior patterns only to intrapsychic and not to situational or environmental factors (Elliott and Umlauf 1995). Measures such as the Minnesota Multiphasic Personality Inventory and the Hopkins Symptom Checklist-90 should be interpreted cautiously and with the aid of norms correcting for disability-related factors (Barncord and Wanstall 2000). Nonpathological measures such as the NEO Personality Inventory (NEO-PI), the 16 Personality Factor Questionnaire (16PFQ), and the Meyers-Briggs Type Indicator may be more appropriate tests of personality functioning in this population (Elliott and Shewchuck 1995). Yet evidence indicates that certain premorbid personality characteristics are more prominent among individuals with SCI than in the uninjured population. Nearly two-thirds of the patients with SCI have personality characteristics suggesting a strong physical orientation, difficulty expressing emotion, a preference for working with things rather than people, and a dislike of intellectual or academic interests (Rohe and Krause 1998). Neuropsychological evaluation that documents areas of cognitive impairment and strength can be critical in guiding treatment and vocational rehabilitation, especially because comorbid TBI can be expected in most cases, particularly those with cervical SCI (Maccocchi et al. 2008).

Treatment of Psychiatric Disorders in Traumatic Brain Injury and Spinal Cord Injury

General Principles

A patient's specific physical (e.g., spasticity) and cognitive (e.g., defects in executive functions) impairments must be considered in designing a treatment plan for psychiatric

disorders in the rehabilitation setting. A detailed understanding of the patient's physical and psychological stage in rehabilitation and functional goals will help in choosing the most appropriate psychopharmacological or psychotherapeutic treatment modality. Consulting with other members of the multidisciplinary rehabilitation team will provide clues as to the patient's motivation and treatment limitations. Knowledge of the patient's current functional, social, and vocational status is required to tailor the psychiatric treatment to specific practical needs and limitations. For example, initial treatment with an activating antidepressant in a fatigued, cognitively impaired, depressed TBI patient who is not participating optimally in physical therapy may be more appropriate than attempting to engage the patient in cognitive-behavioral therapy (CBT).

Once rapport has been established, it is helpful to discuss the events that led up to the patient's impairment (e.g., the circumstances of the car crash that led to the TBI, the stroke that led to the left-sided hemiparesis) to explore the psychodynamic significance of these events. For example, patients will often blame themselves for their predicament, with such self-attribution leading to guilt and depression. In contrast, patients may not associate their psychiatric symptoms with their physical impairment, which may affect readiness for psychotherapy.

Interviewing the patient's family, friends, and caregivers can provide critical information about the patient's past and present mental state. How patients handled prior losses and health problems can provide clues as to how resilient they will be during rehabilitation. Moreover, patients may report different symptoms from those observed by those close to them. For example, a patient often focuses on physical and cognitive deficits, whereas family members may consider the patient's emotional changes as more disabling (Hendryx 1989; Oddy et al. 1978a; Sherer et al. 1998b). Patients often report significantly less frequent symptoms of depression, aggression, and memory and attention problems on self-ratings compared with ratings by their significant others (Hart et al. 2003). Close communication with family and other caregivers and acquaintances can provide critical longitudinal information about the progress of psychiatric treatment.

Because SCI may result in marked weight loss, alterations in appetite and sleep, and reduced energy and activity, diagnosing depression can be complicated. However, vegetative symptoms should not be dismissed, because altered psychomotor activity, appetite change, and sleep disturbance are predictive of major depression (Clay et al. 1995). Core symptoms of depression in people with physical disabilities such as arthritis and SCI are worthlessness or self-blame, depressed mood, and suicidal ideation (Frank et al. 1992). The patient's own experience and inter-

pretation of the vegetative symptoms can aid the diagnostic process (Elliott and Frank 1996).

As discussed earlier with TBI and SCI, the phenomenological presentation of psychiatric symptoms in rehabilitation patients may differ from symptoms that arise de novo or in other medical settings. Although psychopathology based on DSM-IV-TR criteria should be thoroughly explored, psychiatric symptoms that do not meet DSM diagnostic criteria but that still lead to significant functional impairment are common in the rehabilitation setting (e.g., the depressed TBI patient who has four depressive symptoms but shows apathy that affects his or her level of functioning, or the severely anxious SCI patient with few autonomic symptoms). These syndromes, or symptom clusters, still may warrant close monitoring and treatment to maximize functioning. Therefore, in addition to monitoring and documenting psychiatric signs and symptoms, functional status (e.g., activities of daily living, progress in physical and occupational therapy, role functioning) should be monitored closely as an indicator of overall progress. Consistent with the rehabilitation process’s basic tenet of working toward realistic and measurable goals, psychiatric intervention should begin with defining treatment end points according to measurable outcomes. Examples of useful measures include the PHQ (Spitzer et al. 1999) for depression and anxiety, the Brief Symptom Inventory for general distress (Meachen et al. 2008), the Neurobehavioral Rating Scale (Levin et al. 1987b) for behavior and cognition, and the Rivermead Post Concussion Symptoms Questionnaire (King et al. 1995) or the OAS (Giles and Mohr 2007; Yudofsky et al. 1986) for severe agitation. Improved participation in rehabilitation therapies, which may be the outcome of most concern to the referring physician, can be monitored easily with the Pittsburgh Rehabilitation Participation Scale (Lenze et al. 2004).

Realistic expectations, including the possibility of incomplete remission of symptoms, must be conveyed at the outset so that the patient, who is already frustrated with the often slow and arduous rehabilitation process, does not become even more hopeless or overwhelmed if some symptoms persist (Roy-Byrne and Fann 1997). A survey of 16,403 community-dwelling elderly and disabled Medicare beneficiaries found that persons with disabilities reported poor communication and lack of thorough care as negative aspects of their care (Iezzoni et al. 2003). Because patients may have strong preexisting preferences for specific treatment approaches (Fann et al. 2009b), adequate time must be spent on providing education about evidence-based approaches. Collaboration with rehabilitation psychologists and counselors can provide significant depth of assessment and breadth of intervention. Attending rehabilitation team meetings is often a valuable and efficient way of communi-

cating and coordinating needs and treatment. Because the patient is likely already feeling overwhelmed about his or her situation, framing the psychiatric consultation and intervention as another modality similar to, for example, occupational or speech therapy that can help him or her achieve the rehabilitation goals during a period of intense stress and adaptation can quickly put the patient at ease. Often, appropriately applied treatments may not have been given ample time to work. This problem may be exacerbated by imposed pressures on rehabilitation centers to work within predetermined payment structures and lengths of stay on the basis of medical diagnoses (Carter et al. 2000).

Treatment of psychiatric problems in the rehabilitation setting typically warrants a combination of pharmacological and psychosocial interventions. Because treatments for most chronic diseases are covered in other chapters, the following treatment recommendations focus on TBI and SCI.

Psychopharmacology

Several common physiological changes in SCI (Table 35–7), often more pronounced in tetraplegia than in paraplegia, can have an effect on the pharmacokinetics and tolerability of many psychotropic medications. The goals and potential side effects of pharmacotherapy should be explained thoroughly to the patient and caregivers because unanticipated symptoms caused by medications may be viewed as a sign that the underlying condition is worsening. For example, urinary retention from an anticholinergic psychotropic drug may signal to the patient with SCI that the spinal lesion is progressing. Medications that can cause weight gain, constipation, dry mouth, orthostatic hypotension, or sexual dysfunction also may exacerbate already present pathophysiology. Medications that are sedating are of particular concern in TBI and SCI because they may impair mobility and cognition, increase risk for pressure sores, and interfere

TABLE 35–7. Common physiological changes associated with spinal cord injury

Increased body fat and glucose intolerance
Decreased gastrointestinal motility
Reduced cardiac output
Anemia
Orthostatic hypotension
Bradyarrhythmia
Decreased blood flow to skeletal muscle
Venous thrombosis
Osteoporosis

with rehabilitation. Sedation is a frequent problem because many patients with TBI and SCI are taking multiple central nervous system (CNS) depressants, such as anticonvulsants, muscle relaxants, and opioid analgesics (for discussion of interactions between neurological and psychiatric drugs, see Chapter 38, "Psychopharmacology").

Because patients with TBI or SCI are often more susceptible to sedative, extrapyramidal, anticholinergic, epileptogenic, and spasticity effects (Fann 2002), psychotropic dosages should be started at lower-than-standard levels and be titrated slowly. Despite this need for caution, some patients still may ultimately need full standard doses (Silver and Yudofsky 1994b).

Neuropsychiatric polypharmacy is common in TBI patients and should be critically examined. When multiple psychotropics are needed, they should be initiated one at a time, when possible, to accurately determine the therapeutic and adverse effects of each medication. This practice may become difficult to follow if patients' behavior endangers them or staff or significantly impairs rehabilitation, but it usually will prove beneficial in the long term.

Because few randomized, placebo-controlled studies have tested pharmacotherapy for psychiatric conditions in TBI and SCI populations, many of the following recommendations are based on case series and expert consensus (Warden et al. 2006) or are extrapolated from other neurological populations. Heterogeneous study populations, including those varying in time elapsed since injury, confound the interpretation of study results. When TBI or SCI occurs in the context of a preexisting psychiatric illness, it is logical to continue a previously effective medication regimen, but previously absent side effects may emerge that require changes in dosages and/or drugs. Electroconvulsive therapy for refractory depression (Crow et al. 1996; Martino et al. 2008), mania (Clark and Davison 1987), and prolonged posttraumatic delirium and agitation (Kant et al. 1995) may be considered. However, efforts should be made to lessen cognitive dysfunction in TBI patients (e.g., by using high-dose unilateral electrode placement or twice-weekly treatment frequency), and caution should be exercised in treating patients with SCI who may have unstable spinal columns. Preliminary studies of low-intensity magnetic field exposure (Baker-Price and Persinger 2003), biofeedback with electroencephalogram recording and photic feedback (Schoenberger et al. 2001), acupuncture (Donnellan 2006), and music therapy (Guetin et al. 2009) for improving mood after TBI have been reported and require further study.

Depression, Apathy, and Fatigue

The literature on the efficacy of pharmacological treatment of depression after TBI is limited to small studies varying widely in design, diagnostic and outcome assess-

ment, severity of brain injury, and time after injury (see systematic review on treatment of depression after TBI by Fann et al. 2009a).

Because of a favorable side-effect profile, a selective serotonin reuptake inhibitor (SSRI) usually is the first-line antidepressant for patients with TBI. Ashman et al. (2009) randomly assigned 52 depressed patients at an average of 17.7 years postinjury to sertraline or placebo. Although no statistically significant group differences in response rates or decreases in Hamilton Rating Scale for Depression scores were found over 10 weeks, 59% of the sertraline group responded compared with only 32% of the placebo group. A single-blind, placebo run-in study of sertraline in 15 patients with mild TBI (Fann et al. 2000) and an open study of citalopram in 54 patients with mild to moderate TBI (Rapoport et al. 2008) suggested that SSRIs are efficacious and well tolerated in TBI populations. The study by Fann et al. (2000) found that 67% had remission of their major depression after 8 weeks of sertraline and that treatment also was associated with improvements in postconcussive symptoms, neuropsychological functioning, functional status, and self-ratings of injury severity and distress. The areas of cognitive functioning that improved included short-term memory, mental flexibility, cognitive efficiency, and psychomotor speed. In a 4-week study of depressed patients, H. Lee et al. (2005) found both sertraline and methylphenidate to be superior to placebo in decreasing depression scores. Perino et al. (2001) assessed 20 depressed post-TBI patients before and after administration of citalopram and carbamazepine and found that depression, anxiety, inappropriate and labile affect, and somatic overconcern improved significantly. SSRIs should be started at about half of their usual starting dose and titrated slowly. SSRI-induced akathisia sometimes can be mistaken for TBI-related agitation (Hensley and Reeve 2001). Escitalopram, citalopram, and sertraline all have low potential for significant drug-drug interactions. For patients at high risk for noncompliance (e.g., because of cognitive impairment), fluoxetine should be considered because of its lower risk for withdrawal symptoms.

No clinical trials of antidepressants in persons with SCI are available to help guide pharmacotherapy. The Paralyzed Veterans of America and their partners in the Consortium for Spinal Cord Medicine (1998) have published a clinical practice guideline on depression following SCI for primary care physicians, extrapolated from research conducted in the general population or among other disability groups. Combining an antidepressant and psychotherapy may be effective for major depression (Kemp et al. 2004). Although SSRIs are likely efficacious in patients with SCI, the risk for spasticity may be increased (Stolp-Smith and Wainberg 1999). Similarly, there may be an increased risk of spasticity

and autonomic dysreflexia with tricyclic antidepressants (TCAs) in patients with SCI (Cardenas et al. 2002; Fullerton et al. 1981). Although not yet studied for depression after SCI, venlafaxine may improve voiding in SCI patients with urinary retention (Inghilleri et al. 2005).

The literature on the tolerability and safety of TCAs and monoamine oxidase inhibitors (MAOIs) after TBI is more inconsistent (Dinan and Mobayed 1992; Saran 1985; Wroblewski et al. 1996). Because of the potentially problematic adverse effects of TCAs and MAOIs (e.g., sedation, hypotension, and anticholinergic effects) in patients with CNS impairment and their narrow therapeutic index (which can lead to inadvertent overdose in patients with cognitive impairment), these medications should be used with extreme caution in TBI patients. Autonomic dysfunction in patients with SCI makes them more vulnerable to TCA-related anticholinergic and orthostatic side effects. If a TCA is chosen, nortriptyline or desipramine may cause the fewest side effects.

Although not yet systematically studied, dual-action serotonin–norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine and duloxetine are likely safe and effective in patients with TBI. The one open study ($N=10$) that examined a dual-action SNRI (milnacipran) for minor or major depression after mild to moderate TBI also suggested that it may be efficacious (66.7% responded, 44.4% remitted) and well tolerated (Kanetani et al. 2003). Mirtazapine, nefazodone, and trazodone may prove to be too sedating for some patients, particularly if they have cognitive impairment or gait instability, but if insomnia is a major problem, these drugs may be helpful. Venlafaxine and mirtazapine have low drug–drug interaction potential. Moclobemide, a reversible inhibitor of monoamine oxidase A, showed efficacy in an open subgroup analysis of 26 depressed patients with TBI (Newburn et al. 1999).

Some data suggest that antidepressants, especially TCAs and bupropion, are associated with an increased risk of seizures (Davidson 1989), a particular concern following severe TBI (Wroblewski et al. 1990); however, if the drugs are titrated cautiously, most patients will not experience increased seizures, particularly if they are taking an anticonvulsant (Ojemann et al. 1987).

The symptoms of apathy and fatigue, often associated with CNS impairment, can occur concomitantly with or independently of depression and are often mistaken for primary depression (Marin 1991). For apathy and fatigue, medications that augment dopaminergic activity appear to be the most useful (Marin et al. 1995). Methylphenidate and dextroamphetamine are generally safe at standard dosages (e.g., methylphenidate 10–30 mg/day in divided doses) (Alban et al. 2004) and have been used successfully to enhance participation in rehabilitation (C.T. Gualtieri and

Evans 1988). Methylphenidate and dextroamphetamine also have been shown in case series and double-blind studies to be effective in improving some aspects of mood, mental speed, attention, and behavior, although improvement was not always sustained long term (Bleiberg et al. 1993; C.T. Gualtieri and Evans 1988; Kaelin et al. 1996; Mooney and Haas 1993; Plenger et al. 1996; Speech et al. 1993; Whyte et al. 1997, 2004). Dextroamphetamine may exacerbate dystonia and dyskinesia in some cases. Therapeutic use of these oral psychostimulants in the medically ill rarely leads to abuse in patients without a personal or family history of substance abuse (Masand and Tesar 1996), but substance abuse is overrepresented in the TBI and SCI populations.

Modafinil has been efficacious in treating fatigue in patients with multiple sclerosis (Rammahan et al. 2000; Terzoudi et al. 2000; Zifko et al. 2002) and excessive daytime sleepiness in patients with TBI (Teitelman 2001). Bupropion (Marin et al. 1995) and dopamine agonists such as amantadine (Green et al. 2004; M.F. Kraus et al. 2005; Sawyer et al. 2008), bromocriptine (McDowell et al. 1998; Powell et al. 1996), and levodopa/carbidopa (Lal et al. 1988) have been used for apathy states, fatigue, and cognitive impairment. Bupropion's stimulating properties may be of particular benefit in the fatigued or apathetic depressed patient. Stimulants and dopamine agonists can increase the risk for delirium and psychosis and thus should be used with caution in more vulnerable patients. Amantadine has been associated with an increased risk of seizures (T. Gualtieri et al. 1989), but methylphenidate, dextroamphetamine, and bromocriptine do not appear to lower seizure threshold at typical doses.

There is great interest in pharmacological agents that could improve not only arousal and attention following TBI but also memory; however, data are lacking. Preliminary evidence indicates that the acetylcholinesterase inhibitor donepezil may improve memory and global functioning (Khateb et al. 2005; Whelan et al. 2000; Zhang et al. 2004), but no large randomized controlled trials of cholinesterase inhibitors have been done in patients with TBI.

Another secondary benefit of some antidepressants in TBI and SCI patients is their analgesic properties (Onghena and Van Houdenhove 1992) (see also Chapter 36, "Pain"). TCAs have been shown to be effective for the treatment of chronic nonmalignant pain, including neuropathic pain (McQuay et al. 1996). Amitriptyline improves SCI-related neuropathic pain in the context of comorbid depressive symptomatology (Rintala et al. 2007). SSRIs have not been shown to be effective in neuropathic pain (Jung et al. 1997). Venlafaxine and duloxetine may be effective in treating a variety of pain syndromes, including neuropathic pain (Diamond 1995; Lang et al. 1996; Schreiber et al. 1999).

Mania

For mania following TBI, the mood stabilizers lithium carbonate (Oyewumi and Lapierre 1981; Stewart and Nemsath 1988), valproic acid (Pope et al. 1988), and carbamazepine (Stewart and Nemsath 1988) all have been used successfully. Successful use of the antipsychotics haloperidol, thioridazine, chlorpromazine, olanzapine, and quetiapine, often in combination with another mood-stabilizing agent, also has been documented in case reports (Daniels and Felde 2008; Oster et al. 2007). Electroconvulsive therapy (Clark and Davison 1987) can be used as a second-line modality. Dikmen et al. (2000) have shown that valproic acid is well tolerated after TBI, but lithium and carbamazepine have been associated with neurocognitive adverse effects (Hornstein and Seliger 1989; Schiff et al. 1982). Lithium has a narrow therapeutic window and also can lower the seizure threshold; thus, caution is required when lithium is used in TBI patients whose cognitive impairment may lead to poor adherence or inadvertent overdosage. Although serum blood levels of valproic acid and carbamazepine help in monitoring adherence and absorption, dosing should be guided primarily by therapeutic response and side effects. Possible roles for other anticonvulsants in secondary mania are reviewed in Chapter 10, "Psychosis, Mania, and Catatonia." Carbamazepine, gabapentin, pregabalin, and clonazepam also can be effective for the treatment of neuropathic pain.

Anxiety

Benzodiazepines are the treatment of choice for acute anxiety in TBI, but they should be used initially at lower doses because of their propensity to exacerbate or cause cognitive impairment and oversedation. The high prevalence of substance abuse in patients with TBI and SCI adds to the risk of benzodiazepine use and may preclude their use in some patients. Although few studies exist in TBI patients, antidepressants also appear to be effective for anxiety, particularly in the context of depression. SSRIs also have been found to be effective in decreasing mood lability after brain injury (Nahas et al. 1998; Sloan et al. 1992), although this effect may take as long as their antidepressant effects. In a case report, venlafaxine, 150 mg/day, successfully treated compulsions after TBI (Khouzam and Donnelly 1998). Valproic acid, gabapentin, and pregabalin may be of benefit, especially in patients with concomitant mood lability or seizures (Pande et al. 1999, 2000). Buspirone is another option for generalized anxiety symptoms; however, it has been associated, albeit rarely, with seizures and movement disorders (Levitt et al. 1993).

Sleep Disorders

Treatment of sleep problems in patients with TBI and SCI ideally should be based on diagnosis of a specific sleep dis-

order. Sleep apnea is fairly common in TBI (Castriotta and Lai 2001; Masel et al. 2001) and SCI (Burns et al. 2000), and nocturnal periodic leg movements are frequent in SCI (Dickel et al. 1994). Fichtenberg et al. (2000) found that insomnia often appeared to be associated with depression in post-acute TBI patients. No specific data exist on treating insomnia or other sleep disorders in TBI or SCI, but trazodone is widely used in these patients for middle or late insomnia, and hypnotics are used in as many as 20% of TBI patients (Worthington and Melia 2006). Trazodone-associated orthostatic hypotension may be particularly problematic in the rehabilitation setting, however. Antihistamines such as diphenhydramine should be avoided because of their anticholinergic properties (see Chapter 15, "Sleep Disorders," for general diagnosis and treatment of sleep disorders).

Anger, Aggression, and Agitation

Anger, aggression, and agitation are common following TBI and can occur in isolation or as part of delirium or other psychiatric disorders (see Chapter 7, "Aggression and Violence," for a full review of agitation and aggression in the medically ill). The published literature regarding their treatment is often not diagnostically specific and consists largely of case reports, case series, and reviews (e.g., Fleming et al. 2006; Krieger et al. 2003; Levy et al. 2005; Maryniak et al. 2001).

Treatment can be divided into acute treatment, in which the goal is timely management of behavior to prevent injury to self or others, and chronic treatment, in which the goal is long-term management and prevention (Silver et al. 2002). Many agents take from 2 to 8 weeks to gain full effectiveness. It is important to keep in mind that medications that worsen cognition or sedation can actually worsen confusion and may, therefore, worsen agitation during the confusional state of posttraumatic amnesia after TBI. Because the effects of medications on the patient with TBI can be unpredictable and because their side effects actually may potentiate the behavior problem (e.g., akathisia from antipsychotics), systematically eliminating certain medications, including those that were initially prescribed to treat the behavioral dyscontrol, can prove beneficial. A rationale for such an approach is the clinical observation that some patients have a natural course of recovery and that some medication efficacy may decrease over time.

A survey published in 1997 (Fugate et al. 1997) showed that psychiatrist experts in TBI most often treated agitation with carbamazepine, TCAs, trazodone, amantadine, and beta-blockers. Psychiatrists appear more likely than physiatrists to use atypical antipsychotics (Burnett et al. 1999) and SSRIs.

The atypical antipsychotics afford the clinician many more options in the acute setting than were available a decade ago (Battaglia et al. 2003; Currier and Simpson 2001; Lesem et al. 2001). The efficacy of the atypical antipsychotics in treating acute aggression and agitation in TBI patients is still emerging (Scott et al. 2009), and evidence is mounting to support their efficacy in treating other agitated states associated with neurological syndromes (M.A. Lee et al. 2001; Meehan et al. 2002). The typical antipsychotics given orally or intramuscularly also may be useful in the acute setting (Stanislav and Childs 2000), but the elevated risks of extrapyramidal and anticholinergic effects in TBI patients must be considered. Studies in animals have suggested that haloperidol and other antipsychotics may impede neuronal and cognitive recovery (Hoffman et al. 2008; M.S. Wilson et al. 2003), but this finding has not been supported in humans with TBI.

Antipsychotic use for chronic agitation ideally should be reserved for situations when aggression occurs in the context of psychotic symptoms. Risperidone (Cohen et al. 1998; De Deyn et al. 1999; I.R. Katz et al. 1999; McDougle et al. 1998) and olanzapine (Street et al. 2000) show promise in neuropsychiatric patients, although efficacy data in TBI patients for these and the other atypical antipsychotics such as quetiapine (Kim and Bijlani 2006) are sparse. Clozapine use in TBI patients is limited by its seizure risk, although it has been found to be effective for chronic aggression (J.E. Kraus and Sheitman 2005; Michals et al. 1993).

The benzodiazepines offer rapid sedation that may be useful in the acute setting; however, they also have a high potential for neurocognitive effects, such as mental slowing, amnesia, disinhibition, and impaired balance, in patients with TBI. As a result, low doses of a short-acting agent, such as lorazepam, 1–2 mg orally or parenterally, should be used initially and titrated as needed. If agitation is frequent, a longer-acting agent, such as clonazepam, 0.5–1.0 mg two or three times a day, may be used for short durations. The combination of haloperidol and low-dose lorazepam (e.g., 0.5–1.0 mg) may offer a synergistic calming effect for some acutely agitated patients.

Serotonergic antidepressants, such as the SSRIs, trazodone, and amitriptyline, have been used to treat agitation and aggression in TBI populations (Mysiw et al. 1988; Rowland et al. 1992). In 8-week nonrandomized trials with sertraline, Fann et al. (2000) showed that improved depression was associated with improved anger and aggression scores in patients with mild TBI, whereas Kant et al. (1998) found improved aggression independent of depression scores. One rationale for the use of antidepressants is the observation that serotonin and norepinephrine levels are reduced in the cerebrospinal fluid of agitated patients with

brain injury (van Workeom et al. 1977). SSRIs are also effective in treating emotional incontinence, such as pathological crying or laughter (Muller et al. 1999; Nahas et al. 1998; Sloan et al. 1992).

Buspirone also has shown some efficacy for agitation in TBI and other neurological patients (C.T. Gualtieri 1991; Silver and Yudofsky 1994a; Stanislav et al. 1994) and can be particularly useful when anxiety also is present. Although one 6-week placebo-controlled trial found that methylphenidate significantly reduced anger an average of 27 months after severe TBI (Mooney and Haas 1993), stimulants should be used with caution in the agitated TBI patient because of the risks of exacerbating agitation and psychosis and of abuse.

Among the anticonvulsants, carbamazepine (Azouvi et al. 1999; Chatham-Showalter 1996) and valproic acid (Chatham-Showalter and Kimmel 2000; Lindenmayer and Kotsaftis 2000; Wroblewski et al. 1997) have been studied the most for treatment of behavioral dyscontrol in TBI populations. Although evidence of seizures or epileptiform activity on electroencephalogram is a strong indication for anticonvulsant use in the agitated patient, these agents also have shown efficacy in those without electroencephalographic abnormalities. Oxcarbazepine, gabapentin, lamotrigine, and topiramate also may be efficacious, although data are more limited. Some TBI patients may experience paradoxical agitation with gabapentin (Childers and Holland 1997). Lamotrigine was found to decrease aggressive and agitated behavior in one patient with severe TBI (Pachet et al. 2003), but it could possibly exacerbate aggression, as is seen in some mentally retarded patients with epilepsy (Beran and Gibson 1998; Ettinger et al. 1998). Cognitive functioning may worsen with topiramate in some cases (Martin et al. 1999; Tatum et al. 2001). Topiramate also has been found to attenuate binge-eating behavior in some patients (Dolberg et al. 2005). Some patients may need to achieve serum levels of anticonvulsants that exceed therapeutic levels used for seizure prophylaxis to ensure adequate behavioral control. Lithium is also an effective mood stabilizer and has antiaggressive properties in TBI patients, according to case reports; however, its narrow therapeutic window and high potential for neurotoxicity limit its routine use, particularly in those with significant cognitive impairment or history of seizures.

When anger, aggression, or agitation occurs without signs of other psychiatric syndromes, beta-blockers such as propranolol, pindolol, metoprolol, and nadolol should be considered. Placebo-controlled studies have shown their efficacy in treating agitation in TBI patients (Brooke et al. 1992a; Greendyke and Kanter 1996; Greendyke et al. 1996). A Cochrane review (Fleminger et al. 2006) concluded that among the drugs used to treat agitation and aggression in

TBI, beta-blockers have the best evidence for efficacy. Doses of propranolol in the range of 160–320 mg/day have been effective. Bradycardia and hypotension are potential side effects; contraindications include asthma, chronic obstructive pulmonary disease, type 1 diabetes mellitus, congestive heart failure, persistent angina, significant peripheral vascular disease, and hyperthyroidism. Pindolol is less likely to cause bradycardia.

Psychosis

Because of the increased susceptibility of patients with TBI to experience anticholinergic and extrapyramidal side effects and of patients with SCI to experience problematic anticholinergic sequelae, the newer-generation atypical antipsychotics are the drugs of first choice for psychotic symptoms that emerge after TBI or SCI (Burnett et al. 1999) (see also earlier discussion of antipsychotics for agitation in the “Anger, Aggression, and Agitation” subsection and Chapter 10, “Psychosis, Mania, and Catatonia”). Case reports suggest that olanzapine, 5–20 mg/day, alone and with valproic acid may be helpful and safe for treating post-TBI psychosis (Butler 2000; Umansky and Geller 2000). Despite the relative tolerability of newer-generation antipsychotics, tardive dyskinesia has been reported with aripiprazole after TBI (Zaidi and Faruqui 2008). Clozapine carries a risk of seizures and should be used with extreme caution in TBI patients, particularly when compliance is in question. Augmenting risperidone with the anticholinesterase inhibitor galantamine was effective in decreasing both negative and positive psychotic symptoms following a severe TBI (Bennouna et al. 2005).

Cognitive Impairment

Little evidence is available to guide pharmacological treatments to enhance cognitive recovery following TBI; most data are derived from theoretical or animal models or case reports. Medications targeting the dopaminergic, cholinergic, and noradrenergic neurotransmitter systems have been tried (McElligott et al. 2003). Dopaminergic agents include levodopa/carbidopa, bromocriptine, amantadine, pergolide, the newer dopamine agonists (ropinirole, pramipexole), catecholamine-*O*-methyltransferase (COMT) inhibitors (entacapone, tolcapone), and the monoamine oxidase-B (MAO-B) inhibitor selegiline (McDowell et al. 1998; Meythaler et al. 2002; Zafonte et al. 2001). The SSRI sertraline, which has some dopaminergic activity, may have a cognition-enhancing effect in addition to its antidepressant effect (Fann et al. 2001), although larger controlled studies are needed to confirm this finding and to determine whether sertraline’s effect on cognition is independent of its effect on depression. Medications that enhance cholinergic activity include cholinergic precursors such as lecithin and acetyl-

cholinesterase inhibitors such as physostigmine (Cardenas et al. 1994), donepezil (Khateb et al. 2005; Whelan et al. 2000; Zhang et al. 2004), and galantamine (Bennouna et al. 2005). The noradrenergic agents most commonly used to enhance cognition, perhaps by improving arousal, attention, and awareness, are the psychostimulants methylphenidate (H. Lee et al. 2005; Whyte et al. 2004) and dextroamphetamine, which also have dopaminergic effects. Modafinil also may show some benefit. The opioid antagonist naltrexone helped improve TBI-associated memory impairment in a case series (Tennant and Wild 1987). Although evidence-based guidelines support post-TBI use of methylphenidate and donepezil for deficits of attention and speed of processing, donepezil for memory deficits, and bromocriptine for deficits in executive functioning (Warden et al. 2006), these agents require further study to better delineate appropriate indications, dosages, and treatment durations.

Psychological Treatment

Traumatic Brain Injury

A widely accepted model of psychological effects of TBI distinguishes among symptoms that are reactions to the effects of TBI (e.g., depression, anxiety, irritability, anger, hopelessness, helplessness, social withdrawal, distrust, and phobias), symptoms that are neurologically based (e.g., affective lability, impulsivity, agitation, paranoia, unawareness), and symptoms that reflect long-standing personality traits (e.g., obsessiveness, antisocial behavior, work attitude, social connectedness, dependence, entitlement) (Prigatano 1986). Although the genesis of symptoms can be multifactorial, it is useful to consider the potential contributions of all three factors to observed problem behaviors. Prigatano (1986) argued that reactive problems may be most amenable to psychotherapeutic interventions, whereas neurologically mediated symptoms may require multimodal interventions that also target underlying cognitive impairment. Characterological problems may require making coordinated changes in important environmental contingencies and working with families or caregivers.

Although psychotherapy is considered an important aspect of brain injury rehabilitation (National Institutes of Health Consensus Development Panel 1999), there are few controlled studies of psychotherapeutic interventions in persons with TBI and little guidance on the indications for psychotherapeutic interventions. A systematic review of the literature on psychotherapeutic and rehabilitation interventions for depression after TBI (Fann et al. 2009a) suggests that cognitive-behavioral approaches, particularly holistic treatment programs for TBI that include activity scheduling and increasing positive interaction with the environment, may improve mood along with func-

tional outcomes and productivity. Other treatment components such as problem-solving and goal-setting training that are commonly used in multidisciplinary programs for TBI, including two reviewed here (Powell et al. 2002; Svendsen et al. 2004), also may be important. A telephone-based psychoeducational and problem-solving program aimed at improving functioning after TBI also shows promise in improving depressive symptoms while overcoming barriers to treatment (Bombardier et al. 2009). Empirically supported psychotherapies have been adapted for use in brain-injured individuals (e.g., modified CBT for anxiety [Bryant et al. 2003; Hibbard et al. 2000b; Tiersky et al. 2005], depression [Hibbard et al. 1992], and insomnia [Ouellet and Morin 2004]). Psychological interventions are more likely to require involvement of family members or caregivers to help cue follow-through and generalization to real-world situations. Psychotherapy has been used with selected patients to foster insight in comprehensive post-acute neurorehabilitation programs (Prigatano and Ben-Yishay 1999). Insight-focused psychotherapy often begins with providing the patient with a simple model to explain what has happened. These explanations and coping strategies must be rehearsed repeatedly until they are automatic. Group therapy may be used to foster more insight through feedback from peers.

When insight and self-management approaches are not feasible, applied behavioral analysis can be used to manage a wide variety of brain injury-related behavioral deficits or excesses, such as emotional lability, anger management, compulsions, and impulsivity. Mainly case studies have shown the efficacy of contingency management for enhancing appropriate social behavior, improving participation in rehabilitation, and increasing independent functioning (Horton and Howe 1981). In some cases, such as anger management, both self-control and environmental control strategies can be combined to achieve better outcomes (Uomoto and Brockway 1992).

Therapy for impaired awareness is in its infancy but has included several different strategies. Mildly impaired patients may benefit from information about the effects of brain injury coupled with test data and observations about the specific ways they have been affected, including limited awareness. Basic cognitive compensatory strategies should be used to help patients attend to, understand, and recall this information. Family, friends, or caregivers should be included in these educational processes. With more severe or persistent problems, treatment may include more comprehensive, coordinated, and real-time feedback about impairments, such as via videotaping. Experiential learning paradigms can be used in which the person is asked to predict how well he or she will perform on a given test and is reinforced for successively improving the accuracy of his or

her predictions. Failure experiences may be permitted, although staff should minimize the potential for shame or humiliation that may occur with failures. Improvements may be made in safety behaviors without corresponding changes in verbal awareness, so at times it may be therapeutic to ignore verbal denial and work strictly on the level of behavior. With intractable unawareness, it may be essential to enlist relatives and friends to create a protective environment by ensuring 24-hour supervision, removing access to cars or other dangerous equipment, contacting employers, and providing a written letter signed by the physician that lists all the behavioral restrictions to support caregivers when the restrictions are challenged. When adaptive denial is present, staff may benefit from information about how the denial helps the person psychologically. Staff may be inclined to confront the denial, not realizing the value of defensive denial in managing anxiety and maintaining a sense of self-efficacy.

Cognitive rehabilitation. The science of cognitive rehabilitation has grown tremendously in the past 15 years to the point that evidence-based guidelines have been derived from significant efficacy and effectiveness trials (Cicerone et al. 2000, 2005). Empirically validated approaches are available for remediation of visuoperceptual deficits, language deficits, and impaired pragmatic communication and for memory compensation in patients with mild memory impairment (Cicerone et al. 2000). Some evidence suggests that attention training, including computer-based training modules, is effective (Park and Ingles 2001). Effective strategies are available to train patients to improve visual scanning, reading comprehension, language formation, and problem solving (Cicerone et al. 2000). Optional rehabilitation strategies that may be effective include the use of memory books for persons with moderate to severe impairment, verbal self-instructional training, and self-questioning and self-monitoring to address deficits in executive functioning. Isolated use of computer-based training procedures is not recommended for any form of impairment (Cicerone et al. 2000).

Controlled trials of comprehensive rehabilitation programs are rare for postacute rehabilitation and absent for acute rehabilitation, primarily because of cost and ethical issues associated with withholding usual care. In a recent randomized controlled trial, Cicerone et al. (2008) showed the superiority of a holistic rehabilitation program compared with a standard multidisciplinary rehabilitation program. The holistic program emphasized the integration of cognitive, interpersonal, and functional interventions within a therapeutic environment and produced greater improvements in community integration and self-efficacy for the management of TBI-related symptoms

than did standard neurorehabilitation. The data suggested that greater effectiveness of the holistic program may be attributable to interventions directed at self-regulation of cognitive and emotional processes, including metacognitive processes of self-appraisal, prediction, self-monitoring, and self-evaluation. A current synthesis of the available evidence on comprehensive rehabilitation concluded that the greatest benefits accrue to those patients who receive individualized and integrated treatment oriented toward both cognitive and interpersonal areas of function (Cicerone et al. 2000).

Spinal Cord Injury

Three types of problems may require psychological interventions in the context of SCI: 1) primary psychiatric disorders, 2) problems with adjustment to disability, and 3) problems with adherence to medical and rehabilitation therapies. With the caveat that there may be significant time constraints on implementing psychotherapy during a relatively short rehabilitation stay, abbreviated forms of standard empirically supported psychotherapies can be used in many cases if cognition is intact. Additionally, if a rehabilitation psychologist is on staff, responsibilities for therapeutic interventions can be negotiated between the psychiatrist and the psychologist.

For depression and anxiety disorders, brief CBT is often indicated in conjunction with initiating pharmacotherapy. Rehabilitation activities should afford the patient numerous opportunities to practice CBT skills, such as identification of irrational thoughts and positive reframing within a supportive context. The consultant also can work within the rehabilitation team to accomplish additional therapy goals by proxy. For example, the recreation therapist can carry out graded exposure to being in a motor vehicle for a patient with acute PTSD-related anxiety and avoidance of cars.

Cognitive-behavioral interventions have been adapted for, and studied to a limited degree in, the SCI population. Craig et al. (1997) used a group-based skills-oriented approach for teaching relaxation, cognitive restructuring, social skills, assertiveness, pleasant activity scheduling, and ways to begin sexual adjustment. Subjects with high levels of depressed mood before treatment were significantly less depressed than were historical control subjects 1 year after treatment. At 2-year follow-up, subjects who had received CBT had fewer hospital readmissions, used fewer drugs, and reported higher levels of adjustment compared with subjects in the control group (Craig et al. 1999). P. Kennedy et al. (2003) tested a "coping effectiveness training" approach that involves teaching cognitive appraisal and coping skills in small groups. Compared with matched historical control subjects, the treated subjects reported reduced

depression and anxiety, although improvements were unrelated to changes in coping skills.

Group-based interventions provide unique opportunities to capitalize on the positive coping abilities modeled by participants with better adjustment. Therefore, group-based coping skills training is recommended for people with significant anxiety or depressive symptoms after SCI as an adjunct to or in lieu of individual psychotherapy.

Poor adjustment to disability and management of grief are also common reasons for referrals. As noted earlier, potentially harmful myths exist about the nature and course of grief. Empirically supported approaches to manage grief are lacking (Bonanno et al. 2002), especially with regard to loss of physical function as in SCI. Nevertheless, current conceptualizations of the grieving process may be instructive. Stroebe and Shut (1999) described a dual process model of grief in which aggrieved individuals alternate between confronting and avoiding loss and restoration-related stressors. This model normalizes the transient denial shown by people with SCI and emphasizes that oscillation between confronting and seeking respite from loss experiences is an aspect of adaptive coping. Maciejewski et al. (2007) found that acceptance, not disbelief, is the first most dominant normal grief indicator; that acceptance increases steadily over time; and that by 6 months postloss, disbelief, yearning, anger, and depression have all peaked. Their data suggested that grief indicators that have not begun to subside after 6 months may merit specialized treatment. Finally, effective treatment of more chronic grief requires integration of strategies from interpersonal therapy and exposure therapy (Shear et al. 2001).

Applying these findings to adjustment to SCI suggests that clinicians should resist the temptation to confront patients with their prognosis when they, for example, insist that they are going to walk again. Such denial may simply reflect the loss-avoidance phase of the dual process model and the understandable hope or wish for neurological recovery. Overly direct confrontation may interfere with normal oscillations and damage adaptive defenses. Confrontation also may increase resistance and risk eliciting excessive distress. Tolerance of verbal denial and other adjustment patterns is recommended as long as they do not interfere with rehabilitation progress for more than a day or so. For these patients, staff education about the dual process model may be the main intervention. In the uncommon instance when verbal denial is accompanied by behavioral denial (e.g., refusing to learn adaptive strategies such as wheelchair use and self-catheterization) or persistently interferes with rehabilitation progress, more exposure-based interventions may be needed. In such cases, the psychiatrist may recommend that patients review information about the nature and extent of their injury (including radio-

graphic evidence), prognosis for recovery, and current SCI research with the attending physician, possibly with the consultant present.

Given the action-oriented behavioral style of many patients with SCI (Rohe and Krause 1998), we believe that much adjustment is behaviorally mediated; that is, rather than verbally processing losses associated with SCI, patients accommodate to their impairments largely through physical and occupational therapy wherein they repeatedly experience their abilities and limitations through activities. To the extent that therapists can set attainable incremental goals and maximize the patients' sense of mastery, positive adjustment can be facilitated. Therapies also can be organized to help patients resume participation in their most meaningful, rewarding, and pleasant life activities. Prospective descriptive studies of bereavement (Bonanno et al. 2002) and the incipient empirical use of combined interpersonal therapy and exposure therapy for "traumatic grief" (Shear et al. 2001) may lead to more valid approaches to treating adjustment to loss in SCI.

Nonadherence to treatment, and the associated conflicts with staff, often triggers psychiatric consultation. Causes of nonadherence are varied and include depression, amotivational states due to concomitant TBI, antisocial personality traits, ongoing substance abuse, and unrealistic staff expectations. Adherence is a function of the interaction among somatic, psychological, and environmental variables (Trieschmann 1988). Environmental factors may be particularly salient in cases of nonadherence. Once primary psychiatric disorders are ruled out, the consultant should examine how adherence to prescribed therapies may not be as rewarding for the patient as it should be, perhaps because of pain, withdrawal of social contact, or relinquishing a sense of control. In some cases, nonadherence may inadvertently be rewarded by engaging staff in negative social interactions, asserting independence, or avoiding unwanted responsibilities. One example is patients with dependent traits not improving toward independence because staff attention and expressions of support are contingent on dependent behavior. Behavioral principles such as rewarding successive approximations, ignoring disability-inappropriate behaviors, initiating behavioral activation, using quota systems, and explicitly linking progress in rehabilitation to desired outcomes (such as earlier discharge) may improve adherence to treatment (W.E. Fordyce 1976).

Conclusion

As society's attitudes toward disability continue to evolve and researchers work toward better understanding the potent effects of psychosocial factors in disability, psychia-

trists will have an increasing role in the rehabilitation setting. To achieve comprehensive evaluation and treatment of TBI and SCI, psychiatrists must appreciate and address the multiple complex facets of these conditions, from the acute neurological injury and its attendant psychological trauma through the chronic neurological, medical, psychiatric, and social sequelae of the injury. The multidisciplinary rehabilitation setting affords an environment in which psychiatrists can use their pharmacological and psychotherapeutic skills in psychosomatic medicine to maximize the long-term functional potential of their patients.

Pain

Michael R. Clark, M.D., M.P.H., M.B.A.

IN THIS CHAPTER, I FIRST review definitions, assessment, and epidemiology of pain. I then discuss selected specific acute and chronic pain syndromes, followed by the major psychiatric comorbidities of chronic pain, including somatization, substance use, depression, anxiety, and other emotional states. Finally, treatments are reviewed, including medications, psychological therapies, and interdisciplinary programs. Some pain topics are covered elsewhere in this book, including arthritis (see Chapter 25, “Rheumatology”), fibromyalgia (see Chapter 26, “Chronic Fatigue and Fibromyalgia Syndromes”), postoperative pain (see Chapter 30, “Surgery”), headache (see Chapter 32, “Neurology and Neurosurgery”), pelvic pain and vulvodynia (see Chapter 33, “Obstetrics and Gynecology”), spinal cord injury (SCI; see Chapter 35, “Physical Medicine and Rehabilitation”), and palliative care (see Chapter 41, “Palliative Care”).

Definition and Assessment

Pain is a complex experience that integrates affective, cognitive, and behavioral factors with an extensive neurobiology. Pain has been defined by the International Association for the Study of Pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (Merskey 2007, p. 13). Many terms are used to describe different types of painful experiences (Table 36–1). Pain is the most common reason a patient presents to a physician for evaluation. This physician is rarely a psychiatrist. If the patient has chronic pain, pain persisting on a daily basis for a month beyond what would be considered the usual time for healing of underlying pathology, then many specialists may be involved in the care of the patient (Bonica 1990).

Pain is a subjective experience and difficult to assess, especially in patients with terminal illnesses, cognitive impairments, and other chronic degenerative diseases of the brain (Nikolaus 1997). Pain rating scales attempt to measure the severity and intensity of pain. Many factors can influence these ratings, including disease states, mental disorders, distress, personality traits, and meaningful interpretations based on personal beliefs. In a comparison study of several pain rating scales, such as a vertically oriented visual analog scale (VAS), a verbal descriptor scale (VDS), a pain thermometer, and a numeric rating scale, the VDS was rated as the preferred, easiest, and best assessment tool for rating pain by the elderly (Herr and Mobily 1993). The Geriatric Pain Measure short form is a 12-item self-administered questionnaire targeted at community-dwelling elderly people to improve assessment of pain intensity, pain with ambulation, and disengagement because of pain (Clough-Gorr et al. 2008).

Epidemiology

The U.S. Center for Health Statistics conducted an 8-year follow-up survey and found that 32.8% of the general population experienced chronic pain symptoms (Magni et al. 1993). Health status surveys in six European countries found pain to be a significant problem in 28.5% of the general population (König et al. 2009). In Israel, 46% reported at least one chronic pain complaint, and more than a third of individuals reported severe pain with impaired life activities (Neville et al. 2008). A World Health Organization (WHO) study of more than 25,000 primary care patients in 14 countries found that 22% of patients had pain that was present for most of the time for at least 6 months (Gureje et al. 1998). In people age 65 years or older, musculoskeletal

TABLE 36-1. Definitions relating to pain sensations

Allodynia	Pain from a stimulus that does not normally provoke pain
Deafferentation pain	Pain resulting from loss of sensory input into the central nervous system
Dysesthesia	Unpleasant, abnormal sensation that can be spontaneous or evoked
Hyperalgesia	Increased response to a stimulus that is normally painful
Hyperesthesia	Increased sensitivity to stimulation that excludes the special senses
Hyperpathia	Pain characterized by an increased reaction to a stimulus, especially a repetitive stimulus, and an increased threshold
Hypoesthesia	Diminished sensitivity to stimulation that excludes the special senses
Nociception	Detection of tissue damage by transducers in skin and deeper structures and the central propagation of this information via A delta and C fibers in the peripheral nerves
Paresthesia	Abnormal sensation, spontaneous or evoked, that is not unpleasant
Sensitization	Lowered threshold and prolonged/enhanced response to stimulation

Source. Adapted from Merskey et al. 1986.

pain is associated with three times the likelihood of significant difficulty performing three or more physical activities (Scudds and Robertson 1998). In a community sample of individuals older than 70, chronic pain was present in 52%, and obesity was associated with a two- to fourfold increase in risk of having chronic pain (McCarthy et al. 2009). In persons older than 75, more than two-thirds reported pain, almost half reported pain in multiple sites, and a third rated pain as severe in at least one location (Brattberg et al. 1996).

Acute Pain

The Joint Commission on Accreditation of Healthcare Organizations has implemented pain management standards for all patient encounters (Phillips 2000). In the Veterans Affairs medical centers, pain intensity is defined and tracked as the “fifth vital sign.” Acute pain is usually the result of trauma from a surgery, an injury, or an exacerbation of chronic disease, especially musculoskeletal conditions. Treatment is focused on controlling inflammation, preventing tissue destruction, and repairing injury, with more emphasis placed on pain relief to facilitate reaching these goals.

The approach to acute pain management usually will be successful with straightforward strategies such as relaxation, immobilization, analgesic medications (aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], opioids), massage, and transcutaneous electrical nerve stimulation (Institute for Clinical Systems Improvement [ICSI] 2008). The absence of signs consistent with acute pain, such as elevated heart rate, blood pressure, and

diaphoresis, does not rule out the presence of pain. Acute pain management initiated as early as possible and focused on preventing occurrence and reemergence of pain may allow for lower total doses of analgesics. Analgesics, especially opioids, should be prescribed only for pain relief. Although analgesia may produce many benefits, other symptoms commonly coinciding with acute pain such as insomnia or anxiety should be managed separately from pain. Sleep deprivation and anxiety may intensify the sensation of pain and increase requests for more medication. Reducing anxiety and insomnia often reduces analgesic requirements.

In acute pain management, psychiatric consultation is requested when a patient requires more analgesia than expected or has a history of substance abuse. Patients with an active or recent history of opioid addiction and those receiving methadone maintenance therapy have increased tolerance to opioids and may require up to 50% higher doses of short-acting opioids being used for acute pain management. Although it is important to monitor opioid use carefully in these patients, adequate treatment of acute pain is a priority. Inadequate dosing is significantly more common than abuse or diversion in these patients.

Psychiatric Comorbidity

Pain Disorder and Somatization

When a somatic cause for pain cannot be identified, many clinicians begin to seek psychological causes. Pain “caused” by emotional factors was first classified in DSM-II (American Psychiatric Association 1968) under psychophysiological disorders, and DSM-III (American Psychiatric Association 1980) introduced psychogenic pain disorder.

The lifetime prevalence of somatoform pain disorder (DSM-III-R; American Psychiatric Association 1987) in the general population was 34%, and the 6-month prevalence was 17%. The addition of the DSM-IV (American Psychiatric Association 1994) requirement of “significant distress or psychosocial impairment due to somatoform pain” reduced the lifetime prevalence of pain disorder to 12% and the 6-month prevalence to 5%, with a female-to-male ratio of 2:1 (Grabe et al. 2003).

Pain is the chief complaint, but the experience of pain is augmented by psychological factors. Injured workers with somatoform pain disorder compared with those workers without this disorder had more sites of pain with spread of pain beyond the area of original injury, more opioid and benzodiazepine use, and greater involvement with compensation and litigation (Streltzer et al. 2000). Pain disorder is often equated with “psychogenic” pain with no “real” cause. However, neuroimaging studies show significant decreases in gray matter density in prefrontal, cingulate, and insular cortex that modulate the subjective experience of pain (Valet et al. 2009). Unfortunately, the either/or concept of psychological and physical dualism remains inherent in this diagnosis instead of appreciating how these domains interrelate with each other.

Multiple pain complaints are typical in somatization disorder, but somatization disorder is very uncommon in patients with chronic pain. More common in patients with multiple unexplained painful symptoms are subsyndromal forms of somatization disorder, such as multisomatoform disorder, which affects 4%–18% of primary care patients and is associated with high rates of health care use and persistent somatic complaints (Jackson and Kroenke 2008). These patients are more likely to have catastrophic thinking, believe the cause of their pain to be a mysterious medical disease, have feelings of losing control, and think that physicians believe their pain is imaginary. Patients with chronic pain and medically unexplained symptoms also are at risk for iatrogenic consequences of excessive diagnostic tests, inappropriate medications, and unnecessary surgery. Increased psychiatric morbidity is associated with levels of unexplained medical symptoms far below the number required for the diagnosis of somatization disorder. Overlap between somatoform disorders and depressive or anxiety disorders is common. Patients with somatization experience significant functional disability and role impairment independent of psychiatric and medical comorbidity (Harris et al. 2009). The concept of somatization is more likely a dimensional process based on somatic distress and care-eliciting behavior with varying degrees of severity and persistence across the entire population rather than a set of categorical disorders affecting only a small subset of people (Noyes et al. 2008).

Substance Abuse and Dependence

The prevalence of substance dependence or addiction in patients with chronic pain is estimated to range from 3% to 19% (Derseh et al. 2002; McWilliams et al. 2003). The essential criteria for a substance use disorder in patients with chronic pain include the loss of control in the use of the medication, excessive preoccupation with the medication despite adequate analgesia, and adverse consequences associated with its use. The Researched Abuse, Diversion and Addiction-Related Surveillance System (RADARS) reported that prescription opioid abuse has significantly increased (Cicero et al. 2007). Americans represent less than 5% of the world's population but consume 80% of the global opioid supply, including 99% of the hydrocodone produced (Manchikanti and Singh 2008).

Aberrant medication-taking behaviors can be mistaken for addiction. Persistent pain can lead to an increased focus on taking opioid medications, with the patient taking measures to ensure an adequate medication supply. Patients understandably fear the reemergence of pain and withdrawal symptoms if they run out of medication. Medication-seeking behavior may be the result of an anxious patient trying to maintain a previous level of pain control or improve on a partial but inadequate response to analgesics. These actions may represent pseudoaddiction that results from therapeutic dependence and current or potential undertreatment but not addiction (Kirsh et al. 2002). The distinction between pseudoaddiction and true addiction is based on whether these behaviors abate with adequate analgesic therapy and functioning improves or whether these behaviors persist in the context of deteriorating function.

Several patterns of nonadherence to or misuse of prescribed medications occur when patients have concerns about medications (McCracken et al. 2006). The taking of *more* medication than prescribed was associated with patients' concerns about addiction, tolerance, withdrawal, excessive scrutiny of medication use by others, and a greater perceived need for medication. These factors are likely risk factors for developing an addiction to prescribed medications. During the first 5 years after the onset of a chronic pain problem, patients are at increased risk for developing new drug use problems and disorders. The risk was highest among those with a history of drug use disorder or psychiatric comorbidity. Not infrequently, a history of substance abuse emerges only after the current misuse of medications has been identified, thus requiring physicians to monitor treatment closely. Aberrant medication-taking behaviors occur in approximately 50% of the patients with chronic pain receiving chronic opioid analgesic therapy, with even higher rates in patients with a history of substance abuse (Passik et al. 2006). The Pain Assessment and Documenta-

tion Tool is an effective means to standardize follow-up care and decrease the risk of poor outcome with opioid therapy (Passik et al. 2005). These studies suggest that aberrant medication-taking behavior is a manifestation of addiction or diversion in only 10% of patients.

The process of relapse back to substance abuse in these patients is not well understood and probably involves multiple factors. A cycle of pain followed by relief after taking medications is an excellent example of operant reinforcement of their future use (Fordyce et al. 1973). For patients with chronic pain who develop new substance use disorders, the problem most commonly involved the medications prescribed by their physicians (Long et al. 1988). In a recent comprehensive review, a calculated rate of abuse or addiction in patients with chronic pain was only 3.27% (Fishbain et al. 2008a). In the subgroup of patients with chronic pain who had no history of substance abuse, this rate declined to 0.19%. However, as expected, rates for aberrant medication-taking behaviors and abnormal urine toxicology results were significantly higher, reinforcing the need for risk screening and monitoring. Risk prediction instruments such as the Screener and Opioid Assessment for Patients With Pain (SOAPP), Opioid Risk Tool (ORT), and Current Opioid Misuse Measure (COMM) offer valuable guidance but have significant limitations (Chou et al. 2009). Strategies to optimize outcome and minimize abuse require careful analysis of the behavior of both patients and physicians (Passik and Kirsh 2008).

From the opposite perspective, patients with substance use disorders have increased rates of chronic pain and are at the greatest risk for stigmatization and undertreatment. Opioid-dependent patients with chronic pain have even higher rates of drug use than do those without chronic pain (Peles et al. 2005; Rosenblum et al. 2003). Surprisingly, 84% of the patients with chronic pain who abused prescription opioids and entered a drug abuse treatment facility reported that they had legitimately received a prescription from a physician for the treatment of pain (Passik et al. 2006). However, 91% had purchased prescription opioids through illegitimate sources, and 80% had altered the delivery system of the prescription drug, which suggests that they had progressed to more severe forms of addiction. For example, patients with substance abuse and back pain were less likely to complete a substance abuse treatment program compared with those without pain, although the other factors associated with poor outcome were difficult to define (Stack et al. 2000). Integrating care for chronic pain with innovative stepped-care models of substance abuse treatment would likely improve outcomes by tailoring the intensity of treatment to an individual patient's needs (Clark et al. 2008).

Depression and Affective Distress

The relation between pain and depression is intimate and bidirectional. Physical symptoms are common in patients with major depression. Approximately 60% of patients with depression report pain symptoms at diagnosis. In the WHO's data from 14 countries on 5 continents, 69% (range: 45%–95%) of patients with depression presented with only somatic symptoms, of which pain complaints were most common (Simon et al. 1999). A survey of almost 19,000 Europeans found a fourfold increase in the prevalence of chronic painful conditions in subjects with major depression (Ohayon and Schatzberg 2003). A depressive disorder doubles the risk of developing chronic musculoskeletal pain, headache, and chest pain up to 13 years later (Larson et al. 2004). In patients with early inflammatory arthritis, baseline symptoms of depression predicted future pain better than did initial ratings of pain and disease activity (Schieir et al. 2009).

Individuals with chronic physical complaints have higher rates of lifetime major depression. The prevalence of major depression in patients with chronic low back pain (LBP) is more than three times the rate in the general population (Sullivan et al. 1992). Among patients presenting to chronic pain clinics, one-third to more than one-half meet criteria for current major depression (Dersh et al. 2002). Depression in patients with chronic pain is associated with greater pain intensity, more pain persistence, application for early retirement, and greater interference from pain, including more pain behaviors observed by others (Hasenbring et al. 1994). Depression is a better predictor of disability than are pain intensity and duration. Primary care patients with musculoskeletal pain complicated by depression are significantly more likely than nondepressed patients with musculoskeletal pain to use medications daily, including sedative-hypnotics, and in combinations (Mäntyselkä et al. 2002). In a study of more than 15,000 employees who filed health claims, the cost of managing chronic conditions such as back problems was almost doubled when they had comorbid depression (Druss et al. 2000). In older adults with chronic pain, depression may be characterized by the absence of self-blame and significantly influenced by cognitive-behavioral variables such as catastrophizing and maladaptive coping styles (Lopez-Lopez et al. 2008).

Patients with chronic pain syndromes, such as migraine, chronic abdominal pain, and orthopedic pain syndromes, have increased rates of suicidal ideation, suicide attempts, and suicide completion (Magni et al. 1998). Patients with chronic pain completed suicide at two to three times the rate in the general population (Fishbain et al. 1991). The decrease in self-efficacy experienced by patients with chronic pain is highly associated with depressive

symptoms that result in feelings of hopelessness (Rahman et al. 2008). Although other psychosocial variables play a role, depression is the most consistent and strongest predictor of suicidal ideation and behaviors in patients with chronic pain (Braden and Sullivan 2008). Pain is even more likely to be an independent risk factor for suicide in patients with head or multiple types of pain (Ilgen et al. 2008).

Depression with comorbid pain can be more resistant to treatment (Kroenke et al. 2009). Depression should be treated aggressively and not simply “understood” as an expected outcome of suffering with chronic pain. Pain often subsides with improvement in depressive symptoms. In patients older than 60 years with arthritis, antidepressants and/or problem-solving-oriented psychotherapy not only reduced depressive symptoms but also improved pain, functional status, and quality of life (Lin et al. 2003). In addition to having greater efficacy for the treatment of neuropathic pain, serotonin–norepinephrine reuptake inhibitors (SNRIs) and tricyclic antidepressants (TCAs) are associated with faster rates of improvement in depressive symptoms and lower rates of relapse of major depressive disorder compared with selective serotonin reuptake inhibitors (SSRIs) (Rosenzweig-Lipson et al. 2007). These findings may be explained by the fact that the neurobiology of pain and depression overlap (Bair et al. 2003).

Anxiety, Fear, Catastrophizing, and Anger

Almost 50% of patients with chronic pain report anxiety symptoms, and up to 30% of patients have an anxiety disorder such as generalized anxiety disorder, panic disorder, agoraphobia, and posttraumatic stress disorder (PTSD) (Dersh et al. 2002; McWilliams et al. 2003). One prospective study of 1,007 young adults found that a baseline history of migraine was significantly associated with an increased risk (odds ratio [OR] = 12.8) of first-incidence panic disorder (Breslau and Davis 1993). In patients with non-cardiac chest pain, the presence of panic disorder significantly worsened health-related quality of life (Dammen et al. 2008).

PTSD is increasingly recognized as a comorbid condition with significant consequences for patients with medical illnesses, especially chronic pain disorders (Liebschutz et al. 2007). More than half of fibromyalgia patients reported clinically relevant PTSD-like symptoms that were significantly associated with greater levels of pain, emotional distress, interference, and disability (Sherman et al. 2000). Compared with accident-related factors, PTSD symptoms and other psychological factors were the strongest predictors of the development of chronic pain in people who had severe accidents 3 years earlier (Jenewein et al. 2009).

Conversely, anxiety symptoms and disorders are associated with high levels of somatic preoccupation and phys-

ical symptoms. Pain intensity in rheumatoid arthritis patients was significantly influenced by the presence of anxiety and depression, even after disease activity had been controlled for (Smedstad et al. 1995). Almost two-thirds of patients with panic disorder reported at least one current pain symptom (Schmidt et al. 2002). Pain was related to higher levels of anxiety symptoms, panic frequency, and cognitive features of anxiety. Pain severity, pain-related disability, and health-related quality of life were significantly worse in patients with chronic musculoskeletal pain and comorbid anxiety or depression (Bair et al. 2008).

Fear of pain, movement, reinjury, and other negative consequences that result in the avoidance of activities promote the transition to and sustaining of chronic pain and its associated disabilities (Greenberg and Burns 2003). Patients with chronic LBP who restricted their activities developed physiological changes (muscle atrophy, weight gain) and functional deterioration attributed to deconditioning (Verbunt et al. 2003). This process is reinforced by low self-efficacy, catastrophic interpretations, and increased expectations of failure regarding attempts to engage in rehabilitation. The fear–avoidance model of musculoskeletal pain incorporates components such as pain severity, pain catastrophizing, attention to pain, pain-related fear, escape or avoidance behavior, disability, disuse, and vulnerabilities to explain the transition from acute to chronic LBP (Leeuw et al. 2007).

Fear–avoidance beliefs were one of the most significant predictors of failure to return to work in patients with chronic LBP (Waddell et al. 1993). Operant conditioning reinforces disability if the avoidance provides any short-term benefits, such as reducing anticipatory anxiety or relieving the patient of unwanted responsibilities. In patients with chronic LBP, improvements in disability following physical therapy were associated with decreases in pain, psychological distress, and fear–avoidance beliefs but not specific physical deficits (Mannion et al. 2001). Decreasing work-specific fears was a more important outcome than addressing general fears of physical activity in predicting improved physical capability for work (Vowles and Gross 2003).

Catastrophic thinking about pain has been attributed to the amplification of threatening information, and it interferes with patients' ability to remain involved with productive activities (Crombez et al. 1998). Catastrophizing intensifies the experience of pain and increases emotional distress and self-perceived disability (Sullivan et al. 2001). This multidimensional construct includes elements of cognitive rumination, symptom magnification, feelings of helplessness, and expectations of pessimism (Edwards et al. 2006). Early treatment catastrophizing and feelings of helplessness in patients attending a 4-week multidisci-

plinary pain program predicted late-treatment outcomes (Burns et al. 2003). Pain-related cognitions such as catastrophizing and fear-avoidance beliefs predict poor coping and adjustment to chronic pain better than do objective factors such as disease status, physical impairment, or occupational descriptions (Hasenbring et al. 2001). High levels of catastrophizing and fear of injury prospectively predicted disability due to new-onset LBP 6 months later (Picavet et al. 2002). Catastrophizing has been shown to be a predictor of suicidal ideation independent of depressive symptoms and pain severity (Edwards et al. 2006).

Chronic Pain Conditions

Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is defined as pain persisting or recurring at the site of shingles at least 3 months after the onset of the acute varicella zoster viral rash. PHN occurs in about 10% of patients with acute herpes zoster. More than half of patients older than 65 years with shingles develop PHN, and it is more likely to occur in patients with cancer, diabetes mellitus, and immunosuppression. Other risk factors include longer duration of prodromal symptoms, greater acute pain and rash severity, sensory impairment, and psychological distress (Volpi et al. 2008). Most cases gradually improve over time, with only about 25% of patients with PHN experiencing pain at 1 year after diagnosis. Approximately 15% of referrals to pain clinics are for the treatment of PHN.

Although degeneration and destruction of motor and sensory fibers of the mixed dorsal root ganglion characterize acute varicella zoster, other neurological damage may include inflammation of the spinal cord, myelin disruption, axonal damage, and decreases in the number of nerve endings from the affected skin. Studies have suggested the role of both peripheral and central mechanisms resulting from the loss of large caliber neurons and subsequent central sensitization or adrenergic receptor activation and alterations in C-fiber activity (Truini et al. 2008). Early treatment of varicella zoster with low-dose amitriptyline reduced the prevalence of pain at 6 months by 50% (Johnson 1997). TCAs, SNRIs, anticonvulsants, and opioids are the most common effective treatments for PHN and may have potential for its prevention (Attal et al. 2006; Saarto and Wiffen 2007; Zin et al. 2008). Topical lidocaine recently has been approved by the U.S. Food and Drug Administration for treatment of PHN. A live attenuated varicella vaccine decreased the incidence of herpes zoster and PHN as well as the burden of illness in adults older than 60 years (Harpaz et al. 2008; Johnson et al. 2008).

Peripheral Neuropathy Pain

The most common cause of painful peripheral neuropathy is diabetes mellitus (Veves et al. 2008; Zochodne 2008). Approximately 25% of patients with diabetes mellitus will experience painful diabetic neuropathy, and longer duration of illness and poor glycemic control increase this risk (Tavakoli and Malik 2008). If C-fiber input is preserved but large-fiber input is lost, dysesthesias and pain are the predominant sensory experiences. The pain of a peripheral neuropathy can range from a constant burning to a pain that is episodic, paroxysmal, and lancinating in quality (Mendell and Sahenk 2003). These phenomena are primarily the result of axonal degeneration and segmental demyelination (Tomlinson and Gardiner 2008). Sites of ectopic impulse generation can be found at any point along the peripheral nerve, including the dorsal root ganglion, regardless of where the nerve is actually damaged. Other changes can alter the magnitude and frequency of impulse generation, such as sensitivity to mechanical or neurochemical stimuli. The paroxysms of pain that result from stimulation of hyperexcitable damaged neurons and subsequent recruitment of nearby undamaged sensory afferents may be explained by several forms of nonsynaptic (ephaptic) and prolonged (afterdischarge) impulse transmission. Voltage-dependent sodium channels contribute to hyperexcitability, and central sensitization amplifies and sustains neuronal activity by a variety of mechanisms such as reduced inhibition of dorsal horn cells, *N*-methyl-D-aspartate (NMDA) receptor activation, and excessive glutamate release (Carozzi et al. 2008). Pharmacological treatments are almost identical to those used in the treatment of PHN (Jain 2008; T.S. Jensen and Finnerup 2007).

Parkinson's Disease

Most patients with Parkinson's disease have pain, which is more common in women (Beiske et al. 2009). The pain is typically described as cramping and aching, located in the lower back and extremities, but not associated with muscle contraction or spasm. All forms of chronic pain are represented, including musculoskeletal, neuropathic (radicular, central), and dystonic (Schestatsky et al. 2007). These pains often decrease when the patient is given levodopa, which suggests a central origin. The loss of dopaminergic input could explain how pain is produced. Dopamine is now consistently implicated as having a role in the endogenous pain modulation system (Potvin et al. 2009; Wood 2008). In a review of French health system data, 82% of patients with Parkinson's disease were prescribed analgesics (Brefel-Courbon et al. 2009). Although patients with Parkinson's disease were more commonly prescribed chronic analgesics such as opioids and adjuvant medications when

compared with the general population and diabetic patients, only a minority of patients continued taking these medications. In an open-label trial of duloxetine in patients with Parkinson's disease, their pain improved significantly (Djaldetti et al. 2007). Subthalamic deep brain stimulation may offer relief to patients with symptoms refractory to other therapies (Kim et al. 2008).

Central Poststroke Pain and Spinal Cord Injury

Pain associated with lesions of the central nervous system is common after stroke (8%) or spinal cord trauma (60%–70%) (Finnerup 2008; Ullrich 2007). Symptoms of SCI pain or central poststroke pain are often poorly localized, vary over time, and include allodynia (>50% of central poststroke pain patients), hyperalgesia, dysesthesias, lancinating pain, and muscle and visceral pain regardless of sensory deficits. Pain is described as burning, aching, lacerating, or pricking. Radiographic lesions are present in the thalamus, although other sites are often involved such as the spinothalamic tracts, especially in SCI (Hari et al. 2009). Excitatory amino acids are likely involved in the development of central sensitization associated with this syndrome, and the onset of pain can occur more than a month after the stroke, suggesting multiple processes (Hains and Waxman 2007; Hulsebosch et al. 2009).

As a result, central poststroke pain is difficult to treat, and conventional analgesics and opioids have been shown to be ineffective. Randomized clinical trials have reported efficacy for amitriptyline and for drugs that reduce neuronal hyperexcitability, including lidocaine (intravenous), mexiletine, lamotrigine, fluvoxamine, and gabapentin, but not carbamazepine, phenytoin, or topiramate (Frese et al. 2006). Fluvoxamine significantly improved pain ratings but only in patients within 1 year after stroke (Shimodono et al. 2002). In contrast, patients with SCI experience reductions in continuous and evoked pain with ketamine and opioids, suggesting different mechanisms in different central pain states (Eide et al. 1995). Morphine may be effective against allodynia but not other components of central pain syndromes (Nicholson 2004). Intravenous lidocaine has been efficacious, but the need for intravenous administration and its adverse effects limit its use. Recent reviews support the efficacy of amitriptyline, gabapentin, and pregabalin for the neuropathic pain associated with SCI (Baastrup and Finnerup 2008; Tzellos et al. 2008).

Migraine and Chronic Daily Headache

The International Headache Society has published guidelines for the classification of headache. The peak incidence of migraine occurs between the third and sixth decade of life and then decreases with age (Silberstein et al. 2007). Over the life span, 18% of women and 6% of men will expe-

rience migraine headaches (Lipton et al. 2007). Theories of pathogenesis include the trigeminovascular system and plasma protein extravasation, antagonism of serotonin receptors, modulation of central aminergic control mechanisms, membrane-stabilizing effects through action at voltage-sensitive calcium channels, and increased levels of substance P (Goadsby et al. 2009). Common migraine is a unilateral pulsatile headache, which may be associated with other symptoms such as nausea, vomiting, photophobia, and phonophobia. The classic form of migraine adds visual prodromal symptoms such as scintillating scotomata. Complicated migraine includes focal neurological signs such as cranial nerve palsies and is often described by the name of the primary deficit (e.g., hemiplegic, vestibular, or basilar migraine).

Placebo-controlled clinical trials support use of NSAIDs and triptans for acute treatment of migraine attacks, with propranolol, metoprolol, flunarizine, valproate, and topiramate recommended as the best prophylactic agents (Evers et al. 2006; Mulleners and Chronicle 2008). In general, calcium channel blockers, beta-blockers, antidepressants, and anticonvulsants are the treatments of choice for more refractory migraine (Evers et al. 2006; Silberstein 2008). Behavioral treatments such as cognitive-behavioral psychotherapy and biofeedback or relaxation training are effective therapies (Holroyd and Drew 2006). A group-based multidisciplinary treatment for migraine consisting of stress management, supervised exercise, dietary education, and massage therapy significantly improved various pain characteristics, functional status, quality of life, depression, and pain-related disability (Lemstra et al. 2002).

Headache is the most common pain condition reported by the U.S. workforce as the reason for lost productivity (Stewart et al. 2003). Chronic daily headache affects about 5% of the population and is composed of constant (transformed) migraine, medication-overuse headache, chronic tension-type headaches, new-onset daily persistent headache, and hemicrania continua (Dodick 2006). Individuals with chronic daily headache are more likely to overuse analgesics, leading to rebound headache; to have psychiatric comorbidity such as depression and anxiety; to report functional disability; and to experience stress-related headache exacerbations (Fernández-de-las-Peñas and Schoenen 2009). Patients with transformed migraine have poor quality of life and the worst Short Form 36 (SF-36) Health Survey profile when compared with patients with episodic migraine or chronic tension-type headaches (Wang et al. 2001).

Chronic tension-type headaches typically manifest as daily pain that is difficult to manage and unresponsive to many treatments. Placebo-controlled clinical trials are few but support the use of amitriptyline, gabapentin, tizani-

dine, mirtazapine, topiramate, memantine, and botulinum toxin type A (Dodick 2006). Various medications have been recommended and include serotonin agonists, serotonin antagonists, and α_2 -adrenergic agonists. Olanzapine decreased headache severity and frequency in patients with refractory headaches who failed treatment with at least four preventive medications (Silberstein et al. 2002). Topiramate decreased migraine frequency and severity, number of headache days, and use of abortive medications in patients with both episodic and transformed migraine (Mathew et al. 2002). TCAs coupled with stress management therapy significantly reduced headache activity, analgesic medication use, and headache-related disability (Holroyd et al. 2001). Combined medication and cognitive-behavioral psychotherapy is more effective than either treatment alone (Lake 2001; Lipchik and Nash 2002).

Fibromyalgia

Fibromyalgia is a chronic pain syndrome characterized by widespread musculoskeletal pain in all four limbs and trunk, stiffness, and exaggerated tenderness. These symptoms are usually accompanied by poor sleep, cognitive difficulties, depression, and fatigue. Fibromyalgia is diagnosed in 3.4% of women and 0.5% of men and is clustered in families (Arnold et al. 2004). Current research suggests that fibromyalgia may be a syndrome of dysfunctional central pain processing influenced by a variety of processes, including infection, physical trauma, psychological traits, and psychopathology (Abeles et al. 2007). Guidelines for fibromyalgia treatment have been recently released and recommend multidisciplinary treatment regimens (Carville et al. 2008; Hauser et al. 2009). Placebo-controlled trials suggest pain reduction with cyclobenzaprine, milnacipran, gabapentin, pregabalin, duloxetine, and tramadol (Crofford 2008; Mease et al. 2009). Fibromyalgia is discussed in detail in Chapter 26, "Chronic Fatigue and Fibromyalgia Syndromes."

Phantom Limb Pain

Pain in a body part that has been removed occurs in 50%–80% of amputees within a year of the amputation (Schley et al. 2008). *Phantom limb pain*, considered to be neuropathic and described as stabbing, throbbing, burning, or cramping, is more intense in the distal portion of the phantom limb (Flor 2002). Any area of the body can manifest phantom pain, with phantom breast syndrome common after mastectomy (Bjorkman et al. 2008; Spyropoulou et al. 2008). Although TCAs, gabapentin, and carbamazepine are considered first-line treatments for phantom pain, no controlled trials support their use. Newer antidepressants and anticonvulsants with generally fewer side effects may result in greater effectiveness if patients can tolerate higher

doses. However, morphine, calcitonin, and ketamine have been shown to reduce phantom pain in controlled studies. Morphine, but not mexiletine, decreased postamputation pain lasting more than 6 months (Wu et al. 2008). Controlled trials have discredited anecdotal reports of the effectiveness of neural blockade (Manchikanti and Singh 2004).

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS; formerly reflex sympathetic dystrophy and causalgia) is an array of painful conditions characterized by ongoing spontaneous burning pain that is precipitated by a specific noxious trauma or cause of immobilization and often is associated with hyperalgesia or allodynia to cutaneous stimuli (Hsu 2009; Sharma et al. 2009). Pain is regional but is not limited to a single peripheral nerve or dermatome. Edema, blood flow abnormalities, or sudomotor dysfunction is often evident in the pain region—usually an extremity (Albazaz et al. 2008). These changes may be a result of neurogenic inflammation and neuropeptides such as calcitonin gene-related peptide, cytokines, substance P, and nerve growth factors (Birklein and Schmelz 2008). Motor changes such as weakness, tremor, dystonia, and limitations in movement are common (Harden et al. 2007). Sympathetically maintained pain is present in most, but not all, cases and may result from coupling of sympathetic and sensory neurons or adrenoceptor supersensitivity in nociceptive fibers (Gibbs et al. 2008). Patients with sympathetically maintained pain often report hyperalgesia to cold stimuli and report temporary relief with sympathetic blockade (Pontell 2008).

Patients with CRPS often have mood (46%), anxiety (27%), and substance abuse disorders (14%), generally considered to be a consequence of chronic pain rather than its cause, when coupled with maladaptive personality traits and coping styles (Bruehl and Chung 2006).

Pharmacotherapy for CRPS has limited success, and few randomized controlled studies are available to guide treatment selection (Mackey and Feinberg 2007; Rowbotham 2006). Symptoms often improve with NSAIDs or corticosteroids in the acute, or inflammatory, stage of the disease. Evidence suggests efficacy for gabapentin, pregabalin, carbamazepine, TCAs, and opioids. Randomized controlled trials of calcitonin and bisphosphonates in CRPS found reduced pain and improved joint mobility. Clinical trials of local anesthetic sympathetic blockade, once considered the gold standard therapy for CRPS, have proven inconclusive (Sharma et al. 2006). Other therapies include early intervention with reactivating physical therapies, electrical stimulation, and possibly even surgical sympathectomy (Pontell 2008).

Orofacial Pain

Trigeminal neuralgia (tic douloureux) is a chronic pain syndrome with severe, paroxysmal, recurrent, lancinating pain in the distribution of cranial nerve V that is unilateral and most commonly involves the mandibular division (Obermann and Katsarava 2009; Prasad and Galetta 2009). Sensory or motor deficits are not usually present. Episodes of pain can be spontaneous or evoked by nonpainful stimuli to trigger zones, activities such as talking or chewing, or environmental conditions. Between episodes, patients are typically pain free.

Less common syndromes involving the intermedius branch of the facial nerve or the glossopharyngeal nerve present with pain that can involve the ear, posterior pharynx, tongue, or larynx (Zakrzewska 2002). Other related conditions include cluster headache, which occurs predominantly in men with an onset before age 25 and presents with pain that is episodic, unilaterally surrounds the eye, is described as excruciating, lasts minutes to hours, and is associated with autonomic symptoms. Short-lasting, unilateral neuralgia-form pain with conjunctival injection and tearing (SUNCT) syndrome is a rare condition that more commonly affects older men. Tolosa-Hunt syndrome presents with pain in the ocular area accompanied by ipsilateral paresis of oculomotor nerves and the first branch of the trigeminal nerve that is associated with compromise of ophthalmic venous circulation and improves with steroids. The residual category of atypical facial pain includes atypical odontalgia and is more commonly associated with psychopathology or other psychological factors that amplify the patient's pain, distress, disability, and risk for suicide (List et al. 2007).

Most patients with classic trigeminal neuralgia show evidence of trigeminal nerve root compression by blood vessels (85%), mass lesions, or other diseases (multiple sclerosis, herpes zoster, PHN) that cause demyelination and hyperactivity of the trigeminal nucleus (Joffroy et al. 2001; Love and Coakham 2001). Uncontrolled pain with frequent or severe prolonged attacks increases the risk of insomnia, weight loss, social withdrawal, anxiety, and depression, including suicide.

Pharmacological treatment includes anticonvulsants, antidepressants, baclofen, mexiletine, lidocaine, and opioids (Cheshire 2002; Fisher et al. 2002; Sindrup and Jensen 2002). Placebo-controlled trials identify carbamazepine (number needed to treat of 1.8) as first-line treatment. Trials also support the use of oxcarbazepine and lamotrigine. Evidence is insufficient to recommend clonazepam, gabapentin, phenytoin, tizanidine, topical capsaicin, or valproate (Cruccu et al. 2008). Given the pathophysiological similarities to PHN and painful peripheral neuropathies, other medications such as the TCAs and SNRIs would be

appropriate pharmacological treatments to consider. When pharmacological treatments fail, a variety of surgical procedures such as microvascular decompression via suboccipital craniectomy, percutaneous gangliolysis, and stereotactic radiosurgery may be undertaken (Gronseth et al. 2008; Miller et al. 2009).

Temporomandibular disorder (TMD) is a general term referring to complaints that involve the temporomandibular joint, muscles of mastication, and other orofacial musculoskeletal structures. Pain most commonly arises from the muscles of mastication and is precipitated by jaw function such as opening the mouth or chewing. Associated symptoms include feelings of muscle fatigue, weakness, and tightness as well as changes in bite (malocclusion) or the ability to open or close the jaw. In contrast to the vague, diffuse pain of myalgia, temporomandibular joint dysfunction causes sharp, sudden, and intense pain with joint movement that is often localized to the preauricular area. Joint sounds such as clicking, popping, and crepitation are common. Patients may experience limitations in jaw movements such as catching sensations or actual locking of the jaw. Joint problems are classified as relating to the condyle-disk complex, structural incompatibility of the articular surfaces, and inflammatory joint disorders.

Psychological distress is common in patients with TMD. Patients with pain of muscular origin are usually more distressed and depressed, with greater levels of disability, than are those with temporomandibular joint pain. These factors are responsive to behavioral treatment (Auerbach et al. 2001). Longitudinal data suggest that negative affect in patients with orofacial pain is more likely than pain to cause poor sleep quality (Riley et al. 2001).

Burning mouth syndrome (BMS) is characterized as pain in oral and pharyngeal cavities, especially the tongue, often associated with dryness and taste alterations. Most cases are idiopathic, but BMS may coincide with a plethora of conditions, such as bruxism, poorly fitting dentures, oral candidiasis, xerostomia, malnutrition, food allergies and contact dermatitis, gastroesophageal reflux disease, diabetes mellitus, hypothyroidism, neoplasia, and menopause, as well as psychiatric disorders such as depression, anxiety, and somatization (Drage and Rogers 2003; Grushka et al. 2002). The condition mainly affects middle-aged and postmenopausal women, and the oral mucosa is usually normal. Psychological factors such as severe life events have been associated with the condition.

Potential underlying etiologies, such as depression or anxiety, nutritional deficiencies (iron, folate, B₁₂, and other B vitamins), maladaptive oral habits, and iatrogenic causes such as medications, should be identified and treated (Pinto et al. 2003). Treatment with TCAs or anticonvulsants has brought pain relief in some patients with BMS.

Other treatments include benzodiazepines, topical analgesics, soft desensitizing oral appliances, serotonin reuptake inhibitors, vitamin and hormonal supplements, and habit awareness counseling (Maina et al. 2002; Pinto et al. 2003).

Low Back Pain

LBP is one of the most common physical symptoms and the most expensive condition when lost productivity and health care costs are included (Deyo et al. 2009). Psychological factors, including distress, depressed mood, and somatization, which predict the transition from acute to chronic LBP, are highly correlated with LBP. In one prospective cohort study of 1,246 patients with acute LBP who sought treatment, about 8% had chronic, continuous symptoms for 3 months, and fewer than 5% had unremitting pain for 22 months (Carey et al. 2000). Two-thirds of patients with chronic LBP at 3 months had functional disability at 22 months. The most powerful predictor of chronicity was poor functional status 4 weeks after seeking treatment. In a study of secondary gain, both economic and social rewards were associated with higher levels of disability and depression in patients with chronic nonmalignant back pain (Ciccone et al. 1999). Anxiety, depression, and occupational mental stress predicted lower rates of return to work in patients undergoing lumbar surgeries (DeBerard et al. 2001; Schade et al. 1999; Trief et al. 2000).

The presence of a depressive disorder has been shown to increase the risk of developing chronic musculoskeletal pain. In a 15-year prospective study of workers in an industrial setting, initial depression symptom scores were predictive of LBP and a positive clinical back examination in men but not women (Leino and Magni 1993). In a community-based sample, depression was associated with a nearly fourfold increase in the likelihood of seeking a consultation for a new complaint of back pain lasting longer than 3 months at follow-up (Waxman et al. 1998). In a 13-year follow-up study that examined the longitudinal relation between LBP and depressive disorder by using lifetime reports of symptoms and that excluded other forms of affective distress such as demoralization, grief, and adjustment disorders, depressive disorder was a significant risk factor for incident LBP (Larson et al. 2004). One study concluded that as much as 16% of LBP in the general population may be attributable to psychological distress (Croft et al. 1996). In contrast, these findings do not undermine the fact that chronic, disabling occupational spinal disorders result in high levels of psychopathology that affect outcomes and benefit from treatment (Dersh et al. 2007).

The treatment of chronic LBP has been pursued with multiple modalities alone and in combination (Deyo and Weinstein 2001). Patients with chronic LBP exemplify the complexity of chronic pain treatment. Their symptoms

usually represent numerous diagnoses that require multimodal treatment plans. Although treatments often produce symptom reductions, conflicting evidence exists about their ability to improve functional status, particularly with respect to returning to work (Staiger et al. 2003). Even conservative interventions such as education, exercise, massage, and transcutaneous electrical stimulation produce inconsistent results (Furlan et al. 2002; Pengel et al. 2002). A study of physiotherapy for chronic LBP showed that physiotherapist-led pain management classes offered a cost-effective alternative to outpatient physiotherapy and spinal stabilization classes, with greater reductions in health care use and similar improvements in pain, quality of life, and time off from work (Critchley et al. 2007). Studies of behavior therapies support their effectiveness in comparison with wait-list or no-treatment control conditions, but the efficacy data are less convincing when compared with usual treatment for chronic LBP (van Tulder et al. 2001). Evidence indicates that surgery may be effective for a carefully selected group of patients with chronic LBP (Fritzell et al. 2001). Interdisciplinary rehabilitation programs usually offer the best outcomes for reducing pain and pain-related disability but are the most expensive approach, and high-quality randomized controlled trials are still needed to document long-term efficacy (Huge et al. 2006). Combined therapy with antidepressants and self-management education was effective in the treatment of patients with both depression and musculoskeletal pain (Kroenke et al. 2009). One review found efficacy for intensive multidisciplinary rehabilitation emphasizing functional restoration, but less intensive interventions were ineffective (Guzman et al. 2007). The patient's perception of disability is a critical factor that must be addressed for treatment to succeed.

Pharmacological Treatment

Numerous medications are used in the treatment of chronic pain, especially neuropathic pain, which affects 2%–3% of the world's population (Moulin et al. 2007). The pharmacological targets are mechanisms of peripheral and central nervous system sensitization such as sodium and calcium channel upregulation, spinal hyperexcitability, descending modulation, and aberrant sympathetic-somatic nervous system interactions. Antidepressants and anticonvulsants are the best studied and recommended as first-line therapies (Dworkin et al. 2007). Unfortunately, these medications remain underused and underdosed. In one study of patients with neuropathic pain, 73% complained of inadequate pain control, but 72% had never received anticonvulsants, 60% had never received TCAs, 41% had never received opioids, and 25% had never received any of the above (Gilron et al. 2002). No medication algorithm can provide a

simple, straightforward approach to the complexities encountered during the treatment of chronic pain.

Opioids

Opioids reduce the sensory and affective components of pain by interacting with mu, delta, and kappa opioid receptors located in both the peripheral and the central nervous systems of pain transmission and modulation. Controversy surrounds the long-term use of opioids for chronic nonmalignant pain (Noble et al. 2008). Studies generally last less than 18 months and are complicated by high rates of discontinuation because of adverse events or insufficient pain relief. Opioids should be slowly tapered to avoid withdrawal and completely discontinued if the risks (side effects, toxicities, aberrant drug-related behaviors) outweigh the objective benefits (analgesia, functional improvements).

Guidelines have been established for the use of opioids in chronic pain (American Academy of Pain Medicine and American Pain Society 2008). The U.S. Food and Drug Administration is now discussing risk evaluation and mitigation strategies to standardize the use of opioids and minimize their liabilities. Appropriate patients are those with moderate or severe pain persisting for more than 3 months and adversely affecting functioning or quality of life. Before initiating opioid therapy, additional factors such as the patient's specific pain syndrome, response to other therapies, and potential for aberrant drug-related behaviors (misuse, abuse, addiction, diversion) should be considered (Ballantyne and LaForge 2007). A patient's suitability for chronic opioid therapy can be assessed with standardized questionnaires such as the Opioid Risk Tool (ORT); the Diagnosis, Intractability, Risk, Efficacy (DIRE); and the Screener and Opioid Assessment for Patients in Pain (SOAPP). Treatment outcomes, including analgesia, activities of daily living, adverse events, and potential aberrant drug-related behaviors, can be assessed more easily with the Pain Assessment and Documentation Tool (PADT; Passik et al. 2004). The Current Opioid Misuse Measure (COMM) evaluates patients who are taking opioids for concurrent signs or symptoms of intoxication, emotional volatility, poor response to medications, addiction, inappropriate health care use patterns, and problematic medication behaviors. These scales can be downloaded from the Pain Treatment Topics Web site (www.pain-topics.org/opioid_rx/risk.php#AssessTools).

Clinically available opioids include naturally occurring compounds (morphine and codeine), semisynthetic derivatives (hydromorphone, oxycodone, hydrocodone, oxycodone, dihydrocodeine, and buprenorphine), and synthetic opioid analgesics (meperidine, fentanyl, methadone, tramadol, pentazocine, and propoxyphene). *Morphine*, because of its hydrophilicity, has poor oral bioavailability

(22%–48%) and delayed central nervous system absorption and onset of action. This delay prolongs the analgesic effect of morphine relative to its plasma half-life, which decreases the potential for accumulation and toxicity with repeated dosing. Morphine is a more effective epidural spinal analgesic than oxycodone. *Oxycodone* is an opiate analgesic with higher oral bioavailability (>60%), a faster onset of action, and more predictable plasma levels compared with morphine. Oxycodone, in comparison to morphine, has similar analgesic efficacy but releases less histamine and causes fewer hallucinations (Riley et al. 2008). *Hydrocodone* is similar to oxycodone, with rapid oral absorption and onset of analgesia. Hydrocodone is metabolized by *N*-demethylation to hydromorphone, which has properties similar to those of morphine, except for lower rates of side effects. *Fentanyl* is highly lipophilic with affinity for neuronal tissues, which allows for transdermal or transmucosal delivery. The duration of action of transdermal preparations is up to 72 hours, but interindividual variability is considerable.

Methadone warrants special consideration in the treatment of chronic pain because of its stigma, low cost, high bioavailability, rapid onset of action, slow hepatic clearance, multiple receptor affinities, lack of neurotoxic metabolites, and incomplete cross-tolerance with other opioids. Methadone has significantly greater risk of overdose because of the longer time needed for adaptation with oral use and greater variation in plasma half-life (15–120 hours) (Sandoval et al. 2005). Methadone is unique among opioids in its risk for increasing the QTc interval and causing torsade de pointes (Andrews et al. 2009). Extensive tissue distribution and prolonged half-life prevent withdrawal symptoms with once-daily dosing. However, elimination is biphasic, and the more rapid elimination phase equates with analgesia that is limited to approximately 6 hours. Repeated dosing, with accumulation in tissue, may increase the duration of analgesia to 8–12 hours. In one of the longer follow-up studies, methadone was shown to be effective for decreasing chronic pain in a study of 100 patients over a mean treatment duration of 11 months (Peng et al. 2008b).

The most common side effect of chronic opioid therapy is decreased gastrointestinal motility, causing constipation, vomiting, and abdominal pain. Oral opioids differ in their propensity to cause these symptoms. Transdermal opioids (fentanyl, buprenorphine) have fewer gastrointestinal side effects than do oral opioids (Tassinari et al. 2008). Long-term opiate administration may result in analgesic tolerance or opioid-induced hyperalgesia (Mittra 2008). When tolerance develops, coadministration of other analgesics, opioid rotation to a more potent agonist, or intermittent cessation of certain agents may restore analgesic effect (Dumas and Pollack 2008; Vorobeychik et al. 2008). Opioid rotation from either morphine or hydromorphone

may be beneficial because 3-glucuronide metabolites can accumulate within the cerebrospinal fluid and produce neuroexcitatory effects such as allodynia, myoclonus, delirium, and seizures (Smith 2000). Rotation to mixed agonist-antagonist opiates (buprenorphine, pentazocine) may precipitate withdrawal symptoms in patients receiving chronic opioid therapy. The concomitant use of opioids with monoamine oxidase inhibitors (MAOIs), dextromethorphan, and meperidine should be avoided.

Antidepressants

The neurobiology of pain suggests that all antidepressants would be effective for treatment of chronic pain, but the analgesic properties of these medications remain underappreciated (McCleane 2008). The TCAs and SNRIs, in particular, are effective treatments for many chronic pain syndromes, including diabetic neuropathy, PHN, central pain, poststroke pain, tension-type headache, migraine, and orofacial pain but not nonspecific LBP (Saarto and Wiffen 2007; Verdu et al. 2008). The analgesic effect of antidepressants is thought to be independent of their antidepressant effect and is primarily mediated by the blockade of reuptake of norepinephrine and serotonin, increasing their levels, and enhancing the activation of descending inhibitory neurons in the dorsal horn of the spinal cord (McCleane 2008; Mico et al. 2006). However, antidepressants may produce antinociceptive effects through a variety of pharmacological mechanisms, including modulation by monoamines; interactions with opioid systems; inhibition of ion channel activity; and antagonism by NMDA, histamine, and cholinergic receptors (Dick et al. 2007).

Tricyclic Antidepressants

Meta-analyses of randomized controlled trials concluded that TCAs are the most effective agents for neuropathic pain and effective for headache syndromes. A recent meta-analysis of fibromyalgia treatment trials found positive but diminishing effect when comparing classes of antidepressants: TCAs > MAOIs > SSRIs = SNRIs (Hauser et al. 2009). TCAs have been shown to effectively treat central poststroke pain, PHN, many painful polyneuropathies, and postmastectomy pain syndrome but not SCI pain, phantom limb pain, or painful HIV neuropathy. TCA agents are equally effective for pain, but secondary amine TCAs (e.g., nortriptyline) are better tolerated than are tertiary agents (e.g., amitriptyline) (Dworkin et al. 2007). Antidepressants generally produce analgesia at lower doses and with earlier onset of action than expected for the treatment of depression (Rojas-Corrales et al. 2003). However, lack of analgesic effects may be a result of inadequate dosing and necessitates optimal titration and confirmation with serum level monitoring. Chronic pain of PHN and diabetic peripheral

neuropathy has been treated successfully with TCAs at average doses of 100–250 mg/day (Max 1994). In contrast, a U.S. health insurance claims database found that the average dose of TCAs for the treatment of neuropathic pain in patients age 65 and older was only 23 mg (Berger et al. 2006). Patients in a multidisciplinary pain center study were prescribed the equivalent of 50 mg or less of amitriptyline, suggesting unrealized potential for additional pain relief. Cost-effectiveness research strongly supports the use of TCAs (Cepeda and Farrar 2006).

Serotonin–Norepinephrine Reuptake Inhibitors

Duloxetine, venlafaxine, desvenlafaxine, and milnacipran inhibit the presynaptic reuptake of serotonin, norepinephrine, and, to a lesser extent, dopamine with fewer side effects and less toxicity than TCAs. Duloxetine more potently blocks serotonin and norepinephrine transporters than does venlafaxine (Berrocoso and Mico 2008). Milnacipran has antihyperalgesic effects mediated by monoamine and opioid systems. Clinical trials show efficacy for treatment of fibromyalgia (Clauw et al. 2008; Mease et al. 2009). SNRIs produce better analgesic efficacy compared with SSRIs, even in combination with selective noradrenergic reuptake inhibitors (Jones et al. 2006).

In placebo-controlled trials, venlafaxine significantly reduced neuropathic pain following breast cancer treatment (Tasmuth et al. 2002). Venlafaxine significantly prevents migraine and decreases allodynia and hyperalgesia in both neuropathic pain and atypical facial pain (Bulut et al. 2004; Ozyalcin et al. 2005; Yucel et al. 2005). Response improved with higher doses attributable to increased reuptake inhibition of norepinephrine. In a study of painful diabetic neuropathy, 150–225 mg/day of venlafaxine produced a greater percentage reduction in pain than did 75 mg/day (50% vs. 32%) (Rowbotham et al. 2004). Duloxetine possesses analgesic efficacy in both preclinical models and clinical populations such as patients with fibromyalgia and painful diabetic neuropathy (Arnold et al. 2005; Wernicke et al. 2006). Guidelines for the treatment of neuropathic pain recommend duloxetine as an effective treatment (Argoff et al. 2006). The efficacy of duloxetine in painful diabetic neuropathy was greater in patients with more severe pain but was not related to the severity of diabetes or neuropathy (Ziegler et al. 2007). Patients with depression and painful somatic symptoms experience relief when taking duloxetine, but the analgesic effects were independent of antidepressant actions (Perahia et al. 2006).

Selective Serotonin Reuptake Inhibitors

In clinical trials, the efficacy of SSRIs in chronic pain syndromes has been inconsistent, especially in the treatment of neuropathic pain (Finnerup et al. 2005). A Cochrane review

found SSRIs no more efficacious than placebo for migraine and less efficacious than TCAs for tension-type headache (Moja et al. 2005). However, fluoxetine improved outcome measures in women with fibromyalgia and was comparable to amitriptyline in significantly reducing rheumatoid arthritis pain (Arnold et al. 2002). Citalopram improved abdominal pain in irritable bowel syndrome independent of effects on anxiety and depression (Tack et al. 2006). Patients with DSM-IV-TR pain disorder experienced significant analgesic effects, independent of changes in depression, with citalopram but not with the noradrenergic reuptake inhibitor reboxetine (Aragona et al. 2005). Paroxetine and citalopram, but not fluoxetine, decreased the pain of diabetic peripheral neuropathy in controlled studies (Goodnick 2001). Also, in a comparison study of gabapentin, paroxetine, and citalopram for painful diabetic peripheral neuropathy, patients reported better satisfaction, compliance, and mood with SSRIs with similar efficacy for pain (Giannopoulos et al. 2007). Overall, SSRIs are not recommended as a first-line therapy for chronic pain but are a recommended alternative to TCAs or SNRIs, with a favorable risk-benefit profile.

Novel Antidepressants

Few controlled trials have examined the efficacy of novel antidepressants in pain syndromes, but their pharmacology suggests antinociceptive properties. Mirtazapine decreased the duration and intensity of treatment-refractory chronic tension-type headache in a controlled trial (Bendtsen and Jensen 2004). In a controlled trial of patients with neuropathic pain, bupropion sustained-release decreased pain intensity and interference of pain with quality of life (Semenchuk et al. 2001). Although several reports suggested efficacy for trazodone in chronic pain, controlled studies did not support its use in chronic LBP (Goodkin et al. 1990).

Anticonvulsants

Anticonvulsants inhibit excessive neuronal activity by blocking voltage-gated sodium channels, modulating calcium channels, inhibiting excitatory amino acid neurotransmission, or enhancing gamma-amino acid-mediated inhibitory neurotransmission (Stefan and Feuerstein 2007). Anticonvulsants are effective for trigeminal neuralgia, diabetic neuropathy, PHN, and migraine recurrence. The number needed to treat ranges from approximately 2 to 4 for anticonvulsants, with better compliance when compared with TCAs because of fewer adverse effects (Finnerup et al. 2005).

First-Generation Anticonvulsants

Phenytoin was first reported as a successful treatment for trigeminal neuralgia in 1942 (Bergouignan 1942). Carba-

mazepine is the most widely studied anticonvulsant effective for neuropathic pain (Tanelian and Victory 1995). Valproic acid is most commonly used in the prophylaxis of migraine but is also effective for neuropathic pain. Valproate was an effective prophylactic treatment in more than two-thirds of patients with migraine and almost 75% of those with cluster headache (Gallagher et al. 2002). Improvement occurred in multiple domains of headache severity, use of other medications for acute treatment of headache, the patient's opinion of treatment, and ratings of depression and anxiety (Kaniecki 1997; Klapper 1997; Rothrock 1997).

Second-Generation Anticonvulsants

Pregabalin and gabapentin decrease the influx of calcium and modulate the release of neurotransmitters such as substance P and glutamate (Han et al. 2007; Taylor et al. 2007). They also activate the descending noradrenergic inhibitory system of nociception (Tanabe et al. 2008). Pregabalin and gabapentin are effective for the treatment of painful diabetic neuropathy, PHN, fibromyalgia, post-amputation phantom limb pain, and central neuropathic pain associated with SCI (Arezzo et al. 2008; Richter et al. 2005; Sandercock et al. 2009; Tassone et al. 2007). Patients with chronic pain were more likely to respond to gabapentin if they experienced allodynia. Pregabalin was more cost-effective than gabapentin for the treatment of painful diabetic neuropathy and PHN (Tarride et al. 2006). In patients with PHN, flexible titration strategies resulted in fewer discontinuations, higher final dose, and slightly better pain relief compared with fixed-dose schedules (Stacey et al. 2008).

Lamotrigine has multiple pharmacological actions and produced positive results for pain associated with HIV-related neuropathy and central poststroke pain but was disappointing for other neuropathic pains in a meta-analysis of controlled trials (Wiffen and Rees 2007). Doses greater than 300 mg/day with serum levels lower than 15 mg/L were more effective for the treatment of painful diabetic neuropathy (Jose et al. 2007; Vinik et al. 2007). Topiramate offers the advantages of minimal hepatic metabolism and unchanged renal excretion, few drug interactions, a long half-life, and the unusual side effect of weight loss. Topiramate was effective for migraine prophylaxis and decreased pain from chronic LBP, lumbar radiculopathy, and painful diabetic neuropathy (Keskinbora and Aydinli 2008; Muehlbacher et al. 2006; Silberstein et al. 2006; Van Passel et al. 2006).

Next-Generation Anticonvulsants

Oxcarbazepine is a carbamazepine derivative with an improved safety and tolerability profile. Oxcarbazepine for re-

fractory PHN decreased pain with rapid onset of action and improvements in function and quality of life (Nasreddine and Beydoun 2007). A randomized, placebo-controlled trial in painful diabetic neuropathy found that about 35% of the patients taking oxcarbazepine experienced greater than 50% improvement in their pain (Grosskopf et al. 2006). Tiagabine, vigabatrin, retigabine, levetiracetam, and zonisamide are new anticonvulsants with a spectrum of pharmacological actions and antinociceptive effects in animal models, but few clinical studies exist to support their use as a first-line therapy for chronic pain (Cutrer 2001; Marson et al. 1997). Variable adverse drug reactions from these agents can cause significant cognitive impairment. Tiagabine reduced pain by comparable amounts to gabapentin but resulted in significantly greater improvements in sleep quality (Todorov et al. 2005). Despite multiple mechanisms of action, zonisamide showed mixed results for the treatment of neuropathic pain (Kothare et al. 2008). Riluzole (sodium channel blocker), retigabine (potassium channel opener), ethosuximide (T-type calcium channel blocker), and levetiracetam attenuated nociceptive responses in animals (Munro et al. 2007).

Combinations of anticonvulsants with complementary mechanisms of action may increase effectiveness and decrease adverse effects of treatment. Patients with multiple sclerosis or trigeminal neuralgia who had responded to but had to discontinue treatment with carbamazepine or lamotrigine at therapeutic doses because of intolerable side effects were given gabapentin as an augmentation agent (Solorio et al. 2000). Gabapentin was successfully titrated to pain relief, with no new side effects up to a maximum dose of 1,200 mg/day, at which time either carbamazepine or lamotrigine was tapered until its side effects were no longer present without loss of analgesia. When anticonvulsants were combined with tramadol, synergistic effects were found for inhibiting allodynia and blocking nociception (Codd et al. 2008). Carbamazepine and oxcarbazepine combined with clonidine produced a synergistic antihyperalgesic effect on inflammatory pain (Vuckovic et al. 2006).

Benzodiazepines

Benzodiazepines are commonly prescribed for insomnia, anxiety, and spasticity. In patients with chronic pain, no studies found any significant benefit for these target symptoms (Taricco et al. 2000). Benzodiazepines decreased pain in only a limited number of chronic pain conditions, such as trigeminal neuralgia, tension headache, and TMD (Dellmijn and Fields 1994). Clonazepam may provide long-term relief of the episodic lancinating variety of phantom limb pain (Bartusch et al. 1996). Benzodiazepines cause sedation and cognitive impairment, especially in the elderly and other neurologically vulnerable populations (Buffett-

Jerrott and Stewart 2002). In patients with chronic pain, the use of benzodiazepines, but not opioids, was associated with decreased activity levels, higher rates of health care visits, increased domestic instability, depression, and more disability days (Ciccone et al. 2000). Combining benzodiazepines with opioids may be countertherapeutic and potentially dangerous. Benzodiazepines may exacerbate pain and interfere with opioid analgesia (Sawynok 1987). Studies of methadone-related mortality found high rates of benzodiazepine use, with the cause of death being attributed to a combination of drug effects, especially in patients with chronic pain (Darke et al. 2010; McCowan et al. 2009).

Antipsychotics

Atypical antipsychotics offer a broader therapeutic spectrum, lower rates of extrapyramidal side effects, and the potential for augmentation of antidepressants and mood stabilizers. These benefits have been offset by concerns about weight gain, new-onset diabetes, hyperlipidemias, and cardiac arrhythmias. Antipsychotics have been tried in diabetic neuropathy, PHN, headache, facial pain, pain associated with AIDS and cancer, and musculoskeletal pain, with increasing evidence to support their effectiveness (Fishbain et al. 2004). A meta-analysis of 11 controlled trials concluded that some antipsychotics have analgesic efficacy in headache (haloperidol) and trigeminal neuralgia (pimozide) (Seidel et al. 2008).

Recent trials have focused on fibromyalgia because evidence suggests that dopaminergic D₂ receptor hypersensitivity and decreased release of dopamine from the basal ganglia occur in response to pain (Wood et al. 2007). An open-label study of the addition of quetiapine to patients' existing but ineffective fibromyalgia treatment regimens did not report decreased pain but did produce significant functional improvements on the Fibromyalgia Impact Questionnaire and quality-of-life measures (Hidalgo et al. 2007). Studies of ziprasidone and olanzapine showed beneficial effects but low response rates and poor tolerability (Calandre et al. 2007; Rico-Villademoros et al. 2005). Results are difficult to interpret because of comorbid depressive, anxiety, and sleep disorders in patients with fibromyalgia that might respond to treatment with antipsychotics.

Local Anesthetics

Topical lidocaine has been approved for the treatment of PHN and does not produce significant serum levels (Argoff 2000). It is ineffective against HIV neuropathy pain (Estanislao et al. 2004). Oral mexiletine is an effective treatment for neuropathic pain in painful diabetic neuropathy, peripheral nerve injury, and alcoholic neuropathy; mixed results are reported for phantom limb, and mexiletine is ineffective for cancer-related pain (Wu et al. 2008). Mexiletine

decreased not only reports of pain but also the accompanying paresthesias and dysesthesias. Analgesic effects did not correlate with mexiletine serum levels.

Calcium Channel Blockers

Verapamil is the most commonly prescribed calcium channel blocker for chronic pain and has proven effective in the treatment of migraine and cluster headaches (Lewis and Solomon 1996). Ziconotide, a neuron-specific calcium channel blocker, has been approved for the intrathecal treatment of refractory pain of cancer or AIDS. It has potent analgesic, antihyperesthetic, and antiallodynic activity as well as synergistic analgesic effects with morphine without producing tolerance (Christo and Mazloomdoost 2008).

Psychological Treatments

Cognitive-Behavioral Models

Psychological treatment for chronic pain was pioneered by Fordyce, who used an operant conditioning behavioral model (Fordyce et al. 1973). The behavioral approach is based on an understanding of pain occurring in a social context. The behaviors of the patient with chronic pain not only reinforce the behaviors of others, including physicians, but also are reinforced by others. Pain behaviors such as grimacing, guarding, and taking pain medication are indicators of perceived pain severity and functional disability (Turk and Matyas 1992). In a study of medical practice patterns, only observed pain behaviors were predictive of whether opioid medications were prescribed to patients with chronic pain (Turk and Okifuji 1997). Other aspects of the patient's presentation to a health care practitioner, such as reports of functional disability, distress, pain severity, objective physical pathology, duration of pain, and demographic variables, were not predictive. If pain behaviors are reinforced, the behavioral model assumes pain and disability will persist. In treatment, healthy behaviors are targeted for reinforcement to replace extinguished pain behaviors.

Many psychological interventions have been effective in the reduction of pain and its associated distress (Molton et al. 2007). The cognitive-behavioral model of chronic pain assumes individual beliefs, attitudes, and expectations affect emotional and behavioral reactions to life experiences. Pain and the resultant pain behaviors are influenced by biomedical, psychological, and socioenvironmental variables. If patients believe pain, depression, and disability are inevitable and uncontrollable, then they will likely experience more negative affective responses, increased pain, and even more impaired physical and psychosocial functioning. The

components of cognitive-behavioral therapy (CBT), such as relaxation, guided imagery, biofeedback, meditation, hypnosis, motivational interviewing, external reinforcement, cognitive restructuring, and coping self-statement training, interrupt this cycle of disability. Patients are taught to become active participants in the management of their pain by using methods that minimize distressing thoughts and feelings. The goals of CBT, regardless of techniques used, focus the patient on self-control and self-management to increase activity, independence, and resourcefulness (Turk et al. 2008). Outcome studies of CBT in patients with a variety of chronic pain syndromes have shown significant improvements in pain intensity, pain behaviors, distress, depression, and coping (Eccleston et al. 2009; Turk et al. 2008). The benefits of CBT have been found to continue up to 6 months after the completion of active treatment sessions.

Beliefs

The success of CBT in chronic pain treatment has led to focused attention on many elements of the chronic pain experience, including concepts such as *psychological resilience* and *illness adaptation* (Karoly and Ruehlman 2006). *Adjustment* is defined as the ability to carry out normal physical and psychosocial activities. Three dimensions of adjustment have been defined: social functioning, morale, and somatic health (Lazarus and Folkman 1984). Examples of these domains include pain intensity, medication use, depression, anxiety, employment, health care use, and functional ability.

Beliefs are conceptualized as the thoughts of an individual about his or her personal pain problem (Morley and Wilkinson 1995). Psychosocial dysfunction has been correlated with receiving overly solicitous responses from family, believing emotions are related to pain, and attributing the inability to function to pain (M.P. Jensen et al. 1994b). In contrast, although physical disability was correlated with beliefs about pain interfering with function, patients also endorsed the belief that pain signifies injury, and, therefore, activity should be avoided. A change in perceived control over pain was the most significant predictor of beneficial effects of cognitive-behavioral therapies for chronic TMD pain (Turner et al. 2007).

Cognitive variables derived from social learning theory associated with chronic pain include self-efficacy, outcome expectancies, and locus of control (Solberg et al. 2009). A self-efficacy expectancy is a belief about one's ability to perform a specific behavior, whereas an outcome expectancy is a belief about the consequences of performing a behavior. Individuals are considered more likely to engage in coping efforts they believe are within their capabilities and will result in a positive outcome. Patients with a

variety of chronic pain syndromes who score higher on measures of self-efficacy or have an internal locus of control report lower levels of pain, higher pain thresholds, increased exercise performance, and more positive coping efforts. Interestingly, physician expectations of pain relief were significant predictors of patient pain relief ratings, which supports the important role of other persons in an individual's chronic pain experience.

Acceptance of chronic pain is a two-factor construct (Activity Engagement, Pain Willingness) associated with multiple domains of the experience of chronic pain. Acceptance of pain was found to be associated with reports of lower pain intensity, less pain-related anxiety and avoidance, less depression, less physical and psychosocial disability, more daily uptime, and better work status (McCracken 1998). Acceptance has been found to mediate the effects of catastrophizing on depression, avoidance, and functioning in patients with chronic pain (Vowles et al. 2008). One's acceptance of chronic pain predicts his or her adjustment to the illness and is independent of catastrophizing, coping skills, and pain-related beliefs and cognitions (Esteve et al. 2007; Vowles et al. 2007).

Coping

Coping is "a person's cognitive and behavioral efforts to manage the internal and external demands of the person-environment transaction that is appraised as taxing or exceeding the person's resources" (Folkman et al. 1986, p. 571). Coping strategies, whether active versus passive or adaptive versus maladaptive, generally support the cognitive-behavioral model of chronic pain (M.P. Jensen 2009). Higher levels of disability were found in persons who remain passive or use maladaptive coping strategies of catastrophizing, ignoring or reinterpreting pain sensations, diverting attention from pain, and praying or hoping for relief. In a 6-month follow-up study of patients completing an inpatient pain program, improvement was associated with decreases in the use of passive coping strategies and changing beliefs about pain being an incurable illness (M.P. Jensen et al. 1994a).

The effectiveness of particular coping strategies with improved adjustment to chronic pain is dependent on many aspects of a patient's experience with illness. For example, reinterpreting pain sensations as not being signs of ongoing injury typically has been formulated as useful for reducing the effects of experimentally induced pain. However, in a study of amputees with phantom limb pain, this coping strategy was not associated with reduced pain levels but instead with greater psychosocial dysfunction (Hill et al. 1995). Attempting to reinterpret pain sensations may not always be an appropriate technique for individuals with persistent pain because it requires greater amounts of

time spent focusing on pain and disability. This may prevent patients from engaging in social activities and healthy behaviors. Catastrophic thinking about pain involves the amplification of threatening information and interference with the attentional focus needed to facilitate patients remaining involved with productive instead of pain-related activities (Crombez et al. 1998). In one study, high levels of catastrophizing combined with lower levels of active pain coping predicted higher levels of depressive symptoms and disability (Buenaver et al. 2008). The use of adaptive coping skills decreased pain and disability when patients perceived an increase in the effectiveness of their new skills and reduced their use of maladaptive coping strategies such as catastrophic thinking.

Placebo Response

Placebo effects and patient responses to them are complex phenomena but similar to those of active treatments (Kleinman et al. 1994; Turner et al. 1994). The literature supporting the placebo effect has been criticized as flawed, misinterpreted, and overrated (Kienle and Kienle 1997). Placebo analgesia is a biologically measurable phenomenon (Greene et al. 2009). In a clinical setting, it is difficult to separate "true" improvements from placebo responses to treatment and other factors such as regression to the mean and the natural history of the condition. Multiple patient and practitioner characteristics such as expectancy, conditioning, and learning affect the placebo response, and most are almost impossible to control (Ploghaus et al. 2003; Price et al. 1999). Evidence supports a role for the endogenous opioid and sympathetic nervous systems in placebo-induced analgesia that can be reversed with opioid antagonists (Pollo et al. 2003; ter Riet et al. 1998).

Historically, on the basis of Beecher's original article, placebo interventions were a part of paternalistic medicine's treatment armamentarium (Kaptchuk 1998). In the era of randomized controlled trials, placebos may be used if the cooperation of informed patients is secured. The magnitude of placebo analgesic effects was found to be significantly higher in studies that specifically investigated placebo analgesic mechanisms compared with those controlled trials that simply used a placebo for comparison (Vase et al. 2002). Several important strategies can be used to decrease excessive placebo responses in clinical trials (Dworkin et al. 2005). However, controversy exists about the evidence of clinically important effects to justify the use of placebo interventions (Hrobjartsson and Gotzsche 2003). Use of placebo to determine whether the patient's pain is "real" or to "cure" a psychogenic condition by replacing an analgesic with a "neutral" substance is dishonest, misleading, and counterproductive. A positive placebo response neither proves that the patient's pain is psy-

chogenic nor shows that the patient would not benefit from an active treatment. Such an intervention also can result in loss of the patient's trust and render future treatment less effective.

Interdisciplinary Rehabilitation

Patients with chronic pain have dramatic reductions in physical, psychological, and social well-being with lower-rated health-related quality of life than do those with almost all other medical conditions (O'Connor 2009). A study of sequential trials of different treatment modalities found that the success of nerve blocks was diminished when used later in the treatment sequence. These results suggest that early failures of a single-modality treatment for chronic pain can have devastating consequences for future treatment attempts (Davies et al. 1997). In another study of more than 3,000 patients with low back or neuropathic pain, wide variations in medical practice decreased significantly after the practitioners received information that updated them about treatment modalities being used in the clinic and other available options (Davies et al. 1996). Education programs led by laypeople have produced short-term gains in self-efficacy, cognitive symptom management, and frequency of exercise (Foster et al. 2007). Collaborative care initiatives incorporating pain specialist assistance to primary care practitioners significantly improved pain-related outcomes (Dobscha et al. 2009).

Self-management programs for elderly people with chronic pain show significant reductions in pain intensity and disability (Morrison et al. 2009; Reid et al. 2008). Evidence-based practice guidelines emphasize interdisciplinary rehabilitation, integrated treatment, and well-delineated patient selection criteria (Sanders et al. 2005). The interdisciplinary pain rehabilitation program provides a full range of treatments for the most difficult pain syndromes within a framework of collaborative ongoing communication among team members, patients, and other interested parties (Stanos and Houle 2006). Unfortunately, the type of practitioners and scope of practice of "multidisciplinary" pain clinics vary considerably (Peng et al. 2008a). A recent survey in North Carolina found that only 7% of these clinics met the criteria of having a medical physician, registered nurse, physical therapist, and mental health specialist (Castel et al. 2009).

Substantial evidence indicates that interdisciplinary pain rehabilitation programs improve patient functioning in several areas for patients with various chronic pain syndromes, even the severely disabled (Angst et al. 2006; Lake et al. 2009; McCracken et al. 2007; van Wilgen et al. 2009). In a seminal review, a meta-analysis of 65 studies evaluated the efficacy of treatments in patients who attended multidisciplinary pain clinics (Flor et al. 1992). Although the

study had limitations, it concluded that multidisciplinary pain clinics are efficacious. Combination treatments were superior to unimodal treatments or no treatment, treatment effects were maintained over a period of up to 7 years, and improvements were found not only on subjective but also on objective measures of effectiveness such as return to work and decreased health care use. Current smoking status has been associated with poorer treatment outcome from multidisciplinary treatment, suggesting that these patients should receive targeted or more intensive treatments (Fishbain et al. 2008b). More recent analyses of interdisciplinary programs that use comprehensive assessments, severity-adapted or stepped-care treatments, and rehabilitation goals report significant reductions in pain along with functional and quality-of-life improvements (Kainz et al. 2006; Marnitz et al. 2008).

The goal of treating chronic pain is to end disability and return people to work or other productive activities. Multidisciplinary interventions do show efficacy in returning patients to work (Norlund et al. 2009). In a long-term follow-up study, only half of the patients remained unemployed after treatment in an inpatient pain management program (Maruta et al. 1998). In a 30-month follow-up study of patients with chronic pain receiving multidisciplinary treatment, employment status was predicted by the patient's desire to return to work, the perception of a job's dangerousness, and the patient's education level (Fishbain et al. 1997). Patients not intending to return to work were more likely to complain of their job's excessive physical demands and reported more job dissatisfaction and feelings of disability. *Individualized subjective quality of life* is defined as the appraisal of quality of life based on personal values, desired goal attainment, and life priorities (Moliner et al. 2007). Poorer individualized subjective quality of life was not predicted by work status but by higher levels of distress, pain intensity, and perceived disability.

Conclusion

Chronic pain is a significant public health problem and frustrating to everyone affected by it, especially the patients who feel that health care has failed them. Psychiatrists as medical specialists should take an active role in the care of these patients because pharmacological and psychological treatments are now recognized as effective in the management of chronic pain. Recent advances in the treatment of chronic pain include the diagnosis and treatment of psychiatric comorbidity, the application of psychiatric treatments to chronic pain, and the development of interdisciplinary efforts to provide comprehensive health care to the patient with disabling and refractory chronic pain syndromes. Specifically, the psychiatrist provides the

expertise of examining mental life and behavior as well as understanding the individual person and the systems in which he or she interacts. Finally, psychiatrists can facilitate the integration of the delivery of medical care with other health care professionals and medical specialists.

Medical Toxicology

J. J. Rasimas, M.D., Ph.D.

TOXICOLOGY IS THE CLINICAL SPECIALTY dedicated to caring for illnesses induced by exposure to exogenous compounds. At the intersection of psychiatry and toxicology are several types of conditions, including deliberate overdoses, surreptitious ingestions, accidental poisonings, environmental or occupational exposures to toxins causing neuropsychiatric symptoms, delirium, adverse drug reactions and interactions, and illnesses that represent feared or imagined toxic exposures. Formal toxicology education in the training of psychiatrists is rare (Ingels et al. 2003). This chapter focuses on the presentation, evaluation, and treatment of toxicology patients with particular relevance to psychiatric practice.

As observed by Paracelsus, the first scientist of toxicology, any substance can be a medicine or a poison, depending upon the dose (Deichmann et al. 1986). With very few exceptions, minimal exposures rarely produce progressive or persistent deficits. The level of medical acuity in toxic exposures can vary widely. The effects of toxins may be delayed after exposure, abruptly appearing and progressing. This means that a diagnosis of poisoning may not be obvious upon initial presentation, and seemingly stable patients may suddenly deteriorate and succumb to seizures, arrhythmias, or refractory hypotension (Donovan et al. 2005). Therefore, psychiatrists need to know enough toxicology to make their own assessments, rather than always relying upon another physician's determination that a patient is "medically clear."

Since the brain is the organ most commonly affected by acute poisoning, any patient whose behavior, level of consciousness, or cognition is acutely disturbed should prompt concerns about toxicity (Flomenbaum et al. 2006; Maldonado 2008). Barriers to recognition of a toxic exposure include lack of awareness, deception by patients after intentional ingestion, physicians' failure to consider iatrogenic

toxicity, and manifestations of the toxic exposure itself. The most important diagnostic factor in uncovering a toxic etiology is the clinician's consideration of its possibility.

Toxicology in Psychiatric Practice

The psychosomatic medicine physician is likely to encounter three categories of patients with possible toxic exposures, requiring different approaches:

1. The acutely presenting toxic patient, most often with a purposeful ingestion (the suicidal patient)
2. The neurobehaviorally disturbed hospital patient, sometimes with a mental illness history, whose symptoms may be toxically mediated
3. The subacutely or chronically afflicted outpatient about whom there is a question of toxin exposure versus somatoform illness

Nearly 20% of Americans who die by their own hand accomplish suicide by ingesting toxic substances (Miniño et al. 2007). If an individual remains acutely suicidal after an overdose, the medical setting must be a secure environment with close observation. A patient whose intentional ingestion does not result in a substantial change in mental status and/or level of consciousness may be at high risk due to ongoing self-injurious urges from unmodulated psychiatric distress. Repeat deliberate self-poisoning is quite common after an index medical encounter has ended; 4.5% of overdose patients present to the hospital again within a month, 10% within 6 months, and 14% within 1 year (Carter et al. 1999). In addition, prospective longitudinal research suggests that mortality rates specific to suicide in those with an episode of deliberate self-poisoning are over 10% within 10 years (Nordentoft et al. 1993). General principles in the psy-

chiatric management of the suicidal patient in medical settings are discussed in Chapter 9, "Suicidality."

A number of studies have highlighted the unreliability of patients' reports regarding the identities and amounts of what they ingest in overdose, although stated times of ingestion are typically more accurate and can help to guide management (Pohjola-Sintonen et al. 2000). Cognitive disorders can introduce additional complications, increasing the risk for medication errors that may lead to self-poisoning (irrespective of intent) and interfering with communication of a reliable history to inform toxicological care. The subjective data in any case must therefore always be considered in light of the vital signs, objective physical findings, and laboratory results, all of which more accurately tell the tale of pharmacological misadventure. A short period of observation for a minimally symptomatic patient may be sufficient, but some substances—including extended-release, anticholinergic, and opioid medications—can produce delayed and/or prolonged toxicity.

Physical Examination

Clues evident on physical examination can be particularly helpful in identifying possible overdose or toxin exposure. The most common early presentations of drug toxicity involve gastrointestinal tract symptoms and central/autonomic nervous system effects. Withdrawal states manifest in these physiological systems as well—opioids with a clear-thinking, self-limited though uncomfortable syndrome and alcohol or sedatives with potentially life-threatening hemodynamic changes and delirium. Nystagmus is a non-

specific physical finding, but its new onset strongly suggests a toxic process. Although much attention is paid to examination of the pupils, size and reactivity are highly variable, except in opioid toxicity when they are almost always miotic. Cutaneous abnormalities may suggest specific toxins or indicate intravenous drug use. Unusual odors of the patient's breath, skin, clothing, vomitus, or nasogastric aspirate may also provide useful diagnostic clues (Table 37-1) (Goldfrank et al. 1992). The absence of such odors, however, should not be taken as evidence that suspected agents are not present.

Laboratory Testing

Patients in whom purposeful ingestion is suspected or known will frequently have specific testing for acetaminophen and salicylate levels, because these are readily available, potentially lethal, frequently coingested drugs with nonspecific clinical presentations, and test results can be obtained rapidly to guide management (Hepler et al. 1986). Many other serum levels can be ordered, but intervention is typically required well before the results of quantitative testing become available (Boehnert and Lovejoy 1985).

Abnormalities in conventional laboratory tests such as electrolytes, renal functions, and blood gas analysis can point to specific ingestions. Metabolic acidosis with an increased anion gap suggests the ingestion of methanol, ethylene glycol, paraldehyde, toluene, iron, isoniazid, nonsteroidal anti-inflammatory drugs (NSAIDs), or salicylates. The latter often produces a mixed acid-base picture, with

TABLE 37-1. Selected odors from toxic exposures

Characteristic odor	Possible intoxicant
Bitter almonds/sweaty locker room	Cyanide
Burned rope	Cannabis, opium
Carrots	Water hemlock (cicutoxin)
Fruity	Ethanol, acetone, isopropyl alcohol, paraldehyde, nitrites, chlorinated hydrocarbons (e.g., chloroform)
Garlic	Arsenic, dimethyl sulfoxide (DMSO), organophosphates, white phosphorus, selenium, thallium
Glue	Toluene, organic solvents
Mothballs	Paradichlorobenzene, naphthalene, camphor
Acrid/pearlike	Chloral hydrate, paraldehyde
Violets	Turpentine (metabolites in the urine)
Rotten eggs	Disulfiram, hydrogen sulfide, sulfa drugs, stibine
Shoe polish	Nitrobenzene
Wintergreen	Methyl salicylate

coexisting respiratory alkalosis, as well. An elevated measured serum osmolality compared with a calculated osmolality (i.e., osmolar gap) indicates the presence of low-molecular-weight osmotically active compounds, such as ethylene glycol, methanol, and isopropanol. Hypoglycemia is common in patients poisoned with these toxic alcohols and by isoniazid, acetaminophen, salicylates, propranolol, valproic acid, and sulfonylureas. Serum aminotransferase levels are useful, since they will be elevated in most cases of hepatotoxicity caused by medications; and liver function is crucial in the metabolism of so many compounds. Rhabdomyolysis, indicated by elevated serum creatine phosphokinase and myoglobinuria, may be due to prolonged immobility after any overdose with central nervous system (CNS) depressive effects, but it is also caused directly by compounds that produce muscle rigidity and/or seizures (e.g., strychnine, antipsychotics, antidepressants, lithium, stimulants).

Decreased oxygen saturation of hemoglobin with a normal or increased arterial oxygen partial pressure is found in patients with carbon monoxide poisoning or in methemoglobinemia, which can be caused by metoclopramide, phenacetin, nitroglycerin, topical anesthetics, and some antimicrobials like dapsone. Noncardiogenic pulmonary edema on a chest radiograph suggests opioid or salicylate toxicity. Some drugs are radiopaque (e.g., heavy metals, phenothiazines, potassium, calcium, chlorinated hydrocarbons) and can occasionally be visualized within the gastrointestinal tract on roentgenography, but abdominal X rays are rarely helpful in the evaluation of a poisoned patient except to monitor the decontamination of metals or body packets (Craig 2001).

Toxicological Testing

In some cases, a detailed history, physical examination, and targeted laboratory studies still leave the specifics of a poisoning concealed. Toxicology testing may be helpful in confirming the clinical diagnosis. However, identifying all available toxins with a high degree of specificity and sensitivity is impossible due to limitations of time and expense. Instead, drug screening is sometimes performed. Standard urine drug screening is conducted using immunoassay techniques, offering the advantage of rapid turnaround time with detection of some commonly used and abused compounds. Urine screening utility is limited by relatively high false-negative and false-positive rates.

Comprehensive toxicology screening detects a wide range of analgesics, narcotics, psychotropics, and various other drugs, also by immunoassay, but takes time to complete. Available tests vary between and among institutions. The best chance to detect an unknown toxin is usually via assay of the urine where drugs are excreted in concentrated

form; testing concurrently drawn blood can be useful for quantitation to correlate drug levels with the clinical picture. It is important to note that negative results of comprehensive testing do not rule out a toxic state, because even many commonly ingested agents cannot be assayed and because the gathering of bodily fluids may be mistimed. Even true-positive tests can be misleading, since drugs found on screening may not be those responsible for the patient's symptoms (Donovan et al. 2005; Montague et al. 2001). Substances with a large volume of distribution and/or high fat solubility can be detected in urine for a long time after the last dose, but the clinical presentation may not be the result of those compounds. The history and physical examination (including an account of all available and administered medications before and during hospitalization) are therefore far more important in the acute management of drug toxicity than is a comprehensive drug screen (Pohjola-Sintonen et al. 2000). Toxicology screening may in fact be more useful in the outpatient setting when chronic exposure is suspected and symptoms are less severe, rather than in the acute hospital where the demand for intervention does not allow time for assay (Rainey 2006).

Principles of Acute Exposure Management

The three main goals in the acute phase of toxicological treatment are preventing further drug absorption, providing antidotal therapy, and hastening the elimination of an absorbed poison. Sometimes, toxic effects on patients' behavior can interfere with these goals. Rapid sedation with benzodiazepines can protect against injury, prevent seizures, and allow vital medical interventions to proceed. Antipsychotics are effective as well (Battaglia 2005), but their potential for more adverse effects or interactions with unknown ingestants (e.g., precipitation of seizures, induction of arrhythmias) requires caution in their use (Martel et al. 2005; Olson 2007). If information is available to confirm the specifics of the poisoning and if comorbid conditions and/or toxicities do not preclude its safe use, direct antidote therapy should be instituted immediately. A list of antidotes for selected known exposures is provided in Table 37-2. Guidance from a medical toxicologist or poison control is needed regarding these therapies, since their use is not required in all cases, and some carry risk of adverse effects. Poison control centers and medical toxicologists can provide specific recommendations, especially for more esoteric or unfamiliar poisons and for management of multidrug ingestions with complex clinical courses.

Except for specific lifesaving antidotes against certain toxins, many poisoned patients require only recognition

TABLE 37-2. Emergency antidotes for selected ingestions

Toxin	Antidote
Acetaminophen	<i>N</i> -acetylcysteine (NAC)
Anticholinergics	Physostigmine
Benzodiazepines and nonbenzodiazepine hypnotics	Flumazenil
Beta-adrenergic blockers	Glucagon
Calcium channel blockers	Calcium, insulin + glucose
Cyanide, hydrogen sulfide	Sodium thiosulfate, hydroxocobalamin
Digitalis glycosides	Digoxin immune fab
Ethylene glycol, methanol	Fomepizole (preferred over ethanol)
Iron	Deferoxamine
Lead	Dimercaprol (BAL), calcium disodium versenate (CaNa ₂ EDTA), succimer (DMSA)
Opioids, alpha ₂ agonists	Naloxone, nalmefene
Organophosphates and carbamates	Atropine, pralidoxime
Sulfonylureas	Octreotide
Valproic acid	L-Carnitine

Note. BAL = British anti-Lewisite (2,3-dimercaptopropanol); DMSA = dimercaptosuccinic acid; EDTA = ethylenediaminetetraacetic acid.

and removal of the offending agent with supportive therapy. A standard historical home remedy was gastric emptying by induction of emesis with ipecac. However, ipecac can sensitize the myocardium to arrhythmogenic effects of other ingested substances and also perpetuate bulimic behavior, so it is no longer recommended (American Academy of Pediatrics 2003). Inducing emesis does not improve toxin retrieval significantly when used in the emergency department and may delay the effective use of more beneficial treatments such as activated charcoal and specific antidotes (Kulig et al. 1985).

Activated charcoal minimizes the gastrointestinal absorption of many toxins by adsorptive binding, producing better toxin recovery and fewer complications than emesis or gastric lavage. Therefore, it should be considered as the primary means of decontamination in most overdoses (Albertson et al. 1989). It is not recommended for ingestions of agents that do not adsorb to charcoal, including ions, solvents, alcohols, and most metals (Table 37-3).

Activated charcoal may be beneficial if given early after an ingestion (most effective within an hour) or for drugs that have delayed absorption, including aspirin, anticholinergics, opioids, sustained-release medications, or drug packets in "body stuffers." For patients who present hours after ingestion, charcoal is usually ineffective. Further-

Bromides

more, charcoal aspiration can occur, causing bronchospasm and pneumonitis (Givens et al. 1992). Its use should therefore be limited to conscious patients with an intact gag reflex, unless airway protection is insured via intubation before nasogastric administration in obtunded patients (Chyka et al. 2005). Activated charcoal in multiple doses enhances the serum clearance of certain medications

(Table 37-4), taking advantage of enterohepatic recirculation and adsorption of drugs across the gastrointestinal mucosa (Howland 2006).

Gastric decontamination does not generally improve outcomes in overdose patients, even though it is frequently performed (Bond 2002). Whole-bowel irrigation with a polyethylene glycol solution may be useful in certain cases of massive, recent ingestion of medications with sustained release and delayed absorption, such as some calcium channel antagonists and enteric-coated aspirin. It can aid in the clearance of other toxins, like lead or lithium, which are not well adsorbed by activated charcoal. Whole-bowel irrigation has also been used to aid in the evacuation of large pill fragments and drug packets from “body packers” (Tenenbein 1997).

Gastric lavage with the aim of removing unabsorbed compounds is rarely indicated and should be considered only when a patient is seen less than an hour after ingesting a highly toxic substance (e.g., calcium channel blocker, tricyclic antidepressant [TCA]) and/or one that delays gastric emptying (e.g., opioid, anticholinergic) or forms concretions (Vale and Kulig 2004). It is contraindicated in alkali ingestions because of the increased risk for esophageal perforation. Some studies have shown an increase in adverse outcomes with the use of gastric lavage, including aspiration pneumonitis and prolonged intensive care (Merigian et al. 1990). Given the uncertain benefits of gastric lavage, patients who are otherwise asymptomatic should not be sedated and intubated for the sole purpose of performing this procedure (Vale and Kulig 2004). In general, decontamination procedures should only be used when an ingestion is recent and potentially life-threatening and when such procedures can be performed without undue risk.

For enhancing the elimination of an absorbed poison, the available procedures that have the greatest value are manipulation of urine pH, dialysis, and hemoperfusion. These methods, too, should be used only when the danger of the persisting poison likely exceeds that of removing it and when the method is known to be effective for that toxin.

For alteration of urinary pH to be effective in hastening elimination, the toxin must be excreted primarily by the kidneys. Diuresis does little to clear compounds that are highly protein-bound, highly lipid-soluble, or hepatically excreted. Alkalinization of the urine enhances excretion of weak acid compounds ($3.0 < \text{pK} < 7.2$), aspirin and phenobarbital being the most commonly overdosed drugs in this category. Elevation of urine pH is accomplished by adding sodium bicarbonate to intravenous fluids. In theory, weak bases ($7.2 < \text{pK} < 9.8$) like phencyclidine and amphetamine can be eliminated more rapidly in acidified urine, but this course is almost never recommended. Acidosis (metabolic or respiratory) frequently accompanies

TABLE 37-4. Toxins with enhanced elimination by multiple-dose activated charcoal

Valproic acid and other anticonvulsants (phenobarbital, carbamazepine, phenytoin)

Tricyclic antidepressants
Phenothiazines

severe overdoses, and therefore treatment with acidifying compounds risks worsening the clinical course (Olson 2007), especially in patients with underlying kidney or liver disease (Fortenberry and Mariscalco 2006).

In the setting of impaired renal function or overwhelming intoxication, hemodialysis or hemoperfusion may effectively remove drugs that are poorly protein-bound, are highly water-soluble, and have a low volume of distribution (Table 37-5). Lithium ions and small molecules such as methanol, ethylene glycol, salicylates, and phenobarbital rapidly diffuse across synthetic membranes and are therefore removed effectively by hemodialysis. Hypotension, hemolysis, hypoxemia, and arrhythmias can result from the procedure.

Hemoperfusion has been shown to be a very effective method of extracting some drugs, including barbiturates, TCAs, theophylline, and aspirin. The facilities and skills necessary for hemoperfusion are essentially the same as those needed to perform hemodialysis. Complications include hypotension, thrombocytopenia, hypothermia, and hypocalcemia (Cutler et al. 1987); these risks often outweigh therapeutic benefits of the procedure.

Overdoses and Toxic Exposures

What follows is a survey of common overdoses and exposures not primarily involving psychotropic compounds; the reader is referred to Chapters 38 ("Psychopharmacology") and 17 ("Substance-Related Disorders") and to the "Toxicodromes" section later in this chapter for information regarding psychotropic medication and illicit drug toxicities.

Acetaminophen

Acetaminophen is the pharmaceutical most frequently involved in overdose, both readily available and potentially lethal. Of the 2,054 reported deaths resulting from pharmaceutical substances in 2003, 327 (16%) were attributed to acetaminophen either singly or in combination with other agents (Watson et al. 2004). Over half of the cases of toxicity are reported in patients under 20 years of age, but very few deaths occur in children. Accidental poisoning is more common in young children and in the elderly, whereas almost all adolescents and adults with acute acetaminophen toxicity have intentionally harmed themselves. An acute overdose of as little as 15 g can cause toxicity in adults, and a single ingestion of 200 mg/kg can bring serious harm to children. The analgesic is regularly sold in amounts far in excess of these thresholds. In 1998, the United Kingdom took measures to limit its nonprescription availability, and since the requirement for limited sale of acetaminophen (there, paracetamol) in small blister packs, severity of overdoses and liver transplant rates secondary to overdose have fallen (Hawkins et al. 2007).

Hepatotoxicity is the primary concern and the target for medical intervention. Following oral ingestion, approximately 94% of the drug is metabolized to the glucuronide or sulfate conjugate, and about 2% is excreted unchanged in the urine. Neither the parent drug, nor the conjugated forms are hepatotoxic. The remaining 4%, however, is metabolized primarily through cytochrome P450 (CYP) 2E1 and, to some extent, CYP3A4, to form a toxic metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI). After therapeutic dosing, any NAPQI formed is conjugated with normal hepatic stores of glutathione (GSH) to produce the nontoxic mercapturic acid, which is excreted in the urine. In the setting of a significant overdose, CYP2E1 metabolizes more acetaminophen, large amounts of NAPQI are formed, and the pool of GSH is rapidly depleted. Direct effects of excess NAPQI and liver failure can impact the function of other organ systems including kidneys, pancreas, and CNS.

Clinically, patients present with diaphoresis, nausea, vomiting, and malaise within 24 hours of acute ingestion. Despite evolving liver injury as reflected by elevations in hepatocellular enzymes and prolongation of prothrombin time, there can be a window of time when patients look and

feel better. If they present for care at this stage, and clinicians fail to consider acetaminophen overdose because of the patient's benign appearance, the consequences can be fatal. Coagulation status declines and transaminase levels can exceed 10,000 IU/L before metabolic acidosis, jaundice, and encephalopathy herald fulminant hepatic failure.

Hence, it is vital to quickly identify patients with significant acetaminophen overdose and institute the antidote *N*-acetylcysteine (NAC) without delay. NAC repletes GSH stores to detoxify NAPQI and works as an antioxidant to prevent evolving toxicity until nondamaging metabolic pathways clear the parent drug. The need for treatment after a single overdose can be calculated based on a timed plasma acetaminophen level drawn at least 4 hours after ingestion (Rumack and Matthew 1975).

NAC can be administered either orally/intragastrically or intravenously. No studies have demonstrated the superiority of one particular route, but the intravenous route is more tolerable since the oral agent is highly distasteful and emetogenic (Perry and Shannon 1998). Furthermore, nearly 50% of patients have repetitive vomiting after a serious acetaminophen ingestion, so the intravenous route is certainly preferred to ensure delivery. For a patient who has ingested a potentially toxic amount of acetaminophen and in whom an acetaminophen level cannot be obtained within 8 hours after the ingestion, a loading dose of NAC should be administered immediately (Heard 2008). The same is true for cases of repeat or chronic overdosing. If the acetaminophen level then returns in the nontoxic range and transaminases are normal, the antidote is stopped. Even after 24 hours from the time of ingestion, late administration of NAC has been shown to be of some benefit and should not be withheld if there is evidence of hepatic injury (Tucker 1998). A pregnant woman should be administered a loading dose of NAC as soon as possible, regardless of the time since overdose, because potential exists for fetal toxicity after maternal overdose, and fetal demise has been correlated with treatment delay.

Poor prognostic factors generally relate to propensity of a given individual to produce more of the toxic acetaminophen metabolite or to be less able to withstand its oxidative effects. Advanced age, states of malnutrition (e.g., anorexia nervosa), and active liver disease predispose patients to greater toxicity. Obesity is correlated with higher levels of CYP2E1 activity. Chronic alcohol use also induces CYP2E1 and depletes GSH stores, thus increasing the possibility of a poorer outcome. Alcohol coingestion at the time of overdose, however, can be slightly protective, since ethanol competes with acetaminophen for CYP2E1, thus decreasing production of the toxic NAPQI.

Once NAC treatment is complete, if the patient is asymptomatic and transaminase levels and liver function

tests return to normal, the patient can be discharged to the appropriate psychiatric disposition.

Salicylates

Toxicity from aspirin and other salicylates (found in literally hundreds of medicinal agents) is also a significant source of morbidity and mortality. Child-resistant packaging has decreased the incidence of aspirin ingestion in children, but intentional overdoses of this ubiquitous analgesic still result in adolescent and adult deaths. The diagnosis of salicylism is often delayed because its symptoms of fever, vomiting, and tachypnea may be attributed to the disease process for which the salicylate is used therapeutically.

Aspirin is absorbed rapidly from the upper small intestine under normal circumstances. In the setting of overdose, absorption is slowed, and salicylate serum concentrations can increase for more than 24 hours after ingestion. At therapeutic doses, most salicylate is bound to plasma proteins, but in overdose, the amount of non-protein-bound drug increases, which increases the potential for significant toxicity. Conditions that deplete albumin and other proteins (e.g., anorexia nervosa) predispose patients to a disproportionate risk of toxicity at a given plasma concentration (Alv  n et al. 1981). Salicylates are eliminated primarily through the kidneys via both glomerular filtration and tubular secretion.

The toxic pathophysiology of salicylism is complex. Acute overdose, particularly in children, produces nausea and vomiting, which can cause metabolic alkalosis. Metabolic acidosis subsequently results from several systemic effects of salicylates. Salicylates also produce hyperventilation secondary to direct stimulation of the CNS respiratory center leading to respiratory alkalosis; unexplained hyperpnea should raise suspicion for aspirin overdose and not merely be attributed to anxiety. The classic acid–base presentation is a mixed one of anion-gap metabolic acidosis with a slight alkalemia driven by respiratory alkalosis (Gabbow et al. 1978). Severe dehydration, electrolyte disturbances, and significant glycemic shifts can occur with salicylate toxicity, as well.

The usual symptoms of acute toxicity include tinnitus, nausea, vomiting, dehydration, hyperpnea, hyperpyrexia, acute tubular necrosis, and oliguria, with progression to delirium, seizures, and coma. Other less common findings include bleeding, hemolysis, pulmonary edema, bronchospasm, and anaphylaxis. Reversible ototoxicity is directly related to unbound serum salicylate concentration. The onset of symptoms usually occurs within 1–2 hours of an acute ingestion, but may be delayed 4–6 hours due to sustained-release preparations, pylorospasm, or formation of gastric concretions.

There is no direct antidote for salicylates, so management is aimed at preventing further absorption and increasing elimination, including activated charcoal and fluid resuscitation with sodium bicarbonate solutions to promote alkaline diuresis (Proudfoot et al. 2004). Plasma salicylate levels should be drawn every 2 to 4 hours until they are clearly decreasing. In severe cases, hemodialysis should be considered. Most salicylate-poisoned patients survive with minimal sequelae (Stolbach et al. 2008).

Nonsteroidal Anti-Inflammatory Drugs

Although much less toxic than salicylates, other NSAIDs are even more widely used in nonprescription products and therefore more frequently encountered in recent cases of suicidal ingestion. Ibuprofen, naproxen, and ketoprofen exert both therapeutic and toxic effects through competitive, reversible inhibition of type I cyclooxygenase. Enzymatic selectivity with the type II cyclooxygenase inhibitors (celecoxib, meloxicam, rofecoxib, and valdecoxib) is lost at extremely high doses, so these agents can produce a similar toxic presentation in massive overdose.

After an acute ingestion, gastrointestinal distress in the form of epigastric pain, nausea, and vomiting is virtually always present, and its absence makes toxicity unlikely (Hall et al. 1988). Metabolic acidosis with an elevated anion gap is common. In very large overdoses, confusion and depressed level of consciousness with progression to seizures, coma, and death can result (Halpern et al. 1993). Activated charcoal effectively binds NSAIDs. In addition to supportive measures, aggressive intravenous fluid therapy is indicated to more rapidly eliminate the drug, resolve acidosis, and protect the kidneys from acute damage. Unless complications develop from CNS depression, most patients poisoned with NSAIDs survive without long-term consequences.

Carbon Monoxide

Carbon monoxide (CO) is a toxic gas that is essentially undetectable by human sensory modalities. Sources of exposure include automobile exhaust, smoke from fires, fuel stoves, and, to a lesser extent, cigarette smoke. Purposeful exposure to exhaust fumes or burning charcoal is a particularly lethal suicide method from which only a fraction of attempters are rescued. In fact, carbon monoxide is the leading cause of poisoning morbidity and mortality in the United States, with most events being the result of intentional acts involving car exhaust (Mott et al. 2002). The toxin binds to hemoglobin with 250 times greater affinity than oxygen, thereby markedly reducing tissue oxygen delivery. Most patients experience nausea, headache, and dizziness. Psychosis, depression, mutism, amnesia, and delirium

have all been reported as presenting symptoms. Syncope and coma follow more severe exposures. Cardiovascular toxicity progresses from dyspnea and angina to hypotension, myocardial infarction, and potentially lethal arrhythmia.

When a patient is thwarted in the midst of a suicide attempt, CO poisoning may be obvious. With a mild presentation in the absence of such a history, diagnosis can be challenging. Very few patients actually display classic cherry-red skin; most appear “shocky” and gray. Routine blood gas analysis and pulse oximetry fail to identify poisoning despite profound systemic hypoxia. Serum carboxyhemoglobin concentration is diagnostic and helps to guide therapy; it should be assayed without delay in any overdose patient found in a vehicle. Treatment with 100% oxygen is critically important, as it helps to address hypoxia and enhance elimination of the toxic gas. Hyperbaric oxygenation further speeds elimination of CO and may produce better outcomes in more severely poisoned patients. Persistently altered mental status with poor visuospatial functioning and signs of ataxia and apraxia are the most important indicators of the need for hyperbaric treatment (Weaver 2009). The potential for in utero toxicity due to avid binding interactions between CO and fetal hemoglobin lowers the threshold for more aggressive oxygen therapy in pregnant patients.

Survivors of severe CO poisoning are likely to have residual deficits from hypoxic injury to the CNS. Neuroimaging can reveal cerebral atrophy, periventricular white matter changes, and low-density lesions in the basal ganglia (J.S. Brown 2002). Neuropsychiatric sequelae may be present in up to one-half of patients and range from mild memory and concentration deficits to mood and personality changes, parkinsonism, and dense encephalopathy (Asian et al. 2004; Ku et al. 2006; S.P. Lam et al. 2004). Patients have similar complaints after chronic exposure to low levels of carbon monoxide (Myers et al. 1998), but no studies have demonstrated objective neuropsychiatric effects in the absence of a severe, acute episode of poisoning.

Toxic Alcohols

A handful of liquids that are more acutely dangerous than ethanol are occasionally consumed as substitutes by severe alcoholics. Sometimes children are drawn to their attractive colors and/or sweet tastes. More frequently, however, these agents are ingested with suicidal intent. Ethylene glycol is the primary ingredient in antifreeze. Propylene glycol is also found in antifreeze and as a diluent in parenteral formulations of lorazepam, diazepam, esmolol, and other medications, making continuous infusions a potential source of toxicity (Zar et al. 2007). Windshield washer fluid and fuel additives contain methanol. Isopropanol is found

in rubbing alcohol. Like ethanol, all of these compounds are rapidly absorbed after oral ingestion, and their metabolism depends upon alcohol dehydrogenase. It is the body's enzymatic handling of ethylene glycol, propylene glycol, and methanol that creates much of their toxicity.

The toxic alcohols produce an initial clinical presentation that is similar to ethanol, with slurred speech, ataxia, and CNS depression that can progress to stupor and coma in severe overdose. Because rapid breakdown by alcohol dehydrogenase produces organic acids from both methanol (formic acid) and ethylene glycol (glycolic and oxalic acids), metabolic acidosis with an elevated anion gap is a key finding. Isopropanol is metabolized to acetone, so the result of this ingestion is CNS depression and ketosis (along with the characteristic fruity breath odor) without significant acidosis. The parent compounds and some of their breakdown products are also osmotically active, so an osmolar gap is present. Acidosis and the direct toxic effects of the alcohols and their metabolites lead to end-organ damage with potentially lethal consequences, including nephrotoxicity with ethylene glycol, and blindness with methanol. Methanol also can cause necrotic damage to the putamen, the result being an irreversible movement disorder with symptoms similar to parkinsonism (Sefidbakht et al. 2007).

In addition to supportive care, the mainstay of toxic alcohol treatment is to inhibit metabolism while enhancing elimination. For years, the acute intervention was administration of ethanol to metabolically compete for alcohol dehydrogenase and slow the formation of toxic species from ethylene glycol and methanol. (Inhibiting metabolism of isopropanol only prolongs CNS effects without providing systemic protection from toxicity and is therefore not appropriate therapy in a rubbing alcohol overdose.) Continuous titrated infusion of ethanol to maintain serum concentrations between 100 and 150 mg/dL was the therapeutic goal (Barceloux et al. 1999, 2002). More recently, a synthetic inhibitor of alcohol dehydrogenase has become available. Fomepizole has a much higher affinity for the enzyme than does ethanol and, although more expensive, is preferred. It does not compound CNS depression induced by the original ingestion and also avoids other ethanol toxicities such as hepatitis and pancreatitis (Brent et al. 1999, 2001). Elimination of the toxic alcohols can then be effectively enhanced by hemodialysis if necessary. If any delay to advanced hospital treatment is anticipated, oral doses of ethanol can be temporizing and potentially lifesaving (Jacobsen and McMartin 1997). Supplementation with pyridoxine and thiamine after ethylene glycol ingestion, and folic or folinic acid after methanol ingestion, can also reduce production of toxic metabolites and support recovery.

Hydrocarbons and Inhalants

Like the toxic alcohols, hydrocarbons are found in commonly available products, most of them polishes, solvents, lubricants, and fuels. They are typically ingested orally in error by children and with suicidal intent by adults, but fatal outcomes are rare. Several hydrocarbons are abused as inhalants; sniffing, huffing, and bagging these agents are all intended to produce a euphoric high. Psychiatric consequences of intentional or unintentional inhalation of hydrocarbons include mood disorders (e.g., affective lability, irritability, depression, mania), psychosis, insomnia, amnesia, confusion, and bizarre/violent behavior. While purposeful solvent abuse was not documented until 1951, the history of accidental exposure with serious consequences is much older. In the nineteenth-century rubber industry, carbon disulfide toxicity induced mood and psychotic symptoms that resulted in suicides of factory workers (Hartman 1988). Neuropsychiatric impairment is a serious problem with other agents such as trichloroethylene, methyl chloride, toluene, ethylene oxide, propane, acetone, and nitrous oxide. However, the magnitude and duration of solvent exposure necessary to cause psychiatric problems remains controversial, as does the potential duration of CNS symptoms following cessation of use. Inhalant abusers have high rates of comorbid psychiatric disorders (Wu and Howard 2007). Many will show brain abnormalities on computed tomography (CT) or magnetic resonance imaging (MRI), including diffuse white matter changes, cerebral and cerebellar atrophy, callosal thinning, and damage to the basal ganglia (J.S. Brown 2002). After chronic abuse of sufficient dose and duration, such changes are frequently irreversible (Schaumberg 2000). Psychometric testing may delineate functional correlates for the anatomic pathology and help to guide rehabilitation (Filley et al. 1988). Neuropathies can also develop with chronic use and persist long after discontinuation. Large acute exposures may lead to ataxia, cranial nerve palsies, delirium, seizures, and coma. "Sudden sniffing death" can result from cardiac dysrhythmias, usually involving inhalation of fluorinated hydrocarbons (Kulig and Rumack 1981). The primary danger with oral ingestion of hydrocarbons and other solvents is aspiration, leading to chemical pneumonitis. Pneumonitis and associated respiratory compromise can occur merely with huffing, even when the solvent is not aspirated in liquid form.

The management of acute hydrocarbon ingestion is primarily symptomatic. Gastric emptying procedures should be avoided, as they increase the risk of aspiration. Activated charcoal is ineffective in hydrocarbon ingestion, and there are no specific antidotes. Care of patients with chronic toxicity involves rehabilitative therapies, chemical

dependency intervention, targeted psychopharmacology, and neuropsychiatric reassessment.

Pesticides

Agents used to kill animal, plant, and fungal pests have the potential to cause significant acute and chronic toxicity in humans. They represent a variety of chemical classes with diverse mechanisms of action. In the United States exposures rarely cause death, but intentional ingestions of more toxic mixtures in Africa and the Indian subcontinent result in thousands of completed suicides every year (Gunnell et al. 2007). In the West, environmental toxicity causing more subtle, chronic somatic and neuropsychiatric manifestations is the major public health issue. Additionally, the use of some of these compounds in times of war has produced questions about whether they may have an etiological role in unexplained symptoms found in veterans (J.S. Brown 2007; see also "Gulf War Syndrome" later in this chapter). The following subsections focus on selected pesticides most relevant to psychiatrists.

Strychnine

Strychnine is an alkaloid botanical derivative that was once marketed for therapeutic uses, but is now commercially available only as a laboratory reagent and in products used to kill small mammals and birds. It is, however, a fairly common adulterant in illicit drugs such as heroin, ecstasy, and cocaine (O'Callaghan et al. 1982). Strychnine is occasionally employed with suicidal or homicidal intent. It has been found in some Chinese and Cambodian herbal medicines designed to treat rheumatism and gastrointestinal illness (Chan 2002; Katz et al. 1996). Strychnine toxicity causes rapid, widespread peripheral manifestations of neural excitation including nystagmus, hyperreflexia, and severe generalized painful skeletal muscle contraction, often resulting in hyperthermia, rhabdomyolysis, renal failure, tonic respiratory paralysis, and death.

The myoclonus, *risus sardonius*, and opisthotonic posturing of strychnine toxicity may be mistaken for seizures. The differential diagnosis also includes tetanus, serotonin syndrome, neuroleptic malignant syndrome, stimulant toxicity, and drug-induced dystonia. Patients have both metabolic and respiratory acidosis, as well as myoglobinuria and elevated levels of creatine phosphokinase and serum aminotransferases. Activated charcoal can be useful early after an oral ingestion. Benzodiazepines and, in severe cases, nondepolarizing paralytics such as pancuronium are most effective for muscular hyperactivity (Smith 1990). Patients who survive strychnine poisoning do not generally have long-term physical sequelae, but posttraumatic stress

disorder may be very common in light of the harrowing conscious experience of painful physical symptoms.

Insecticides

There are a number of insecticides that produce toxicity in man. Although resolution of even severe, acute exposure to many insecticides is expected to proceed without sequelae, chronic exposure is a well-documented source of morbidity that may be misattributed or remain medically unexplained. Case reports of low-level exposures suggest a range of chronic problems, including memory loss, peripheral neuropathy, and nonspecific dermatological findings (Roldan-Tapia et al. 2006).

Organophosphates are not only used to eliminate pests, but some (sarin, tabun, and soman) have also been used in chemical warfare. In rural areas of Taiwan, China, and India, purposeful ingestion of organophosphates leads to many deaths every year (Wei and Chua 2008). Accidental exposure on the farm or in the garden, particularly in children, is also a significant source of toxicity. Medication errors or overdoses with carbamates (e.g., pyridostigmine, neostigmine) pose a similar danger. These substances all exert their effects through inhibition of acetylcholinesterase, resulting in characteristic manifestations of excess cholinergic activity (discussed in the "Toxidromes" section later in this chapter). Organophosphates, as a rule, more readily cross the blood-brain barrier than do carbamates (Gallo and Lawryk 1991) and are likely to produce seizures with progression to coma. Organophosphates are also more deadly if there is any delay in treatment, because their binding to the enzyme is irreversible and produces more severe, longer-lasting cholinergic toxicity (Gallo and Lawryk 1991).

Treatment first involves careful decontamination of skin and clothing to prevent further exposure to the patient (and health care providers), followed by specific antidotes. Atropine counteracts the effects of excessive vagal stimulation; multiple doses are usually necessary. Pralidoxime reactivates cholinesterase by dislodging the toxin from the active site (Wong et al. 2000). Patients who do recover from acute poisoning often suffer no sequelae, although delirium, mood changes, anxiety, and self-limited parkinsonian movements have been described, and some psychiatric symptoms can last for months after the event (Gallo and Lawryk 1991; Gershon and Shaw 1961; Merrill and Mihm 1982; Rosenstock et al. 1990).

Chronic organophosphate toxicity usually arises from work-related exposure. Symptoms include blurred vision with miosis, nausea, diarrhea, diaphoresis, weakness, and other neurological complaints (Clark 2006). Pyramidal tract signs are sometimes found (Bhatt et al. 1999; Müller-Vahl et al. 1999); data are mixed on the association between

organophosphate exposure and the development of frank parkinsonism (L.S. Engel et al. 2001; Stephenson 2000; Taylor et al. 1999). Peripheral neuropathy and CNS effects, including memory complaints, mood changes, and irritable or otherwise abnormal behavior have also been reported secondary to chronic organophosphate exposure (Jamal 1997). Red blood cell cholinesterase testing is a sensitive assay that can reveal the diagnosis (Gallo and Lawryk 1991).

Other insecticides have been implicated in toxic syndromes with relatively low levels of exposure. Organic chlorines (e.g., dichlorodiphenyltrichloroethane [DDT]) all lower the seizure threshold (Ecobichon and Joy 1994). Some related compounds such as the antihelminthic lindane may adversely affect cognition and behavior, particularly in children for whom this low-cost scabies treatment is most frequently prescribed. Chronic occupational exposure to chlordecone, a highly lipophilic insecticide, can cause diffuse tremors, ataxia, an exaggerated startle reflex, opsoclonus, weakness, weight loss, and metabolic liver injury (Faroon et al. 1995). Intentional overdose of *N,N*-diethyl-3-methylbenzamide (DEET), found commonly in commercial bug sprays, may cause seizures. Encephalopathy and seizures have been reported in young children with excessive skin exposure to DEET (Briassoulis et al. 2001).

Radiation

Ionizing radiation sources include nuclear weapons and reactors, natural elements (e.g., radon), and consumer products, as well as diagnostic and therapeutic isotopes. Ionizing radiation preferentially harms cells with high turnover rates, including those of the skin, immune system, pulmonary epithelium, and gastrointestinal tract. In the CNS, damage and necrosis can produce neurological dysfunction and mental status changes, although the mere stress from perceived or actual exposure to ionizing radiation can also result in psychiatric impairment. Symptoms of toxicity include depression, sleep disturbance, fatigue, memory problems, poor concentration, and, rarely, psychosis (J.S. Brown 2007). Cranial irradiation, while often necessary for cancer survival increases the risk of neuropsychiatric abnormalities, particularly in children (V.A. Anderson et al. 2004; Cole and Kamen 2006). However, not all cranial irradiation causes dysfunction, and in some cases, improvement in cognition results, depending on the location and type of tumor, and the specifics of treatment (P.D. Brown et al. 2003; L.C. Lam et al. 2003; Torres et al. 2003). Ionizing radiation is a developmental teratogen, so high-level exposure to fetuses can cause mental retardation.

The question of whether low levels of ionizing radiation cause neurocognitive dysfunction has been confounded by the frequently high levels of comorbid stress and unrelated illness and injury in those who are suspected

to suffer exposure. Gulf War veterans with bodily retained fragments of depleted uranium from exploded ammunition have demonstrated subtle changes in neurological status (McDiarmid et al. 2000, 2002), although objective neurological signs are rare. Studies of Hiroshima survivors did not correlate radiation exposure with dementia (Yamada et al. 1999, 2002, 2003). One nested case-control study of female nuclear weapons workers did find a small but significant increased risk of dementia-related death associated with total lifetime radiation exposure (Sibley et al. 2003). Most long-term studies of radiation survivors conclude that survivors are at high risk for mood and anxiety disorders, particularly the latter due to lasting worries about health consequences of the exposure (Honda et al. 2002; Kawano et al. 2006; Yamada and Izumi 2002). Posttraumatic responses to the mere threat of irradiation after an accident or attack are significant, and psychiatric symptoms are commonly reported even when little or no energy has been released (J.S. Brown 2002). "Radiophobia" refers to the substantial burden of psychological and functional somatic syndromes that appear after radiation exposure, which are forms of stress response not due to the radiation itself (Dawson and Madsen 1995; Pastel 2002; Pastel and Mulvaney 2001). It typically accompanies fears about cancer and other illnesses being caused by various exposures from nuclear power plants to natural sources to diagnostic radiography.

Non-ionizing radiation does not have the toxic potential outlined above, because the low energy of electromagnetic frequencies (e.g., radar, microwaves, television signals, mobile telephone transmission) is not sufficient to induce atomic reactive change. Nevertheless, there are patients with syndromic symptoms similar to those reported in idiopathic environmental intolerance (see "Psychosomatic Medicine and Blame-X Syndromes" section later in this chapter) who are "sensitive" to radiation in the electromagnetic range and who demonstrate some perceptual differences relative to study control subjects (Landgrebe et al. 2008). A clear causal relationship between exposure and symptoms is lacking (Feychting et al. 2005; Rubin et al. 2005), but patients may be helped with psychological interventions such as cognitive-behavioral therapy (Hillert et al. 1998; Rubin et al. 2006).

Metals

Despite advances in preventing exposures, metal poisonings continue to cause serious illness, with frequent neuropsychiatric symptoms. The neurotoxic metals of greatest importance to psychosomatic practice are lead, arsenic, thallium, manganese, selenium, and mercury. Toxicity can occur from acute ingestion, but most cases are the result of chronic exposures with insidious development of vague

physical symptoms and psychiatric manifestations. A general workup for neuropsychiatric symptoms suspected to be the result of metal toxicity includes a careful neurological and mental status examination, complete blood count, and screening assays of serum and urine for metals. Neuropsychological testing can help to delineate cognitive impairment and guide rehabilitation. Specific details about each element follow.

Lead

The syndrome resulting from lead poisoning was classically referred to as *plumbism*. Although acute symptomatic lead poisoning and plumbic encephalopathy are rare since the removal of this metal from house paints and gasoline, lead toxicity remains a major problem, particularly in pediatrics, where it is still underdiagnosed. The fact that the major source of lead for children is old paint places inner-city residents at increased risk simply from the high metal content of dust in their homes (Chiodo et al. 2004; Reyes et al. 2006). Lead paint has a sweet flavor, and consumption of a single 1 g flake can exceed the permissible weekly intake for any individual (especially a small child) by orders of magnitude. Some imported toys and low-cost jewelry may be decorated with lead-based paints as well (Weidenhamer and Clement 2007).

Adult lead poisoning results from occupational or environmental exposures to lead-based products (H.A. Anderson and Islam 2006). Removing lead from gasoline has markedly reduced airborne emissions, and blood lead concentrations have correspondingly declined. But hobbies such as stained glass and ceramics may introduce lead into household air and dust. Some cosmetics traditionally used by Hindu and Muslim populations have extremely high concentrations of lead. Some Mexican folk remedies, such as *azarcon* and *greta*, used for gastrointestinal disorders, contain large amounts of lead as well.

Lead interferes with normal development and function of the CNS. Elevated serum levels are associated with lower IQ, poor concentration, sleep problems, and mood dysregulation (Bellinger et al. 1987). With acute, progressive poisoning, headache, vomiting, clumsiness, staggering, and drowsiness may presage the onset of encephalopathy, which may progress to convulsions, stupor, and coma (Wiley et al. 1995). Other systemic signs and symptoms can help to distinguish milder, chronic plumbism in differential diagnosis. Gastrointestinal effects include crampy pain, anorexia, weight loss, nausea, and constipation. Lead also causes anemia, peripheral motor neuropathy, nephropathy, and adverse reproductive outcomes. The metal has a long half-life in neuronal tissue and is stored for an extremely long time in bone. Because the majority of total body lead is found in bone, and late-life demineralization allows the metal back

into systemic circulation, early exposure has been proposed as a risk factor for Alzheimer's dementia (Shcherbatykh and Carpenter 2007). Conditions such as massive traumatic fracture, hyperthyroidism, and pregnancy can also remobilize lead, with the potential for toxicity to emerge in an adult or in a developing fetus.

An elevated whole-blood lead level is the most useful indicator of exposure. The threshold for acceptable lead levels was originally set at 60 $\mu\text{g}/\text{dL}$, but evidence of attributable risk with lesser exposures has led to steady reductions to the current 10 $\mu\text{g}/\text{dL}$ level. Over 2% of children in the United States under 6 years of age have blood lead levels greater than 10 $\mu\text{g}/\text{dL}$ (Woolf et al. 2007). And even in the absence of other physical symptoms, there is good evidence for toxic neuronal injury below 10 $\mu\text{g}/\text{dL}$ in the form of cognitive and behavioral impairment (Chiodo et al. 2004; Shannon 2003). Deficits in speech and language, attention, and classroom behavior also have been reported in relation to low-level lead exposure. A follow-up of lead-exposed but apparently asymptomatic subjects into young adulthood found that the high-lead group had a sevenfold increase in high school graduation failure and a sixfold increase in reading disabilities (Needleman et al. 1990). Behavioral dyscontrol and antisocial features are also found more commonly in lead-exposed cohorts in a dose-response relationship.

The cornerstone of lead toxicity treatment is identifying the source of lead and terminating exposure. In an acute ingestion (e.g., lead paint chips), activated charcoal is frequently used but may do little to adsorb the metal. Whole-bowel irrigation should be strongly considered. It is also important to consider removing lead-containing buckshot, shrapnel, or bullets from firearm trauma patients to prevent plumbism from delayed absorption.

The three major chelating agents for lead toxicity are ethylenediaminetetraacetic acid (EDTA), dimercaptosuccinic acid (DMSA, or succimer), and 2,3 dimercaptopropanol (British anti-Lewisite, or BAL). Encephalopathic patients should be treated with BAL and EDTA (Goyer et al. 1995). Less severely affected or asymptomatic patients can be treated with the oral chelator DMSA. It is unlikely that patients with a serum level lower than 10 $\mu\text{g}/\text{dL}$ will benefit from chelation therapy of any kind; the mainstay of treatment in these cases is to minimize further exposure. Neuropsychiatric impairments may resolve slowly and incompletely, with a resulting need for rehabilitation, symptomatic psychopharmacology, and psychosocial and educational accommodations (Needleman 2006).

Arsenic

Arsenic is found in commercial, industrial, and pharmaceutical products, and a range of different exposures results in toxicity. Poisoning has been reported from unintentional,

suicidal, homicidal, occupational, environmental, and iatrogenic means (Hunt et al. 1999). Contaminated water, soil, and food are the primary sources of exposure for most people. Arsenic is also found in herbicides, fungicides, and pesticides. Arsenic trioxide is used to treat acute promyelocytic leukemia. Asian natural remedy preparations sometimes contain significant levels of arsenic (Saper et al. 2008). Inorganic arsenic is odorless and tasteless and well absorbed by a variety of routes.

Acute oral poisoning produces nausea, vomiting, and severe diarrhea within minutes to hours (Schoolmeester and White 1980). Hypotension, tachyarrhythmias, and shock often follow. Delirium typically manifests early, but can be delayed in onset by days. Peripheral neuropathy with severe dysesthesias and dermatological changes emerge within weeks of ingestion.

Low-level exposure to arsenic over time produces a different picture (Yoshida et al. 2004). Fatigue, anemia, leukopenia, skin hypopigmentation, and hyperkeratosis are common. Peripheral vascular insufficiency, including Raynaud's phenomenon, is observed. Patients suffer from noncirrhotic portal hypertension with elevated transaminases. Memory loss, cerebellar dysfunction, and mild cortical impairment are seen in adults with chronic exposure. Anxiety, irritability, and personality changes have also been reported (J.S. Brown 2007). Children show signs of mental retardation.

Diagnosis should be confirmed by 24-hour urine collection, given that single-specimen urinary excretion and serum levels of arsenic are highly variable. In a case where arsenism is suspected but urinary assays are negative, hair or nail testing can reveal the diagnosis. Acutely poisoned patients should receive chelation therapy with dimercaprol (BAL) as soon as possible (Muckter et al. 1997). Chronically intoxicated patients should not begin chelation therapy until confirmatory testing results are received, and the drug of choice is oral succimer (Muckter et al. 1997).

Thallium

Poisoning with thallium is much less common in recent years, since removal of depilatory and rodenticide compounds from the market has drastically reduced its availability. It still occurs, however, from accidental exposures as well as homicide and suicide attempts (Rusyniak et al. 2002). Thallium is used in the manufacture of some jewelry. It may be ingested in herbal preparations and adulterated illicit drugs like heroin and cocaine (Insley et al. 1986; Questel et al. 1996; Schaumberg and Berger 1992). Occupational exposures are rare. Delirium, seizures, and respiratory failure mark the mortal trajectory after acute ingestion.

Chronic thallium toxicity should be suspected in patients when neuropsychiatric complaints (e.g., depression,

irritability, paranoia, memory loss, confusion) are accompanied by alopecia, nail dystrophy, painful neuropathy and gastrointestinal disturbances (Bank 1980). Chorea and ophthalmoplegia are sometimes observed. CNS pathology includes cerebral and brain stem edema. Psychiatric symptoms may persist long after resolution of other toxic sequelae (Rusyniak et al. 2002).

Multiple-dose activated charcoal, potassium supplementation, and Prussian blue can be helpful to enhance elimination and prevent end-organ toxicity (Thompson and Callen 2004). In chronic toxicity, removal of the source of exposure is the most crucial intervention, although there may be a role for potassium and Prussian blue therapy.

Manganese

Manganese intoxication is usually the result of chronic occupational exposure in miners, metalworkers, and welders who inhale the metal. The earliest descriptions of poisoning in Chilean manganese miners in the early twentieth century outlined symptoms of uncontrollable affective expression with agitation and psychosis, and a similar syndrome is still recognized (Bouchard et al. 2006; Bowler et al. 2007). "Manganese madness" was the term used to describe the initial psychiatric syndrome of compulsive behavior, emotional lability, and hallucinations. Memory and concentration deficits are common. There is also a manganese-based fungicide that is suspected as a cause of chronic neuropsychiatric toxicity. Parkinsonism and other movement disorders are frequently comorbid but usually do not manifest until psychiatric problems have been present for some time. In these cases, brain MRI often identifies manganese deposition, especially in the basal ganglia (Bowler et al. 2006). Serum and urine assays can be performed, but results do not correlate with symptoms in chronic toxicity. Treatment for acute inhalation is supportive, and therapy of chronic neuropsychiatric sequelae is frequently ineffective after manganese has damaged the brain (Bouchard et al. 2006).

Selenium

Selenium is an essential trace element that causes toxicity from exposure to industrial compounds or dietary supplements. Fatalities are usually the result of purposeful ingestion of selenous acid or selenium salts (Pentel et al. 1985). The acid (found most commonly in gun bluing solutions) causes corrosive injury to the upper gastrointestinal tract, vomiting, diarrhea, hypotension, myopathy, renal impairment, respiratory failure, and progressive CNS depression (Köppel et al. 1986). Chronic selenosis results in fatigue, brittle hair and nails, and a variety of dermatological changes. Accumulation of selenium also causes hyper-

reflexia, paresthesias, irritability, depression, and anxiety (Holness et al. 1989).

Assays for whole-blood and erythrocyte concentrations of selenium are more reliable for confirming toxicity than serum levels (Barceloux 1999). Activated charcoal may be useful in acute ingestions, but no other treatments apart from supportive care have established efficacy. Reversing chronic selenosis depends primarily upon identifying and removing the source of ongoing exposure. The antioxidants ascorbic acid and NAC may have some value in acute or chronic toxicity.

Mercury

Mercury is found in pharmaceuticals, folk medicines, laboratory and agricultural chemicals, industrial devices, and substituted alkyl compounds that accumulate in the bodies of large carnivorous fish. Toxicity from the metallic form of mercury is mediated through inhalational exposure, whereas organic mercury and its salts cause poisoning via ingestion.

Acute inhalation can cause severe chemical pneumonitis. Acute ingestion of mercury salts produces hemorrhagic gastroenteritis. It is more chronic exposure that gives rise to neuropsychiatric symptoms. Chronic inhalation can lead to a singular combination of personality changes with shyness and withdrawal alternating with explosive, flushed-face irritability. This syndrome is known as *erethism*. Volatile mercury was once used to prepare fur for hats; *erethism* is the condition referenced when labeling someone "mad as a hatter" (J.S. Brown 2002). Anxiety, mania, memory loss, and poor concentration have been reported with elemental mercury poisoning. Patients can also develop tremors and choreiform movements (Sue 2006).

The CNS is the primary site of toxicity with ingestion of organic mercury, as well. Symptoms usually differ from those caused by inorganic mercury and include paresthesias, dysarthria, ataxia, and loss of vision and hearing (Winship 1986). Organic mercury compounds are also teratogenic, manifest as mental retardation and neurological impairment that mimics cerebral palsy. As a result, pregnant and nursing women are advised to limit their intake of predatory fish (Mozaffarian and Rimm 2006).

Much attention has been given to the possibility that autism is caused by ethylmercury thiosalicylate (Thimerosal), a preservative used in childhood vaccines. Rigorous epidemiological studies have found no evidence to support a link between mercury in vaccines and autism (Andrews et al. 2004; Heron et al. 2004; Parker et al. 2004; Smeeth et al. 2004). Randomized controlled trials of chelation therapy for autism were halted in late 2008 due to safety concerns (Mitka 2008). See also Chapter 27, "Infectious Diseases."

Laboratory testing for mercury toxicity is complicated and is best undertaken with a combination of both whole-blood and urine assays (Rosenman et al. 1986). Acute toxicity management is focused on supportive care. Early activated charcoal and gastric decontamination are recommended, except with oral ingestion of liquid mercury, since it passes through unabsorbed in patients without preexisting gastrointestinal abnormalities. Succimer will chelate metallic mercury well. Salts are best bound by dimercaprol, but this chelator should not be used in other states of mercurism, because it can transport more of the toxic metal to the brain. Organic mercury poisoning, with its high risk of CNS pathology, may be treated with succimer plus either NAC or *N*-acetyl-*D,L*-penicillamine, but data are limited regarding effectiveness in reversing neuropsychiatric sequelae (Clarkson et al. 1981). There is no evidence to suggest that the small amount of mercury in dental amalgam produces systemic toxicity that warrants filling extraction or chelation therapy (Y.K. Fung and Molvar 1992).

Over-the-Counter Remedies

Medicines available without a prescription are commonly used in supratherapeutic doses (both mistakenly and purposely) and are also ingested with suicidal intent. Cough and cold preparations are too often administered by parents and other child care providers to induce sedation, even in the absence of allergic or infectious symptoms, occasionally with lethal consequences for young children (Dart et al. 2009). In addition to analgesics (discussed above) some products contain a number of different potentially toxic compounds in combinations that can complicate diagnosis and treatment.

Dextromethorphan

Dextromethorphan is ubiquitous in cough and cold products. This antitussive is a synthetic analog of codeine that is frequently abused by teenagers (Baker and Borys 2002). Its potency in cough suppression is roughly equivalent to that of codeine, but it has very weak opioid activity, even in overdose. The drug primarily inhibits serotonin reuptake mechanisms and, to a lesser degree, glutamate receptors. These neurotransmitter alterations mediate both its desirable and harmful effects. At low levels of intoxication, euphoria and hallucinosis can occur along with dizziness, ataxia, nystagmus, and akathisia. Serotonin syndrome is common in large overdose and in cases of coingestion with other serotonergic agents. More severe poisoning causes seizures and CNS depression with progression to respiratory failure and coma. The drug is bound well by activated charcoal in the recent wake of an acute ingestion. Naloxone has been reported to improve mental status in some symptomatic cases (Schneider et al. 1991), but benzodiazepines and supportive

care (i.e., to treat serotonin syndrome and its sequelae) are the cornerstone of management (Chyka et al. 2007).

Decongestants and Related Drugs

Some sympathomimetic drugs are used to induce local and peripheral vasoconstriction, thereby acting as nasal decongestants. They can be found alone or in combination preparations for use in managing symptoms of upper respiratory infection and environmental allergies. Pseudoephedrine and phenylephrine are the most commonly used, both of which are alpha-adrenergic agonists with the former carrying some beta-stimulatory activity, as well (Johnson and Hricik 1993). Ephedrine also has more non-specific adrenergic effects and is found in herbal preparations used recreationally, to enhance energy, or as adjuncts to fitness regimens (Nelson and Perrone 2000). The U.S. Food and Drug Administration (2004) declared ephedrine-containing dietary supplements illegal in 2004, but they remain readily available on the Internet. Hypertension is the main toxic effect of acute concern with all of these agents, particularly in large overdose. However, they have psychiatric effects as well, including anxiety, irritability, euphoria, and insomnia—the presentation of acute and/or chronic abuse can resemble mania and lasts considerably longer than the physical effects on hemodynamics (Dalton 1990; Lake et al. 1983). After an acute ingestion, aggressive blood pressure control and intensive monitoring are essential, with readiness to manage seizures, intracranial hemorrhage, and arrhythmias. Direct vasodilators such as phenolamine or nitroprusside are the preferred agents; as with acute cocaine intoxication, beta-blockers are to be avoided. Survival of the acute phase of toxicity from these short-acting compounds without an adverse vascular event generally leads to full recovery.

Antihistamines

Histamine receptor antagonists are used for the treatment of allergies, motion sickness, and short-term insomnia. This discussion is confined to histamine 1 (H_1) receptor blockers, since the H_2 blockers are relatively harmless, even in massive overdose (Illingworth and Jarvie 1979; Krenzelok et al. 1987). Accidental supratherapeutic ingestions occur (frequently in children), but toxicity from H_1 blockers is most commonly encountered either in elderly patients with delirium or in suicidal patients after intentional overdose with the most widely available and potentially toxic agent in the class, diphenhydramine. Doxylamine and hydroxyzine are also problematic in overdose. Newer H_1 blockers are more selective for peripheral H_1 receptors and correspondingly less toxic (Nolen 1997).

Acute intoxication presents as anticholinergic poisoning due to direct activity of these compounds on mus-

carinic receptors and the overlap of histaminergic and cholinergic neurotransmission pathways. Patients often have classic symptoms of flushed dry skin, fever, tachycardia, impaired consciousness, hallucinations, and abnormal movements. Given that H_1 receptor activity is important in memory, attention, concentration, executive function, and regulation of the sleep-wake cycle, it is no surprise that antihistamines precipitate delirium. Slowing of gastrointestinal motility may prolong absorption and the duration of toxicity. Seizures and rhabdomyolysis occur in serious overdose. Massive diphenhydramine ingestion can produce cardiac conduction disturbances and precipitate lethal arrhythmias secondary to sodium channel blockade (similar to TCA toxicity). Activated charcoal is recommended in patients with intact airway protection. Cardiotoxicity, as with TCAs, requires alkalinization of the serum using bicarbonate-containing intravenous fluids. The cholinesterase inhibitor physostigmine is an effective antidote for anticholinergic symptoms (Burns et al. 2000). In more severe poisonings, multiple doses of this short-acting remedy may be required; its use is discussed in more detail in the following section.

Toxidromes

Certain constellations of signs and symptoms, commonly called toxidromes, may suggest poisoning by a specific class of compounds (Table 37-6). The findings represent direct physiological manifestations of the pharmacology of the agents in question, thus providing objective clinical data about the status of the patient and what has been ingested. Recognition of such patterns can be very helpful, but clinical pictures are not always so obvious. It is important to seek historical information regarding all the potential medications and substances to which a patient may have access and attend well to the details of the presentation and evolving course, because polydrug overdoses may result in overlapping and confusing mixed syndromes that require careful management. Nevertheless, recognizing the dominant features of particular classes of pharmacological toxicities can be a vital diagnostic and therapeutic starting point in psychosomatic consultation.

Anticholinergics

The anticholinergic syndrome occurs frequently because many common medications and other xenobiotics have anticholinergic properties. It is a particularly prevalent problem in the elderly medically ill who, on average, take more medications and are more sensitive to their adverse effects. Polypharmacy is a major concern, as a number of commonly used drugs not typically classified as anticho-

linergics (e.g., antipsychotics, muscle relaxants, antihypertensives) do possess some anticholinergic activity (Tune 2000). Anticholinergic toxicity in the CNS causes delirium, frequently with mumbling speech and carphology or floccillation—aimless “picking movements” of the fingers. Vivid visual hallucinosis and undressing behavior are not uncommon. Peripheral anticholinergic syndrome signs include tachycardia, dry mouth, flushed skin, temperature elevation, mydriasis, ileus, and urinary retention. The duration and severity of CNS manifestations typically exceed peripheral effects (Tune 2001).

Most patients recover with removal of offending agents and supportive therapy, but delirium may last for over 24 hours after an acute overdose of anticholinergics—considerably longer if medications that add to the problem continue to be administered. Physostigmine is a useful intravenous antidote that can rapidly resolve delirium. It has a short half-life, and repeated 2-mg doses may be needed in severe anticholinergic toxicity. Primarily on the basis of two case reports of asystole, its use has been curtailed in the setting of a possible TCA overdose or in patients with prolonged QRS or QTc intervals (Pentel and Peterson 1980). However, extensive subsequent clinical experience has documented its safety and utility in anticholinergic states induced by medications that can affect cardiac conduction (Burns et al. 2000; Schneir et al. 2003). Relative contraindications to the use of physostigmine include reactive airway disease, parkinsonism, and atrioventricular blockade. Side effects of excessive physostigmine dosing include nausea, vomiting, diarrhea, bronchospasm, bradycardia, and seizures.

Cholinergics

The cholinergic syndrome is uncommon but is important to recognize because lifesaving treatment is available. Cholinergic toxicity produces a “wet” patient (profuse sweating, sialorrhea, lacrimation, vomiting, diarrhea, urinary incontinence) as opposed to the anticholinergic syndrome, which causes the patient to be “dry.” The CNS (e.g., seizures, coma) and skeletal muscles (e.g., weakness, fasciculations) can also be involved. Cholinergic excess is most frequently caused by accidental organophosphate or carbamate pesticide exposure, which may occur through unsuspected dermal contamination (Hodgson and Parkinson 1985). Such agents and cholinesterase inhibitors used therapeutically for dementia can be employed in suicide attempts, as well. Cholinergic effects are also the cause of toxicity from “nerve gases” like sarin and from clitocybe and inocybe mushrooms. Recognition of the syndrome should prompt the use of atropine and, in cases of severe toxicity, the cholinesterase regenerator pralidoxime (Eddleston et al. 2002). Some phosphate-based insecticides

TABLE 37-6. Toxidromes: prominent clinical findings

Drug class	Examples	Clinical signs	Antidote
Anticholinergics	Atropine, antihistamines, scopolamine, antispasmodics, TCAs, phenothiazines, antiparkinsonian agents, jimsonweed	Agitation, hallucinations, picking movements, tachycardia, mydriasis, dry membranes, hyperthermia, decreased bowel sounds, urinary retention, flushed/dry skin	Physostigmine
Cholinergics	Organophosphates, carbamate insecticides, cholinesterase inhibitors	Hypersalivation, lacrimation, incontinence, gastrointestinal cramping, emesis, bradycardia, diaphoresis, miosis, pulmonary edema, weakness, paralysis, fasciculations	Atropine, pralidoxime
Opioids	Oxycodone, hydrocodone, hydromorphone, fentanyl, morphine, propoxyphene, codeine, methadone, heroin	CNS and respiratory depression, miosis, bradycardia, hypotension, hypothermia, pulmonary edema, hyporeflexia	Naloxone, nalmefene
Sedative-hypnotics	Benzodiazepines, zolpidem, zaleplon, eszopiclone, barbiturates, ethanol, chloral hydrate, ethchlorvynol, meprobamate	CNS depression, hyporeflexia, slow respirations, hypotension, hypothermia, bradycardia	Flumazenil (for some)
Sympathomimetics	Psychostimulants, amphetamines, pseudoephedrine, phenylephrine, ephedrine, cocaine	Hypertension, tachycardia, arrhythmias, agitation, paranoia, hallucinations, mydriasis, nausea, vomiting, abdominal pain, piloerection	Benzodiazepines
Neuroleptics	Typical and atypical antipsychotics, phenothiazine antiemetics	Hypotension, oculogyric crisis, trismus, dystonia, ataxia, parkinsonism, anticholinergic manifestations (some)	Physostigmine (for some)
Serotonergics	SSRIs, SNRIs, TCAs, MAOIs, buspirone, tramadol, dextromethorphan, antiemetics, triptans, sibutramine	Akathisia, tremor, agitation, hyperthermia, hypertension, diaphoresis, hyperreflexia, clonus, lower extremity muscular hypertonicity, diarrhea	Benzodiazepines, cyproheptadine?

Note. CNS = central nervous system; MAOIs = monoamine oxidase inhibitors; SNRIs = serotonin–norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

are very long acting due to their fat solubility and therefore may require prolonged pralidoxime treatment.

Opioids

Toxicity from opioids progresses from analgesia to anesthetic CNS depression, coma, and death. Respiratory depression is particularly pronounced with opioid overdose, and the tidal volume or respiratory rate can be diminished before decreases in blood pressure or pulse occur. Miosis is also characteristic and, in pure opioid toxicity, a fairly reliable finding (Sporer 1999). The diagnosis of opioid overdose is often confirmed by the use of naloxone or nalmefene in adequate doses that reverse the toxidrome (Hoffman and Goldfrank 1995). Naloxone has an elimination half-life of

about 1 hour, whereas that of nalmefene is over 10 hours, thus making the latter antidote potentially useful in the case of opioid toxicity from a long-acting drug (e.g., methadone) (Glass et al. 1994). In most patients, naloxone is the preferred agent, since a shorter-acting antidote allows for more careful titration of toxidrome reversal without precipitation of withdrawal. A dose of 0.4 mg is adequate; higher doses merely increase the likelihood of agitated withdrawal without added benefit to neurological or respiratory status—unless the antidote is being employed to reverse imidazole (e.g., clonidine, guanfacine, tizanidine) toxicity, where doses of 2 mg or more may be useful (Seeger 2002). Conversely, in known chronic users of opioids, unless apnea is present and not yet addressed with adequate assisted ven-

tilation, starting with 0.2 mg doses of naloxone and carefully repeating as needed is reasonable to avoid dangerously agitated withdrawal. Ongoing monitoring after antidote administration is vital, since cardiopulmonary symptoms are not reversed as durably as CNS depression, and life-threatening symptoms can recur.

Sedative-Hypnotics

Sedative-hypnotic agents can produce neurological depression similar to opioids, and are frequently coingested (or, unfortunately, coadministered in the hospital) to the point of toxicity. “Pure” gamma-aminobutyric acid (GABA)-ergic toxidromes can sometimes be distinguished on the basis of history, relatively preserved pulmonary function, and the absence of constricted pupils (see Table 37–6). When taken in sufficient dosage, sedative-hypnotics cause general anesthesia with a complete loss of awareness and reflex activity, and ultimately, deterioration in cardiopulmonary function. Reversal of this syndrome can be accomplished with the benzodiazepine antagonist flumazenil. In addition to toxicity from benzodiazepines and nonbenzodiazepine hypnotics (e.g., zolpidem, zaleplon, eszopiclone), this antidote has also shown some efficacy in overdoses of the centrally acting skeletal muscle relaxants baclofen, carisoprodol, and metaxalone (Kim 2007). It should not, however, be used without caution in a mixed overdose that may include agents that are proarrhythmic or proconvulsant, since GABA activity is protective against drug-induced arrhythmias and seizures (Seger 2004). As long as doses are kept low (0.5 mg) and delivered over at least 30 seconds into a flowing intravenous line, side effects due to flumazenil (including benzodiazepine withdrawal) are generally mild, although patients can emerge from sedation in a state of anxiety (Ngo et al. 2007). Flumazenil is short acting, so multiple doses may be necessary, and continued neurological and cardiopulmonary monitoring is vital.

Sympathomimetics

The sympathomimetic syndrome is usually seen after acute or chronic abuse of cocaine, amphetamines, or decongestants, the latter of which have been previously discussed. The clinical picture overlaps with serotonin syndrome, as these compounds have multiple catecholamine effects. Signs include agitation, tachycardia, hypertension, mydriasis, and piloerection. In contrast to anticholinergic poisoning, the skin is typically not dry, but the two toxidromes can be difficult to distinguish on clinical examination. Mild toxicity rarely leads to cardiac complications, but large overdoses of sympathomimetic agents can produce arrhythmias, cardiovascular compromise, and shock. Patients may be psychotic, with intricate and paranoid delusions (Ber-

man et al. 2009). Seizures are common, and the postictal state can contribute further to alterations in mental status. No specific antidotes exist, but benzodiazepines are the cornerstone of treatment because they attenuate catecholamine release, reduce hypertension, prevent seizures, and provide helpful sedation. Beta-blockers are contraindicated because they would leave alpha-adrenergic stimulation unopposed; thus, direct vasodilators such as hydralazine, nitroprusside, or phentolamine are preferred for treatment of severe hypertension that does not respond to benzodiazepines. Failure of confusion and agitation to resolve with physostigmine can help to distinguish this toxidrome and serotonin syndrome from anticholinergic delirium. Psychiatric sequelae from sympathomimetic toxicity can linger long after physical symptoms have resolved and may require antipsychotic medication (Berman et al. 2009).

Antipsychotics

Toxidromes involving psychotropic compounds that block dopaminergic transmission are discussed in depth in Chapter 38, “Psychopharmacology.” While antidopaminergic effects may dominate adverse reactions with therapeutic use, many antipsychotic medications are highly anticholinergic in overdose, making physostigmine a potentially useful antidote. Neuroleptic malignant syndrome is an idiopathic reaction that results in severe muscle rigidity, hyperthermia, autonomic instability, and altered mental status; it requires discontinuation of antipsychotic medication and aggressive symptom-focused medical interventions. The varied and complex pharmacological effects of neuroleptics make supportive care after removal of the offending agent key to management in any case of toxicity.

Serotonergics

Serotonergic agents (sometimes in suicidal monoingestion or unintentional combined polypharmacy, but even more frequently with concomitant use of cocaine) can produce serotonin syndrome, characterized by neuromuscular symptoms, hyperthermia, and altered mental status. Classic signs of lower extremity muscle rigidity, hyperreflexia, and especially clonus, along with increased gastrointestinal motility and diaphoresis help to distinguish this potentially lethal toxidrome from anticholinergic poisoning (see Table 37–6). In addition to differences in precipitating medications, neuroleptic malignant syndrome does not cause gastrointestinal symptoms and typically results in more generalized and severe muscle rigidity without hyperreflexia (Boyer and Shannon 2005; Caroff 2003). Serotonin toxicity demands removal of the offending agents and supportive care with fluids and cooling measures; benzodiazepines are the mainstay of pharmacologi-

cal treatment. The oral antihistamine cyproheptadine has some antiserotonergic activity and has often been prescribed, but it has not been demonstrated to improve outcomes. It may reduce symptoms but can only be administered orally, so severely afflicted patients are unable to benefit from its use and instead require large doses of parenteral benzodiazepines. Serotonin syndrome is discussed further in Chapter 38, "Psychopharmacology."

Gulf War Syndrome

Gulf War syndrome refers to the medically unexplained somatic symptoms of thousands of military and civilian personnel who served in conflicts in the Persian Gulf. Over 10% of returning troops have reported a variable host of symptoms, including rashes, gastrointestinal upset, fatigue, muscle aches, paresthesias, headaches, memory impairment, concentration difficulties, irritability, and insomnia (Cohn et al. 2008). These presentations, however, do not constitute a toxidrome, for with the majority of the symptoms being subjective, nonspecific, and referable to multiple organ systems requiring multiple pharmacological mechanisms, the likelihood of a toxic etiology is quite low (Iversen et al. 2007; Kang et al. 2009).

In order to protect troops from insect pests and chemical warfare, they received preemptive repellants and antidotes in therapeutic doses. Vaccinations against botulism and anthrax were also provided. The question has been raised of whether the combination of these agents may have precipitated Gulf War syndrome. Although combinations of DEET, pyridostigmine, and the pyrethroid permethrin have shown synergistic neurotoxicity in very-high-dose animal models, low-level exposure to these and other agents is unlikely to account for soldiers' myriad symptoms through toxicological mechanisms (Abou-Donia et al. 1996; McCain et al. 1997). Similarities between the troops' presentations following the latest conflict and those returning from previous wars lead some experts to conclude that Gulf War syndrome represents a complex reaction of psyche and soma to the many severe traumas of armed conflict (Holland 2006). Subtle CNS effects of insecticides and/or as-yet-unidentified toxins (e.g., combustion products, warfare agents) may contribute, in part, to the complex symptoms in some patients. Treatment, however, is not best accomplished using a disease model that anticipates identification of a specific etiological agent. Since toxicological mechanisms neither explain the disability nor suggest interventions to address it, a population-based approach to anticipatory management coupled with multidisciplinary biopsychosocial attention to individual patient needs is advised (C.C. Engel et al. 2006; Mahoney 2001).

Psychosomatic Medicine and Blame-X Syndromes

In some cases, not only does the history fail to reveal a specific toxic exposure, but also the examination and laboratory testing do not suggest that a xenobiotic is responsible for the patient's suffering. Similar to the Gulf War syndrome, there is a growing number of conditions in which a constellation of complaints are attributed to an exposure with lack of corresponding objective toxicological data. Some involve a single suspected exposure, while others involve concern about repeated or continuous dosing from the environment. Many times, specific agents have been investigated but failed to meet causality standards, and in other instances, a toxic etiology seems plausible but no compounds have yet been identified. Although it is clear that psychiatric factors play a major role for many such patients, it is important to remember that the history of medicine is filled with illnesses viewed as psychogenic until treatable physiological causes were elucidated.

A helpful framework for conceptualizing the emergence and evolution of these syndromes in the modern world has been laid out by Dr. Alvan Feinstein. He refers to functional somatic presentations with external attributions as the Blame-X syndrome (Feinstein 2001). Availability of almost limitless diagnostic (including toxicological) testing contributes to medicalization of distress. On the basis of mere statistical probability, some abnormal results are bound to arise, even if they have nothing to do with a patient's complaints. There is then a tendency to abandon the demand for pathophysiological correlation of symptoms and objective findings. As a result, early suspicion and a corresponding desire for answers prompts the appellation of new diseases before etiologies have been rigorously established. Such Blame-X rendering of diagnoses can stand in the way of patients' functional recovery and also impede ongoing critical research that could properly elucidate underlying causes (Feinstein 2001). Three of these related syndromes involving toxicological issues are discussed below.

In all of these Blame-X syndromes involving medically unexplained symptoms, there is a broad psychiatric differential diagnostic spectrum, including somatoform, post-traumatic stress, obsessive-compulsive, psychotic, and factitious disorders, as well as hypochondriasis, abnormal illness behavior, and malingering. The longitudinal course of symptoms that are initially unexplained is variable, depending upon a host of factors including their nature and severity as well as the demographics of the population in which they arise (Carson et al. 2003; Crimlisk et al. 1998). It is true that long-term complaints, especially those that wax and wane or worsen with time, are very unlikely to be

toxicological in origin unless some ongoing exposure can be documented (Leikin et al. 2004). In some cases, a medical etiology is uncovered for initially unexplained symptoms, but even if it is not, diagnosis of a psychological cause by exclusion alone is not appropriate (see discussion of medically unexplained symptoms in Chapter 12, "Somatization and Somatoform Disorders").

Medication Sensitivity

Some patients have an extensive list of medication intolerances. The term *medication sensitivity* is not being used here to label a new syndrome, but merely to describe a characteristic of patients commonly encountered in psychosomatic practice. It is distinguished from multiple chemical sensitivity, a condition synonymous with idiopathic environmental intolerance (discussed next), particularly with reference to those who are sensitive to odors and airborne substances. Some patients have concerns about both therapeutics and environmental xenobiotics, so medication sensitivity is used here to describe a phenomenon that defines patients whose adverse experiences are attributed specifically to medications. Patients with extensive medication sensitivity may blame current symptoms on a relatively benign medication given in the recent or remote past, but they lack objective physical or pathological findings. As a group these patients, indeed, display an attributional cognitive style similarly seen in idiopathic environmental intolerance (Waddell 1993).

The majority of drug allergy entries in most charts are not indicative of true allergic reactions, but are instead presumed medication toxicities. Most patients who seem to respond poorly to a number of drugs do not have elevated allergic sensitivity to antigenic challenge (Mitchell et al. 2000). Medication rechallenge studies, especially double-blinded trials, which would help to document a starting point for further toxicological study of these patients, are also lacking (Waddell 1993). Some of these drug reactions are "nocebo" responses—adverse effects that would occur even with placebo due to the patient's anticipatory anxiety and pessimistic expectation that a drug will produce unpleasant or harmful side effects (Amanzio et al. 2009). Although little research has been performed to better understand patients with extensive nonallergic medication intolerance, clinical experience indicates a high rate of psychiatric comorbidity (Black 2000). Advising other providers as to the potential for intolerance of rather than relief from new prescriptions can be an important consultative intervention in such cases.

Idiopathic Environmental Intolerance

Some patients report a constellation of symptoms that they ascribe to the toxic effects of one or more components

of the external environment. They are distinguished here from the previous category of individuals in that most do not identify a medication as the precipitant, and many cite ongoing exposures to various agents as the driving force for chronic impairment. Idiopathic environmental intolerance has also been labeled multiple chemical sensitivity, environmental somatization syndrome, environmental allergy syndrome, and, in earlier terms, total allergy syndrome or twentieth-century disease (the latter name emphasizing the suspected role of ecological threats from the modern industrialized world). Characteristics of the syndrome include 1) acquisition after environmental exposure that may have produced minimal (or no) objective evidence of health effects, 2) waxing and waning of symptoms that may vary in response to stimuli and are referable to multiple organs and systems, and 3) lack of evidence of organ damage or abnormal test results to account for symptoms (F. Fung 2004a).

Suspected toxins include construction materials, fabrics, food additives, drinking water, fumes, and agrochemicals. Symptoms are as varied as the causes, and they may include shortness of breath, palpitations, headaches, fatigue, insomnia, cough, nausea, diarrhea, constipation, paresthesias, muscle twitching, skeletal pain, bloating, and diaphoresis. Controlled studies reveal no evidence of toxic exposures or positive allergy testing that might explain the symptoms (Mitchell et al. 2000). "Clinical ecologists" have advanced the hypothesis that low-level exposure to multiple environmental compounds that are generally deemed nontoxic can, in susceptible individuals, precipitate multi-system disease (Stewart and Raskin 1985). Their treatments have included homeopathic remedies and rotary diets. Patients often use air and water purifiers and make moves or take holidays to avoid exposures. Hygienic factors should be considered but rarely contribute to an effective treatment plan unless an epidemic of exposure—and therefore, perhaps, a bona fide toxin—is suspected (Göthe et al. 1995). Relief of symptoms from all these remedies is usually minimal, although outcome studies are lacking.

Sufferers of idiopathic environmental intolerance are more commonly female and have a high rate of psychiatric comorbidity. In one series from a university-based consultation psychiatry service, every patient had at least one DSM diagnosis of mood, anxiety, psychotic, or personality disorder (Stewart and Raskin 1985). Malingering is also not uncommon. Patients share features with those suffering from somatoform disorders to such a great extent that formal research has failed to distinguish the two groups (Bailer et al. 2005; Bornschein et al. 2002). In outpatient toxicology clinic studies, lack of objective physical findings in patients presenting with concerns about a single toxin correlate with negative chemical assay results and

high degrees of maladaptive projection and somatization (Leikin et al. 2004; Zilker 2002). Unfortunately, these individuals typically resist psychiatric intervention or any suggestion of psychogenic etiology (Göthe et al. 1995). Initial treatment of idiopathic environmental intolerance should be directed toward minimizing external attributions and emphasizing functionality through behavioral and cognitive therapies (Staudenmayer 2000). Management of comorbid psychiatric illness is indicated and can provide a starting point for longer-term mental health intervention in this group that otherwise tends to flee from psychotherapeutic interventions.

Sick Building Syndrome

Concerns about symptoms attributable to a particular indoor environment, usually the workplace, characterize the sick building syndrome. Patients frequently complain of lethargy, blocked nasal airways, dry throat, mucosal irritation, and headaches. Some feel chest tightness and dyspnea. Suspected toxins include insulation and other construction materials, residues from office products, and inadequately ventilated airborne contaminants, including fungal spores. In cases where toxic precipitants are identified, susceptible individuals have elevated histamine release that appears to correlate with respiratory symptoms (Meggs 1994). Although direct evidence of infectious disease or toxic exposure in individual patients is typically lacking, there are some studies supporting the possible role of mold species in buildings where prevalence rates are high (Burge 2004; Cooley et al. 1998), but other studies have been inconclusive (Straus et al. 2003). Some patients present with complaints of neuropsychiatric impairment claimed secondary to brain damage from mold exposure, but medical workups do not correlate any neural pathology. Malingering on neuropsychological testing of litigious individuals in this group is not uncommon (Stone et al. 2006).

Psychosocial factors related to workplace stress and job satisfaction do also correlate with somatic symptoms but in limited controlled studies do not account for patient differences attributable to factors about the buildings themselves (Skov et al. 1989). The prevalence of sick building syndrome is higher in women who have desk jobs involving computer work and who perform a substantial amount of photocopying. Toxins in these specific environments, however, have not been identified, and variable symptoms are found in similar workspaces. Infectious agents have been considered, but treatment studies with antibiotics and antifungals have yet to yield benefit (Straus et al. 2003). When an underlying disease such as bronchitis, asthma, or hypersensitivity pneumonitis is discovered, targeted treatment can be effective. Staying away from the building in

question does resolve many, but not all cases of this illness (F. Fung 2004b). Supportive mental health treatment to aid with management of associated stress and comorbid conditions is the only currently relevant psychiatric intervention in sick building syndrome.

Conclusion

A thorough history (often gathered from several sources) and astute physical examination are key to toxicological diagnosis. Medication toxicities are a frequent and commonly misdiagnosed problem in hospitalized patients. Many psychiatric patients misuse drugs with a variety of motivations and corresponding outcomes. Exposures to other poisons may be intentional or accidental, obvious or hidden, at home, in the workplace, or even in the hospital. The CNS toxicity of many agents should include them in the differential diagnosis of unexplained acute or chronic neuropsychiatric symptoms. Removal of ongoing exposure and institution of selected treatments are required. In patients with functional impairment and attributed toxic reactions who have no demonstrable underlying toxic pathology, psychotherapeutic interventions beginning with a supportive stance and an eye toward other etiological factors help to facilitate well-being and recovery.

PART IV

Treatment

Psychopharmacology

James A. Owen, Ph.D.

PSYCHOPHARMACOLOGICAL interventions are an essential part of the management of the medically ill; at least 35% of psychiatric consultations include recommendations for medication (Bronheim et al. 1998). Appropriate use of psychopharmacology in the medically ill requires careful consideration of the underlying medical illness, potential alterations to pharmacokinetics, drug-drug interactions, and contraindications. This chapter reviews basic psychopharmacological concepts, including pharmacokinetics and pharmacodynamics in the medically ill, side effects, toxicity, drug interactions, and alternative routes of administration for each psychotropic drug class, as well as safety in pregnancy and lactation. Important considerations are critically examined for the use of psychotropic drugs in patients with major organ disorders. The use of complementary medicines, including herbal medicines and nonherbal dietary supplements, is also briefly reviewed.

Pharmacokinetics in the Medically Ill

Pharmacokinetics describes what the body does to the drug. It characterizes the rate and extent of drug absorption, distribution, metabolism, and excretion. These pharmacokinetic processes determine the rate of drug delivery to, and its concentration at, its sites of action. *Pharmacodynamics* describes the effects of a drug on the body. Pharmacodynamic processes determine the relationship between drug concentration and response for both therapeutic and adverse effects.

Absorption

Absorption of a drug is influenced by the characteristics of the absorption site and the physiochemical properties of a

drug. Specific site properties that may affect absorption include surface area, ambient pH, mucosal integrity and function, and local blood flow. Orally administered drugs absorbed through the gastrointestinal tract may be extensively altered by “first-pass” hepatic metabolism before entering the systemic circulation. Sublingual, intranasal, topical, and intramuscular administration of drugs minimizes this first-pass effect, and rectal administration may reduce the first-pass effect by 50%. Drug formulation, drug interactions, gastric motility, and the characteristics of the absorptive surface all influence the *rate* of absorption, a key factor when rapid onset is desired. The *extent* of drug absorption, however, is more important with chronic administration. The *bioavailability* of a drug describes the rate and extent to which the drug ingredient is absorbed from the drug product and available for drug action. Intravenous drug delivery has 100% bioavailability.

Distribution

Systemic drug distribution is influenced by serum pH, blood flow, protein binding, lipid solubility, and the degree of ionization. Most drugs bind to proteins, either albumin or alpha₁ acid glycoprotein (AAGP), to a greater or lesser extent. Disease may alter the concentrations of serum proteins as well as binding affinities. For example, albumin binding is decreased in pregnancy and in a number of illnesses (e.g., cirrhosis, bacterial pneumonia, acute pancreatitis, renal failure, surgery, and trauma). In contrast, some disease states, such as hypothyroidism, may increase protein binding. AAGP concentrations may increase in Crohn’s disease, myocardial infarction, stress, surgery, and trauma.

Typically, acidic drugs (e.g., valproate, barbiturates) bind mostly to albumin, and more basic drugs (e.g., phenothiazines, tricyclic antidepressants [TCAs], amphetamines, most benzodiazepines) bind to globulins. In general, only

free (unbound to plasma proteins) drug is pharmacologically active. Decreases in protein binding increase the availability of the “free” drug for pharmacological action, metabolism, and excretion. Providing metabolic and excretory processes are unchanged by disease, any changes to protein binding of a drug are compensated by an increase in drug elimination (metabolism and excretion) resulting in little change of steady-state plasma concentrations of pharmacologically active free drug. However, although free drug levels may remain unchanged, changes in protein binding will reduce plasma levels of total drug (free + bound fractions). While of no consequence therapeutically, therapeutic drug monitoring procedures that measure total drug levels could mislead the clinician by suggesting lower, possibly subtherapeutic, levels and might prompt a dosage increase with possible toxic effects. For this reason, during pregnancy or in patients with uremia, chronic hepatic disease, hypoalbuminemia, or a protein-binding drug interaction, the use of therapeutic drug monitoring for dosage adjustment requires caution; clinical response to the drug (e.g., international normalized ratio [INR] for warfarin), rather than laboratory-determined drug levels, should guide dosage. Where therapeutic drug monitoring is employed, methods selective for unbound drug should be used, if available, for phenytoin, valproate, tacrolimus, cyclosporine, amitriptyline, haloperidol, and possibly carbamazepine (Dasgupta 2007).

Most diseases that affect protein binding also affect metabolism and excretion. In this case, disease-induced changes in free drug availability may have clinically significant consequences, especially for drugs with a low therapeutic index.

Volume of distribution is a function of a drug's lipid solubility and plasma- and tissue-binding properties. Most psychotropic drugs are lipophilic but are also extensively bound to plasma proteins. Volume of distribution is unpredictably altered by disease and is not useful in guiding dosage adjustments for medically ill patients.

Metabolism (or Biotransformation) and Elimination

Biotransformation occurs throughout the body, with the greatest activity in the liver and gut wall. Most psychotropic drugs are eliminated by hepatic metabolism and renal excretion. Two phases of hepatic metabolism enable drug excretion by increasing its water solubility. Phase I metabolism consists of oxidation (i.e., cytochrome P450 monooxygenase system), reduction, or hydrolysis, which prepares medications for excretion or further metabolism by phase II pathways. The monoamine oxidases (MAOs) are also considered part of phase I processes. Phase II metabolism consists of many conjugation pathways, the most common

being glucuronidation, acetylation, and sulfation. The hepatic clearance of drugs may be limited by either the rate of delivery (i.e., hepatic blood flow) of the drug to the hepatic metabolizing enzymes or the intrinsic capacity of the enzymes to metabolize the substrate. Clinically significant decreases in hepatic blood flow occur only in severe cirrhosis, and when possible, parenteral administration of drugs is preferred because this route bypasses first-pass metabolism. Hepatic disease may preferentially affect anatomic regions of the liver, thereby altering specific metabolic processes. For example, oxidative metabolic reactions are more concentrated in the pericentral regions affected by acute viral hepatitis or alcoholic liver disease. Disease affecting the periportal regions, such as chronic hepatitis (in the absence of cirrhosis), may spare some hepatic oxidative function. In addition, acute and chronic liver diseases generally spare glucuronide conjugation reactions. Metabolic reactions altering the intrinsic capacity of the enzymes through inhibition and induction are discussed in the next section (“Drug-Drug Interactions”).

The kidney's primary pharmacokinetic role is drug elimination. However, renal disease may affect absorption, distribution, and metabolism of drugs. Creatinine clearance is a more useful indicator of renal function than serum creatinine. Specific drugs and their use in renal failure are covered later in this chapter. In general, despite the complexity of pharmacokinetic changes in renal failure, most psychotropics, other than lithium, gabapentin, pregabalin, topiramate, memantine, paliperidone, paroxetine, desvenlafaxine, and venlafaxine, do not require drastic dosage adjustment.

Disease processes, particularly those involving the gastrointestinal tract, liver, heart, and kidneys, can alter absorption, distribution, metabolism, and elimination. Table 38-1 summarizes how disease in these organ systems may alter the pharmacokinetics of psychotropic medications.

Drug-Drug Interactions

Drug-drug interactions are pharmacodynamic or pharmacokinetic in nature. Pharmacodynamic interactions involve alterations in the pharmacological response to a drug, which may be additive, synergistic, or antagonistic. These interactions may occur directly, by altering drug binding to the receptor site, or indirectly through other mechanisms. Pharmacokinetic interactions include altered absorption, distribution, metabolism, or excretion and often change the drug concentration in tissues.

Pharmacokinetic interactions are understood in terms of the actions of an interacting drug (a metabolic inhibitor or inducer) on a substrate drug. A *substrate* is an agent or a

TABLE 38-1. Pharmacokinetics in the medically ill

Pharmacokinetic parameter	Potential factors	Clinical significance
Liver disease		
Absorption	Gastric acidity Gastric and intestinal motility Small intestine surface area (e.g., short gut) Enteric blood flow Reduced hepatic blood flow Portosystemic shunting	Minimize gastrointestinal side effects of psychotropics Liquid formulations may be better or more quickly absorbed than solid drug formulations Motility, secretory, and enteric blood flow changes in gastrointestinal disease usually do not require dosage change Consider parenteral administration
Distribution	Alterations in liver blood flow Changes in plasma proteins Albumin may fall AAGP may rise Decreases in binding affinities Fluid shifts (e.g., ascites)	Reduce dose Serum levels of drugs (bound + free) may be misleading
Metabolism and excretion	Reduced hepatic blood flow Reduced intrinsic capacity of the enzymes	Clinically significant reductions only occur in severe cirrhosis
Renal disease		
Absorption	Ammonia buffering may raise gastric pH	Rarely clinically significant changes in pharmacokinetics Major exceptions—lithium and gabapentin
Distribution	Altered body water volume Reduced protein binding	Exact prediction of pharmacokinetic changes in the context of renal disease is impractical clinically Monitor drug levels more frequently but interpretation of blood levels difficult Serum levels of drugs (bound + free) may be misleading
Metabolism and excretion	Reduced renal blood flow Glomerular function	Creatinine clearance is a useful indicator of renal function to guide dose adjustments Serum creatinine may be confounded by some diseases that affect creatinine metabolism Dialysis alters pharmacokinetics
Cardiac disease		
Absorption	Decreased perfusion of drug absorption sites Intestinal wall edema may reduce absorption Changes in autonomic activity may affect GI motility and cause vasoconstriction	Congestive heart failure may decrease absorption of drugs through the gastrointestinal tract Intramuscular drug absorption may be decreased by vasoconstriction
Distribution	Changes in plasma proteins AAGP may rise Albumin may fall Volume of distribution is reduced Regional blood flow redistributions	Acute doses should be reduced by approximately 50% Intravenous infusions should be given at a slower rate to avoid toxicity
Metabolism and excretion	Reduced renal and hepatic blood flow	A 50% reduction of dosage for chronic drug administration should be considered

Note. AAGP = α_1 acid glycoprotein; GI = gastrointestinal.

drug that is metabolized by an enzyme. An *inducer* is an agent or drug that increases the activity of the metabolic enzyme, allowing for an increased rate of metabolism. Induction may decrease the amount of circulating parent drug and increase the number and amount of metabolites produced. The clinical effect may be a loss or decrease in therapeutic efficacy or an increase in toxicity from metabolites. An *inhibitor* has the opposite effect, decreasing or blocking enzyme activity needed for the metabolism of other drugs. An enzyme inhibitor increases the concentration of any drug dependent on that enzyme for biotransformation, thereby prolonging the pharmacological effect or increasing toxicity.

The hepatic cytochrome P450 (CYP) enzyme system catalyzes most phase I reactions and is involved in most metabolic drug interactions. Three CYP enzyme families are important in humans: CYP1, CYP2, and CYP3. The families are divided into subfamilies identified by a capital letter (e.g., CYP3A), and the subfamilies further divided into isozymes based on the homology between subfamily proteins. CYP enzymes for drug metabolism are CYP1A2, 2C9, 2C19, 2D6, and 3A4. Because some of these enzymes exist in a polymorphic form, a small percentage of the population has one or more CYP enzymes with significantly altered activity. These individuals are identified as either poor or extensive metabolizers for that specific isozyme.

Phase II reactions are conjugation reactions in which the drug is coupled to water-soluble molecules to enhance its excretion. The most abundant phase II enzymes belong to the superfamily of uridine glucuronosyltransferases (UGTs). The UGT superfamily of enzymes is classified by a system similar to that for CYP enzymes. There are two clinically significant UGT subfamilies: 1A and 2B. As with the CYP system, there can be substrates, inhibitors, and inducers of UGT enzymes. For example, the benzodiazepines primarily metabolized by conjugation (oxazepam, lorazepam, and temazepam) are glucuronidated by UGT2B7. A number of nonsteroidal anti-inflammatory drugs (NSAIDs) are competitive inhibitors of UGT2B7. Phenobarbital, rifampin, and oral contraceptive drugs appear to be inducers of UGT2B7. The role of UGTs in clinical pharmacology is being increasingly recognized.

A third system involved in drug elimination is P-glycoprotein (P-gp). P-gp is an efflux transporter present in the gut, liver and biliary systems, gonads, kidneys, brain, and other organs. P-gps protect the body from harmful substances by transporting certain hydrophobic compounds out of the brain and other organs and into the gut, urine, and bile. The distribution and elimination of many clinically important therapeutic substances are altered by P-gps. For example, P-gps in the gut limit absorption of certain compounds and significantly influence oral bioavail-

ability and "first-pass" effects. P-gps in the blood-brain barrier contribute to the functional integrity of the barrier.

As with the CYP and UGT enzyme systems, there are substrates, inhibitors, and inducers of the P-gp transporters. Administration of a P-gp inhibitor will increase oral bioavailability and central nervous system (CNS) access of a substrate drug, with opposite effects for an inducer. For example, loperamide (an over-the-counter antidiarrheal) is a P-gp substrate normally transported out of the brain and therefore without central opiate effects. When coadministered with quinidine (a P-gp inhibitor), loperamide brain concentrations increase and signs of respiratory depression can occur (Sadeque et al. 2000). Many factors can alter P-gp function and influence P-gp-based interactions; these include genetic differences, gender, herbal supplements, foods, and hormones (Cozza et al. 2003). As with UGTs, the role and interactions of P-gps in clinical pharmacology is being increasingly recognized.

General Principles

Prescribing in a polypharmacy environment, usually the norm in medically ill patients, requires vigilance regarding the many potential drug-drug interactions. To commit to memory all potential drug-drug interactions associated with psychotropic medications is practically impossible as these interactions are constantly changing with our knowledge and the development of new medications. Knowing a drug's metabolic pathways and the metabolic inhibitory or inductive effects of the coadministered drug enables a rough prediction of potential interactions. However, it should be remembered that drug concentration changes do not necessarily translate into clinically meaningful interactions. Cozza et al. (2003) advised that physicians prescribing in a polypharmacy environment should, whenever possible, avoid medications that significantly inhibit or induce CYP enzymes and prefer those eliminated by multiple pathways and with a wide safety margin.

Identification of Potential Pharmacokinetic Interactions

Most pharmacokinetic drug-drug interactions involve the effects of an interacting drug on the CYP-mediated metabolism of a substrate drug. The interacting drug may be either an inhibitor or an inducer of the critical CYP isozymes involved in the substrate drug's metabolism. However, not all combinations of interacting drug with substrate will result in clinically significant drug-drug interactions. For these interactions to be clinically relevant, the substrate must have certain characteristics. A *critical substrate* drug is a drug with a narrow therapeutic index and one primary CYP isozyme mediating its elimination. For example, nifedipine, like all calcium channel blockers, is primarily metab-

olized by the CYP3A4 isozyme. The addition of a drug that is a potent CYP3A4 inhibitor, such as fluoxetine, will inhibit nifedipine's metabolism. Without a compensatory reduction in nifedipine dose, nifedipine levels will rise and toxicity may result. On the other hand, the addition of an inhibitor or inducer that interacts with a CYP isozyme other than CYP3A4 will have no significant effect on nifedipine levels. Table 38-2 lists those drugs that are critical substrates and significant inhibitors and inducers of CYP isozymes, MAO, UGT, and P-gp.

Metabolic drug interactions are most likely to occur in three situations:

1. The addition of an interacting drug to a medication regime containing a substrate drug at steady-state levels may dramatically alter substrate drug concentration. If the interacting drug is an inhibitor, substrate drug concentrations will rise as its elimination is reduced and toxicity may result. Conversely, addition of an enzyme inducer will increase elimination of the substrate, thereby lowering its concentration and therapeutic effect.
2. A much overlooked interaction involves the withdrawal of an interacting drug from an established drug regimen containing a critical substrate drug. Previously, the substrate drug dosage will have been titrated in the presence of the interacting drug to optimize therapeutic effect and minimize adverse effects. Withdrawal of an enzyme inhibitor will allow metabolism to return (increase) to normal levels. This increased substrate drug metabolism will result in lower levels and decreased therapeutic effect. In contrast, removal of an enzyme inducer will increase substrate drug levels and may lead to drug toxicity as metabolism of the substrate decreases to a normal rate.
3. The addition of a critical substrate drug to a drug regimen containing an interacting drug can result in a clinically significant interaction if the substrate is dosed according to established guidelines. Dosing guidelines do not account for the presence of a metabolic inhibitor or inducer and thus may lead to substrate concentrations that are, respectively, toxic or subtherapeutic.

Metabolic drug interactions can be minimized by avoiding drugs that are known critical substrates or potent inhibitors or inducers. Unfortunately, this is not always possible. However, by identifying medications that are critical substrates or potent inhibitors or inducers, making appropriate dosage adjustments, and monitoring drug levels (where possible), the adverse effects of these metabolic interactions will be reduced.

Drug interactions that affect renal drug elimination are clinically significant only if the parent drug or its active metabolite undergoes appreciable renal elimination. Changes in urine pH can modify the elimination of those compounds whose ratio of ionized/un-ionized forms is dramatically altered across the physiological range of urine pH (4.6 to 8.2) (i.e., the compound has a pKa within this pH range). Common drugs that alkalinize urine include antacids and carbonic anhydrase inhibitor diuretics. Un-ionized forms of drugs undergo greater glomerular resorption, whereas ionized drug forms are resorbed less and so have greater urinary excretion. For a basic drug such as amphetamine, alkalinization of urine increases the un-ionized fraction, enhancing resorption and so prolonging activity. Other basic psychotropic drugs, such as amitriptyline, imipramine, meperidine, methadone (Nilsson et al. 1982), memantine, and flecainide, may be similarly affected (Cadwallader 1983; Freudenthaler et al. 1998).

Side Effects and Toxicity of Major Psychotropic Drug Classes

Antidepressants

Antidepressant drugs are used to treat affective, anxiety, eating, and some somatoform disorders as well as insomnia, enuresis, incontinence, headaches, and chronic pain.

Selective Serotonin Reuptake Inhibitors and Novel/Mixed-Action Agents

Adverse effects of selective serotonin reuptake inhibitors (SSRIs) and novel/mixed-action agents are common, but they are usually mild, dose related, and abate over time. However, serotonergic agents, especially when used in combination, can induce the potentially fatal serotonin syndrome (see "Serotonin Syndrome" subsection later in this section).

Common short-term side effects with SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) include nausea, vomiting, anxiety, headache, sedation, tremors, and anorexia. Common long-term side effects include sexual dysfunction, dry mouth, sweating, impaired sleep, and potential weight gain. Trazodone and nefazodone do not disrupt sexual function or sleep. Trazodone causes sedation in 20%–50% of patients and is often used for its sedating properties. It also rarely causes priapism. Trazodone and nefazodone can cause orthostatic hypotension, and nefazodone can cause hepatotoxicity.

Frequent duloxetine side effects are nausea, dry mouth, fatigue, dizziness, constipation, somnolence, decreased appetite, and increased sweating (Eli Lilly 2010c). Mirtazapine is associated with a high incidence of sedation, increased

appetite, and weight gain (Thompson 1999). Common adverse effects of bupropion include agitation, insomnia, anxiety, dry mouth, constipation, postural hypotension, and tachycardia. Nausea and vomiting are much less common with bupropion than with SSRIs (Vanderkooy et al. 2002). Patients treated with reboxetine (used only in Europe) often report dry mouth, insomnia, constipation, sweating, and hypotension (Andreoli et al. 2002). Milnacipran, an SNRI approved for depression in Europe and Japan and approved by the U.S. Food and Drug Administration (FDA) for fibromyalgia, is associated with constipation, flushing, sweating, vomiting, palpitations, increased heart rate and hypertension, and dry mouth (Cypress Bioscience 2010), similar to the other SNRIs.

Central nervous system. An association between SSRI use and increased suicidal ideation was proposed by Teicher et al. in 1990 on the basis of case reports. However, an early review of controlled antidepressant trial reports by the FDA suggested no difference in suicide risk between antidepressant- and placebo-treated depressed patients or between SSRIs and other antidepressants (Khan et al. 2003). In contrast, Fergusson et al. (2005), following a review of 345 controlled trials, suggested that SSRIs have a suicide attempt rate similar to that of TCAs and more than double the rate of placebo. Supporting these findings, a later FDA meta-analysis of 23 placebo-controlled pediatric clinical trials for nine modern antidepressants in 4,582 patients identified a twofold increased risk for suicide for all drugs examined (Hammad et al. 2006). In May 2007, the FDA concluded that all antidepressants increase the risk of suicidal thinking and behavior in young adults (age ≤ 24 years) during initial treatment and required manufacturers to include in their labeling a warning statement that recommends close observation of young adult and pediatric patients treated with these agents for worsening depression or the emergence of suicidality.

Bupropion causes a dose-related lowering of the seizure threshold and may precipitate seizures in susceptible patients receiving dosages above 450 mg/day. The incidence of seizure rises with increasing dosage, from 0.1% at 100–300 mg/day, through 0.4% at 300–450 mg/day, to 2.3% at dosages over 600 mg/day (McEvoy 2008). The seizure risk reported for other antidepressants ranges from 0.04% for mirtazapine to 0.5% for clomipramine (Harden and Goldstein 2002; Rosenstein et al. 1993). Given that the annual incidence of first unprovoked seizure is 0.06% in the general population, seizure risk for patients taking most antidepressants is not elevated. However, it is clear that certain antidepressants, including bupropion, clomipramine, maprotiline, and venlafaxine, are associated with a greater seizure risk than are other antidepressants

(Harden and Goldstein 2002; Whyte et al. 2003), but this is rarely significant except at toxic doses.

Potential side effects of SSRIs include SSRI-induced extrapyramidal symptoms (EPS), likely resulting from serotonergic antagonism of dopaminergic pathways in the CNS. Akathisia, dystonia, parkinsonism, and tardive dyskinesia-like states have been reported, with akathisia being the most common effect and tardive dyskinesia-like states being the least common. Certain patients appear to be at increased risk, such as the elderly, patients with Parkinson's disease, and patients concurrently treated with dopamine antagonists (Leo 1996).

Serotonin syndrome. Serotonin syndrome is an uncommon but potentially life-threatening complication of treatment with serotonergic agents. Overall, there is considerable heterogeneity in the reported clinical features of serotonin syndrome (Table 38–3), reflecting the variation in the degree of severity of the syndrome. The incidence of the syndrome is unknown, in part because many physicians are unaware of the syndrome as a clinical diagnosis (Mackay et al. 1999) and because uniform diagnostic criteria are lacking. Virtually all medications that potentiate serotonergic neurotransmission in the CNS have been reported in association with serotonin syndrome. The antidepressant combinations most commonly implicated have been monoamine oxidase inhibitors (MAOIs; reversible and irreversible) and TCAs, MAOIs and SSRIs, and MAOIs and venlafaxine. Table 38–4 lists other serotonergic drugs.

Currently there is no formal consensus regarding diagnostic criteria for serotonin syndrome. The first operationalized criteria were proposed by Sternbach (1991) but were found to have low specificity. The Hunter Serotonin Toxicity Criteria have subsequently gained acceptance as a simple set of highly sensitive and specific decision rules; these criteria are listed in Table 38–5 (Dunkley et al. 2003). Laboratory findings have not been commonly reported in cases of serotonin syndrome, but some reports have noted leukocytosis, rhabdomyolysis with elevated creatine phosphokinase (CPK), serum hepatic transaminase elevations, electrolyte abnormalities (hyponatremia, hypomagnesemia, hypercalcemia), and disseminated intravascular coagulopathy. The differential diagnosis includes CNS infection (e.g., encephalitis, meningitis), delirium tremens, poisoning with anticholinergic or adrenergic agents, neuroleptic malignant syndrome (NMS), and malignant hyperthermia. Differentiating serotonin syndrome from NMS can be very difficult in patients receiving both serotonergic and antipsychotic medications (see “Neuroleptic Malignant Syndrome” subsection under “Antipsychotics” later in this chapter).

TABLE 38-3. Clinical features of serotonin syndrome

Category	Clinical features
Mental status and behavioral	Delirium, confusion, agitation, anxiety, irritability, euphoria, dysphoria, restlessness
Neurological and motor	Ataxia/incoordination, tremor, muscle rigidity, myoclonus, hyperreflexia, clonus, seizures, trismus, teeth chattering
Gastrointestinal	Nausea, vomiting, diarrhea, incontinence
Autonomic nervous system	Hypertension, hypotension, tachycardia, diaphoresis, shivering, sialorrhea, mydriasis, tachypnea, pupillary dilation
Thermoregulation	Hyperthermia

Source. Compiled in part from Keck and Arnold 2000.

Serotonin syndrome is often self-limited and usually resolves quickly after discontinuation of serotonergic agents. Management includes the following basic principles: 1) discontinue all serotonergic agents, 2) provide necessary supportive care, 3) anticipate potential complications, 4) consider administering antiserotonergic agents, and 5) reassess the need for psychopharmacological therapy before reinstituting drug therapy (Keck and Arnold 2000). Some patients will require admission to an intensive care unit, but most will show some improvement within 24 hours with supportive care alone. There are no specific antidotes available for the treatment of serotonin syndrome. The antihistamine cyproheptadine is the most consistently effective serotonin antagonist reported. The recommended adult dose is 4–8 mg and may be repeated every 1–4 hours up to a maximum daily dose of 32 mg. There is limited information on drug rechallenge in patients who have developed serotonin syndrome. General guidelines include reevaluating the necessity for drug therapy, considering a switch to a nonserotonergic medication, using single-drug therapy when serotonergic medications are required, and considering an extended (6-week) serotonin “drug-free” period before restarting a serotonergic agent (Mills 1997).

Autonomic and cardiovascular. The SSRIs and the novel/mixed-action antidepressants have a much safer cardiovascular profile than the TCAs and MAOIs. In general, the SSRIs have little effect on blood pressure or cardiac conduction (Glassman et al. 2002). Fluoxetine has been reported to rarely cause mild bradycardia in elderly patients with preexisting cardiac arrhythmias (Upward et al. 1988), and this may occur with other SSRIs as well (Roose and Miyazaki 2005).

TABLE 38-4. Drugs that potentiate serotonin in the central nervous system

Mechanism	Drug
Enhance serotonin synthesis	L-Tryptophan
Increase serotonin release	Cocaine Amphetamine Sibutramine Dextromethorphan, meperidine, fentanyl MDMA (Ecstasy) Lithium
Stimulate serotonin receptors	Buspirone Triptans Ergot alkaloids Trazodone, nefazodone
Inhibit serotonin catabolism	Antidepressant MAOIs Moclobemide Selegiline Linezolid Isoniazid Procarbazine
Inhibit serotonin reuptake	SSRIs Mirtazapine Trazodone, nefazodone Venlafaxine, desvenlafaxine, duloxetine, milnacipran TCAs Dextromethorphan, meperidine (pethidine) Tramadol

Note. MAOIs = monoamine oxidase inhibitors; MDMA = 3, 4-methylenedioxymethamphetamine; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

The novel/mixed-action agents venlafaxine, desvenlafaxine, duloxetine, bupropion, nefazodone, mirtazapine, and reboxetine have little effect on cardiac conduction but may affect blood pressure or heart rate (Khawaja and Feinstein 2003; Pfizer 2010b). Venlafaxine exhibits dose-related increases in heart rate (mean increase of 4 beats/minute over placebo) and blood pressure. Placebo-controlled clinical trials of venlafaxine observed an average diastolic pressure increase of 7 mm Hg at dosages of more than 300 mg/day and clinically significant diastolic pressure increases (≥ 15 mm Hg) in 5.5% of patients taking the drug at dosages of more than 200 mg/day (Feighner 1995). Similar effects would be expected for desvenlafaxine. Duloxetine appears to be without clinically significant effects on heart rate, blood pres-

TABLE 38–5. Diagnostic criteria for serotonin syndrome**Use of a serotonergic agent****Plus any of the following symptoms:**

- Spontaneous clonus
- Inducible clonus plus either agitation or diaphoresis
- Tremor plus hyperreflexia
- Muscle rigidity plus elevated body temperature plus either ocular clonus or inducible clonus

Exclude:

- Infection, metabolic, endocrine, or toxic causes
- Neuroleptic malignant syndrome
- Delirium tremens
- Malignant hyperthermia

Source. Compiled from Boyer and Shannon 2005; Dunkley et al. 2003; Prator 2006.

sure, or QT interval (Wernicke et al. 2007b). Bupropion is reported to cause hypertension without affecting heart rate in some patients. In patients using transdermal nicotine, bupropion is associated with a 6.1% incidence of hypertension (Khawaja and Feinstein 2003). Reboxetine has also been associated with an increase in heart rate of 8–11 beats/minute (Fleishaker et al. 2001) but without any significant effect on electrocardiography (Andreoli et al. 2002). Trazodone lacks significant effects on cardiac conduction but in rare cases was reported to cause ventricular ectopy and ventricular tachycardia. The most frequent cardiovascular adverse effect of trazodone is postural hypotension, which may be associated with syncope. Nefazodone is structurally related to trazodone but has a lower incidence of postural hypotension (3%). Mirtazapine does not have significant effects on cardiac conduction, but because of its moderate α_1 -antagonist activity, it has a 7% incidence of orthostatic hypotension (Khawaja and Feinstein 2003). Hypotension is observed in 10% of patients receiving reboxetine.

Gastrointestinal. Nausea is the most common adverse effect associated with the serotonergic antidepressants. Nausea is most likely to occur in patients receiving fluvoxamine (36%), venlafaxine (37%), and duloxetine at a starting dose of 60 mg/day (35%–40%) (Detke et al. 2002a, 2002b). Other serotonergic antidepressants have a lower incidence (20%–26%) of nausea, but these incidences are still much higher than those seen with placebo (9.3%–11.8%) (Nelson 1997; Repchinsky 2009). Diarrhea was more prevalent with sertraline than with other SSRIs (Meijer et al. 2002).

Although most adverse gastrointestinal effects of serotonergic antidepressants are dose related and generally de-

crease with continued treatment, sometimes severe side effects require antidepressant discontinuation. Potential severe hepatotoxicity with nefazodone has led to its removal from the market in a number of countries, and it should not be used in patients with preexisting liver disease (D.E. Stewart 2002). Duloxetine-related hepatotoxicity in 1.1% of patients has prompted product monograph warnings (Eli Lilly 2010c); however, a review of duloxetine hepatic safety suggested no increase in hepatotoxicity compared with other conventional antidepressants (McIntyre et al. 2008). Pancreatitis has also rarely been reported with mirtazapine (Hussain and Burke 2008).

Hematological. SSRIs are associated with a slightly increased risk of bleeding disorders, including gastrointestinal bleeding. This effect is discussed in the “Psychotropic Drug Use in the Medically Ill” section later in this chapter.

Weight gain/loss. Weight gain is a relatively common problem during both acute and long-term treatment with antidepressants. TCAs and the MAOI phenelzine are more likely to cause weight gain than other antidepressants, with the exception of mirtazapine. Mirtazapine was associated with weight gain (defined as $\geq 7\%$ weight increase during treatment) in 26% of patients followed by SSRIs and venlafaxine (16%–19%). Bupropion and nefazodone rarely cause weight gain (12%) (Papakostas 2007). Duloxetine may cause less weight gain than SSRIs (Dunner et al. 2008).

Sexual dysfunction. Refer to Chapter 16, “Sexual Dysfunction,” for a discussion of the sexual side effects of psychotropic medications.

Drug interactions. Many SSRIs and novel/mixed-action antidepressants are potent inhibitors of CYP isozymes and may significantly increase the blood levels, and the potential for toxic effects, of other coadministered narrow-therapeutic-index medications metabolized by these enzymes. See Table 38–2 for a listing of critical narrow-therapeutic-index drug substrates for these enzymes.

The use of multiple serotonergic drugs can induce serotonin syndrome (see “Serotonin Syndrome” subsection earlier in the chapter).

Serotonin discontinuation syndrome. Abrupt discontinuation of SSRIs or SNRIs, especially those with short half-lives (e.g., fluvoxamine, paroxetine, venlafaxine), may give rise to a discontinuation syndrome characterized by a wide variety of symptoms, including psychiatric, neurological, and flulike symptoms (nausea, vomiting, sweats); sleep disturbances; and headache (Haddad 1998), usually resolving within 3 weeks. Antidepressants, like all psychoactive med-

ications, should be gradually withdrawn. Discontinuation symptoms can cause misdiagnosis and inappropriate treatment, particularly in a patient with an active medical illness, as well as erode future compliance.

Tricyclic Antidepressants

TCAs are now viewed as second-line treatments for depression because their adverse-effect profile is less benign than that of SSRIs and novel/mixed-action agents. Death from TCA-induced cardiac conduction abnormalities was not uncommon in overdose.

Many adverse effects of TCAs are due not to their effects on serotonin (5-HT) or norepinephrine reuptake inhibition but rather to secondary pharmacological activities. TCAs are antagonists at histamine H₁, adrenergic alpha₁, and muscarinic receptors and have Type 1A antiarrhythmic (quinidine-like) effects from their blockade of voltage-dependent Na⁺ channels. Adverse effects of TCAs include sedation, anticholinergic effects (dry mouth, dry eyes, constipation, urinary retention, decreased sweating, confusion, memory impairment, tachycardia, blurred vision), and postural hypotension. Tolerance to these effects usually develops over time. TCAs at or just above therapeutic plasma levels frequently prolong PR, QRS, and QTc intervals but rarely to a clinically significant degree in patients without preexisting cardiac disease or conduction defects (Glassman 1984). TCAs can cause heart block, arrhythmias, palpitations, tachycardia, syncope, and heart failure and should be used with caution in patients with preexisting cardiovascular disease or at risk of suicide. Following the discovery that class I antiarrhythmic drugs can increase mortality in patients with ischemic heart disease, it is prudent to assume that TCAs may carry the same risk in these patients (Cardiac Arrhythmia Suppression Trial [CAST] Investigators 1989; Roose and Miyazaki 2005).

Drug interactions. The combination of TCAs and other drugs with sedating, hypotensive, antiarrhythmic, or seizure threshold-lowering properties may lead to additive toxicity.

Concomitant use of TCAs and drugs with anticholinergic properties may cause an anticholinergic crisis characterized by delirium, hyperthermia (especially in hot environments), tachycardia, and paralytic ileus.

Coadministration of TCAs with MAOIs and other drugs with MAOI activity may precipitate serotonin syndrome or hyperpyretic crisis (hyperpyrexia, sweating, confusion, myoclonus, seizures, hypertension, and tachycardia), either of which may be fatal. The combination of serotonergic effects from cotherapy with some TCAs and SSRIs may precipitate serotonin syndrome (see "Serotonin Syndrome" subsection earlier in this chapter).

TCAs are narrow-therapeutic-index drugs, each metabolized predominantly by either CYP2D6 or CYP3A4. Inhibitors of these enzymes can cause TCA toxicity by dramatically increasing TCA serum levels. Many agents, including several SSRIs and novel/mixed-action antidepressants, are potent inhibitors of these CYP isozymes (see Table 38-2). Plasma levels of TCAs should be monitored if they are coadministered with such inhibitors.

Toxicity/overdose. TCA overdose carries a risk of death from cardiac conduction abnormalities that result in malignant ventricular arrhythmias. Initial symptoms of overdose involve CNS stimulation, in part due to anticholinergic effects, and include hyperpyrexia, delirium, hypertension, hallucinations, seizure, agitation, hyperreflexia, and parkinsonian symptoms. The initial stimulation phase is typically followed by CNS depression with drowsiness, areflexia, hypothermia, respiratory depression, severe hypotension, and coma. Risk of cardiotoxicity is high if the QRS interval is 100 msec or more (Boehnert and Lovejoy 1985) or if the total TCA plasma concentration is greater than 1,000 ng/mL; concentrations greater than 2,500 ng/mL are often fatal (Foulke and Albertson 1987).

Treatment for overdose includes removal of any unabsorbed medication from the stomach (gastric lavage and then activated charcoal to reduce absorption), followed by supportive therapy and close monitoring (see Chapter 37, "Medical Toxicology"). Cardiac conduction abnormalities, arrhythmias, and hypotension may be treated with administration of intravenous sodium bicarbonate to produce a serum pH of 7.4–7.5. Life-threatening anticholinergic effects may be managed with physostigmine. Because of their large volumes of distribution and extensive protein binding, TCAs are not removed by dialysis.

Abrupt discontinuation of TCAs may give rise to a discontinuation syndrome characterized by dizziness, lethargy, headache, nightmares, and symptoms of anticholinergic rebound, including gastrointestinal upset, nausea, vomiting, diarrhea, excessive salivation, sweating, anxiety, restlessness, piloerection, and delirium (Dilsaver and Greden 1984). This syndrome can be avoided by gradual withdrawal.

Monoamine Oxidase Inhibitors

MAOIs, with the possible exception of moclobemide (not available in the United States), are seen as third-line antidepressants because of their significant drug interactions and the dietary restrictions that accompany their use (Howland 2006). Moclobemide, a short-half-life reversible inhibitor of monoamine oxidase type A (MAO-A), is less susceptible to dietary interactions provided that it is taken after meals. Common adverse effects of MAOIs include

orthostatic hypotension, dizziness, headache, sedation, insomnia or hypersomnia, tremor, and hyperreflexia. Interactions between MAOIs and direct- or indirect-acting sympathomimetics or dopaminergic agonists may cause a hypertensive crisis. MAOIs may trigger serotonin syndrome when combined with other medications (see “Serotonin Syndrome” subsection earlier in chapter). Moclobemide shares the potential to cause hypertensive crises and serotonin syndrome with the irreversible agents. MAOIs may greatly potentiate the hypotensive effects of antihypertensive agents, including diuretics.

Selegiline, a semiselective monoamine oxidase type B (MAO-B) inhibitor used to treat Parkinson’s disease, and now as a transdermal patch indicated for depression, may also contribute to serotonin syndrome. At oral dosages greater than 10 mg/day, and with patch strengths greater than 6 mg, selegiline also inhibits MAO-A and thus shares many of the adverse effects and drug–food interactions, including hypertensive crisis, of the antidepressant MAOIs.

Toxicity/overdose. Symptoms of MAOI overdose are an extension of the normal adverse-effect profile. Treatment for overdose includes removal of any unabsorbed medication from the stomach and supportive measures.

Treatment for hypertensive crisis involves discontinuing the MAOI and slowly administering intravenous phenolamine (typical adult dose: 5 mg). **Beta-blockers should never be used;** beta-blockade allows unrestrained alpha-adrenergic stimulation, which further exacerbates the hypertension.

Mood Stabilizers/Anticonvulsants

Mood stabilizers are used in the medically ill to treat primary and secondary mood disorders as well as for symptoms such as headache and chronic pain.

Many, but not all, anticonvulsants appear to have mood-stabilizing properties. Valproate, carbamazepine, and oxcarbazepine are the most commonly used anticonvulsant mood stabilizers. Controlled studies do not support the use of gabapentin as a mood stabilizer (Evins 2003).

Lithium

Most patients using lithium experience some side effects, both acute (gastrointestinal distress and tremor) and long term (polyuria and polydipsia, hypothyroidism, weight gain, impaired cognition, sedation, impaired coordination, edema, acne, and hair loss), most of which are mild and dose related (Freeman and Freeman 2006; Peet and Pratt 1993). Adverse effects of lithium can be minimized by reducing the dose or decreasing the rate of absorption from the gut by administering the drug either in divided doses with meals or in a slow-release dosage form.

Central nervous system. Headache, fatigue, hand tremor, and mild cognitive impairment are reported by up to 50% of patients beginning lithium treatment. Hand tremor is usually a benign, fine, rapid, intention tremor that resolves over time or can be managed by dose reduction or low-dose beta-blockers. The tremor does not respond to antiparkinsonian drugs. Muscle weakness, fatigue, and ataxia are also common initial adverse effects that usually resolve (McEvoy 2008). Mild cognitive impairment may be experienced during the first 6–8 months of treatment; although rarely progressive, this impairment is the most common reason for noncompliance (Gitlin et al. 1989). Compliance may be improved by patient education and use of the lowest effective dose (Berk and Berk 2003).

Autonomic and cardiovascular. Lithium causes benign reversible repolarization electrocardiographic changes in 20%–30% of patients (Mitchell and Mackenzie 1982), including T wave depression and inversion. Other cardiovascular effects of lithium include decreased heart rate, prolonged QT interval, and arrhythmias (Burggraf 1997; van Noord et al. 2009).

Renal. Lithium reduces renal response to antidiuretic hormone, resulting in polyuria and/or polydipsia initially in 30%–50% of patients and persisting in 10%–25%. Stopping lithium usually reverses this nephrogenic diabetes insipidus (McEvoy 2008). Apart from dry mouth, patients do not generally exhibit signs of dehydration. Management of polyuria may include changing to a single daily bedtime dose of lithium, decreasing dosage, and/or administering amiloride, considered the treatment of choice, or thiazide diuretics. If thiazide diuretics are added, lithium dosage should be reduced by 50% to compensate for thiazide-induced reduction of lithium excretion (Jefferson et al. 1987). Use of amiloride does not require a reduction in lithium dosage (Bendz and Aurell 1999). Edema has been reported in patients with a high sodium intake (>170 mEq/day), responsive to reduction in sodium intake or spironolactone (Stancer and Kivi 1971).

Both functional and morphological changes of the kidneys have been reported in lithium-poisoned patients. Chronic use of lithium may result in altered kidney morphology—including interstitial fibrosis, tubular atrophy, urinary casts, and, occasionally, glomerular sclerosis—in 10%–20% of patients (Bendz et al. 1996). These changes are not generally associated with impaired renal function. Although long-term lithium treatment is the only well-established factor associated with lithium-induced nephropathy, other factors such as age, previous episodes of lithium toxicity, and the presence of comorbid disorders may also contribute. Lithium dose is not strongly related

to nephrotoxic effects (Freeman and Freeman 2006). The progression of lithium nephrotoxicity to end-stage renal disease is rare (0.2% to 0.7%) and requires lithium use for several decades (Presne et al. 2003). Lithium is so efficacious in bipolar disorder that the risk of renal dysfunction during chronic use is considered acceptable with yearly monitoring of renal function.

Endocrine and metabolic. The prevalence of overt hypothyroidism has been reported to be as high as 8%–19% for patients taking lithium, compared with a prevalence of 0.5%–1.8% in the general population. Subclinical hypothyroidism has been reported in up to 23% of patients receiving lithium therapy, compared with rates of up to 10.4% in the general population. Elevated thyroid-stimulating hormone is present in approximately 30% of patients taking lithium for 6 months or more, and progression to overt hypothyroidism (elevated thyroid-stimulating hormone and low free T_4) may occur in as many as 5%–10% of patients per year (Kleiner et al. 1999) with greater risk in thyroid antibody-positive individuals (Bocchetta et al. 2007). Thyroid function should be assessed before lithium is started and periodically during therapy. Hypothyroidism can be treated with L-thyroxine and is not a contraindication to continuing lithium (Bauer and Whybrow 1990; see also Chapter 22, “Endocrine and Metabolic Disorders”).

Lithium-induced weight gain (>8% of baseline body weight) (Chengappa et al. 2002) is the second most common reason cited by patients for lithium noncompliance (Gitlin et al. 1989). Weight gain is a consequence of increased caloric intake in part due to consumption of high-calorie fluids in response to increased thirst (McEvoy 2008).

Dermatological. Dermatological adverse effects include dry skin, hair loss, and acne. Lithium-induced acne occurs in more than 30% of patients (Chan et al. 2000). These effects usually respond to standard treatment and rarely require lithium discontinuation. Alopecia and exacerbation of psoriasis occur less frequently. Lithium-induced psoriasis has been shown to respond to inositol supplements (Allan et al. 2004; see also Chapter 29, “Dermatology”).

Drug interactions. Lithium is almost entirely renally excreted, and most lithium filtered by the glomeruli is reabsorbed with sodium in the proximal tubule. Serum lithium levels are increased by thiazide diuretics, NSAIDs, angiotensin-converting enzyme inhibitors, sodium depletion, dehydration (Dunner 2003), and possibly verapamil (Wright and Jarrett 1991) and angiotensin receptor antagonists (Su et al. 2007). Acutely, loop diuretics increase lithium excretion, but with chronic use, compensatory changes leave lithium levels not greatly changed. Carbonic anhydrase in-

hibitors and osmotic diuretics reduce lithium levels. Potassium-sparing diuretics may increase lithium excretion (Owen and Levenson 2010). The effect of the direct renin inhibitor aliskiren on lithium excretion is presently unknown. (See Thomsen and Schou [1999] for a review of lithium drug interactions.)

Lithium may potentiate the neurological adverse effects of other drugs, for example, EPS and tremor (Dunner 2000). Several case reports suggest that lithium in combination with other serotonin-enhancing drugs may precipitate serotonin syndrome (Adan-Manes et al. 2006; Schweitzer and Tuckwell 1998).

Toxicity/overdose. Toxicity increases markedly as serum lithium levels exceed 1.5 mEq/L, and serum levels greater than 2.0 mEq/L are dangerous. However, some patients experience toxicity at “therapeutic” levels. Initial symptoms of toxicity include marked tremor, nausea, diarrhea, blurred vision, vertigo, confusion, and increased deep tendon reflexes, progressing to seizures, coma, cardiac arrhythmia, and possibly permanent neurological impairment as lithium levels increase.

Treatment for lithium toxicity includes gastric lavage or emesis followed by supportive measures. These measures include volume resuscitation with isotonic or one-half isotonic sodium chloride solution to enhance renal elimination of lithium in individuals with mild to moderate toxicity or hemodialysis for patients with severe toxicity and/or lithium levels of 3.5 mEq/L or higher (Jaeger et al. 1993; Menghini and Albright 2000).

Anticonvulsants

Central nervous system. The anticonvulsants valproate, carbamazepine, gabapentin, lamotrigine, oxcarbazepine, topiramate, tiagabine, zonisamide, and levetiracetam share a similar profile of CNS adverse effects. Sedation, ataxia, dizziness, muscle weakness, fatigue, and vision disturbances such as nystagmus and diplopia are common and often resolve with time, dosage reduction, or discontinuation. Studies of oxcarbazepine in epilepsy suggest a lower rate of most adverse effects than carbamazepine (Schmidt and Elger 2004). Patients with a previous psychiatric history were more likely to experience psychiatric adverse effects with levetiracetam, including affective disorder (1%), psychosis (3%), and aggression (2%) (Mula et al. 2003). Psychotic symptoms are an infrequent adverse effect with topiramate (Crawford 1998). Cognitive impairment is a common complication of anticonvulsant use. Among anticonvulsants used in psychiatry, the ranking of cognitive profile is (best to worst) gabapentin, valproate, lamotrigine, carbamazepine, levetiracetam > zonisamide, phenytoin, oxcarbazepine >> topiramate (Arif et al. 2009).

The incidence of adverse effects increases with anticonvulsant multitherapy.

Gastrointestinal. Symptoms of gastrointestinal distress, including nausea, vomiting, dyspepsia, diarrhea, and anorexia, are the most frequent adverse effects experienced with most anticonvulsants. These effects are often dose related and transient and can be minimized by giving the drug in divided doses, with meals, or with slow titration. Gastrointestinal effects appear less often with divalproex sodium than with valproate or sodium valproate. There are fewer gastrointestinal complaints with oxcarbazepine than with carbamazepine. Transient elevations in liver enzymes occur commonly with anticonvulsants (Bjornsson 2008). Significant changes in hepatic function are usually reversible with dosage reduction or discontinuation. However, fatal hepatotoxicity has been reported with valproate and carbamazepine. The risk of hepatic failure may be increased by combination therapy and comorbid hepatic disorders (Konig et al. 1999). Several anticonvulsants, including valproate, carbamazepine, and lamotrigine, are infrequently associated with drug-induced pancreatitis. (For further discussion, see “Gastrointestinal Disorders,” below.)

Hematological. Carbamazepine is frequently associated with transient leukopenia and rarely may cause aplastic anemia. Carbamazepine should be discontinued in patients with white blood cell (WBC) counts less than $3.0 \times 10^9/L$ or neutrophil counts less than $1.0 \times 10^9/L$, and patients must be educated to report early signs of anemia, infection, or bleeding (Sobotka et al. 1990).

Mild, asymptomatic leukopenia and thrombocytopenia have been observed with valproate and are generally reversible with dosage reduction or discontinuation. More severe cases of thrombocytopenia and agranulocytosis have also been reported (Finsterer et al. 2001; Tohen et al. 1995).

Renal. Carbamazepine and oxcarbazepine frequently cause the syndrome of inappropriate antidiuretic hormone secretion (SIADH), leading to hyponatremia and water intoxication. Hyponatremia is twice as likely with oxcarbazepine (29.9% of patients) than with carbamazepine (14.4%) (Dong et al. 2005), and more common in the elderly (van Amelsvoort et al. 1994). (For further discussion of SIADH, see the “Antipsychotics” section later in this chapter.)

Endocrine and metabolic. Weight gain is a common factor in noncompliance (Mendlewicz et al. 1999). Weight gain is especially a problem with valproate, with an average weight gain of >8% of baseline body weight (Chengappa et al. 2002). Gabapentin causes a 1% weight gain (Wang et al. 2002). Although carbamazepine is also reported to cause

weight gain, the incidence is less than with valproate (Corman et al. 1997). Lamotrigine has little effect on weight (Biton et al. 2001), whereas topiramate causes a weight loss of about 0.7% of body weight (Chengappa et al. 2002).

Topiramate inhibits carbonic anhydrase and can cause hyperchloremic, non-anion gap metabolic acidosis; in adult clinical trials, persistent reductions in serum bicarbonate occurred in 32% of patients, and levels were markedly low (<17 mEq/L) in up to 7%, depending on dose. The incidence of a persistent reduction in serum bicarbonate is greater in pediatric patients (Ortho-McNeil 2010). Valproate can cause asymptomatic hyperammonemia and hyperammonemic encephalopathy.

Polycystic ovarian syndrome is 3.8-fold more prevalent in women with epilepsy than in the general population. This increase has been variously attributed to either epilepsy (Joffe et al. 2001) or anticonvulsant medications, especially valproate. Valproate appears to present a reduced risk when used as a mood stabilizer (Bilo and Meo 2008; see Chapter 22, “Endocrine and Metabolic Disorders”).

Immune system. Benign skin rashes occur in 5%–20% of patients receiving anticonvulsants, including valproate, carbamazepine, and lamotrigine. However, serious and potentially fatal immune reactions to anticonvulsants are not uncommon. Anticonvulsant hypersensitivity syndrome has been observed in up to 1% of patients, with initial signs of rash, fever, malaise, and pharyngitis progressing to internal organ involvement. Severe and often fatal hypersensitivity cutaneous reactions in 0.01% to 0.1% of new anticonvulsant users include Stevens-Johnson syndrome and toxic epidermal necrolysis (Mockenhaupt et al. 2005). Mortality occurs in about 5%–10% of patients with Stevens-Johnson syndrome and in up to 45% of those with toxic epidermal necrolysis. In comparison with general medical patients, the risk of developing Stevens-Johnson syndrome or toxic epidermal necrolysis during the first 2 months of anticonvulsant therapy is increased by 120-fold for carbamazepine, 25-fold for lamotrigine, and 24-fold for valproate (Rzany et al. 1999). Clinical trials suggest that 25% of patients with hypersensitivity reactions to carbamazepine will also cross-react to oxcarbazepine (USPDI Editorial Board 2007). The presence of an anticonvulsant-induced rash should prompt drug discontinuation (Herbert and Ralston 2001).

Drug interactions. Significant CYP isoenzyme induction occurs with carbamazepine (CYP1A2, CYP2C, and CYP3A4), oxcarbazepine (CYP3A4), and valproate (CYP2C) (see Table 38-2). Because valproate is highly bound to plasma proteins, it can significantly displace other highly protein-bound drugs. Valproate can also compete for hepatic glu-

curation and so inhibit the elimination of drugs primarily using this route of metabolism, such as lamotrigine and morphine.

Toxicity/overdose. Symptoms of anticonvulsant overdose are often an extension of the normal adverse effects, including stupor, conduction disturbances, and hypotension. Treatment for overdose includes gastric lavage or emesis followed by supportive therapy. Hemodialysis is an effective means of enhancing drug elimination for valproate, gabapentin, pregabalin, topiramate, and levetiracetam.

Antipsychotics

Antipsychotic drugs are used in the medically ill to treat nearly all forms of psychosis, including psychosis secondary to general medical conditions, delirium, and dementia, and less frequently for nonspecific sedation and as analgesic adjuvants.

Central Nervous System

Acute extrapyramidal symptoms. Acute EPS—akathisia, akinesia, and dystonia—occur in as many as 50%–75% of patients who take typical antipsychotics (Collaborative Working Group on Clinical Trial Evaluations 1998). High-potency typical antipsychotics are associated with higher rates of EPS than are low-potency agents. Among the currently available atypical antipsychotics, the hierarchy of EPS risk (greater to lesser) is ziprasidone > aripiprazole > risperidone = paliperidone (estimated) > asenapine (estimated) > iloperidone (estimated) > olanzapine > quetiapine > clozapine (Citrome 2009; Gao et al. 2008; Tandon 2002; Weber and McCormack 2009).

Most akathisia and acute dystonic reactions in the medically ill are caused by phenothiazine antiemetics or metoclopramide, especially at high intravenous doses. When agitated medically ill patients are being treated with haloperidol, it can be very difficult to distinguish akathisia from the original target symptoms. It is also important to exclude other causes of restlessness that may mimic akathisia in medically ill patients, such as hypoglycemia, hypoxia, drug withdrawal, pain, electrolyte disturbances, iron deficiency, and restless legs syndrome. Severe dystonic reactions (e.g., opisthotonus) may be misdiagnosed in the medically ill as status epilepticus.

Chronic extrapyramidal symptoms. Parkinsonian signs and tardive dyskinesia may result from chronic use of antipsychotics, phenothiazine antiemetics, or metoclopramide. Bradykinesia may easily be missed in the elderly or disabled medical patients. Tardive dyskinesias may be difficult to distinguish from other dyskinesias in elderly patients (e.g., “senile dyskinesias,” ill-fitting dentures).

Seizures. Most antipsychotics lower seizure threshold and increase seizure risk. Various reports suggest a dose-dependent seizure risk with phenothiazines of 0.3%–1.2% compared with a rate of first unprovoked seizure in the general population of about 0.1%. Most of the early case reports were of seizures with chlorpromazine. Although there are no controlled comparative studies to allow an accurate assessment of relative seizure risk, it appears that high-potency typical antipsychotics and risperidone (and likely paliperidone) have the lowest rate of seizures, followed by quetiapine, then olanzapine and low-potency typical antipsychotics with an intermediate risk, and finally clozapine with the highest risk (1% at 300 mg/day, increasing to 4.4% at >600 mg/day) (Alldredge 1999; Alper et al. 2007; Devinsky et al. 1991).

Sedation. Sedation is the most common single side effect, especially with the low-potency typical antipsychotics. Among the atypical antipsychotics, the hierarchy of potential for sedation (greater to lesser) is quetiapine > ziprasidone = clozapine > olanzapine > asenapine (estimated) = iloperidone (estimated) > risperidone = paliperidone (estimated) > aripiprazole (Citrome 2009; Leucht et al. 2009; Weber and McCormack 2009). Sedation is most prominent in the early stages of therapy, with some degree of tolerance developing over time.

Thermoregulation. Antipsychotics may interfere with temperature regulation, especially low-potency typical and anticholinergic atypical agents. Medically ill patients, especially elderly ones, are at particular risk because of other anticholinergic drugs and comorbidities impairing thermoregulation (e.g., congestive heart failure, cerebrovascular disease). Depending on environmental exposure, either hyperthermia (heatstroke) or hypothermia may result (S.C. Mann et al. 2003).

Neuroleptic malignant syndrome. NMS is a rare, potentially fatal, idiosyncratic reaction to antipsychotics. NMS (or a similar syndrome) is also reported among patients with extrapyramidal disorders such as Wilson’s disease, striatonigral degeneration, and Parkinson’s disease who have received antipsychotics or dopamine-depleting agents or who have had dopamine agonists abruptly withdrawn (Friedman et al. 1985; Gibb 1988; Gibb and Griffith 1986; Kontaxakis et al. 1988). However, NMS is not specific to any neuropsychiatric diagnosis and has been reported in non-psychiatrically ill individuals who were treated with other dopamine antagonists such as metoclopramide and prochlorperazine (Nonino and Campomori 1999; Pesola and Quinto 1996). Estimates of the incidence of NMS, once thought to be as high as 3%, are now suggested from more

recent data to be 0.01%–0.02% (Stubner et al. 2004). Mortality ranges from 11% to 38% (Jahan et al. 1992). Malnutrition, dehydration, and iron deficiency all appear to increase risk for NMS.

NMS generally develops over a 1- to 3-day period and lasts for 5–10 days after a nondepot antipsychotic is discontinued. Mortality is high, often quoted at 20%–30% but probably lower now because of earlier recognition of the syndrome. The main clinical features of NMS include hyperthermia ($>37^{\circ}\text{C}$), generalized muscle rigidity, mental status changes and autonomic instability (Table 38–6). Hyperthermia is greater than 38°C in the majority of cases and can exceed 40°C , which predisposes the patient to severe complications, including irreversible CNS and other organ damage. Muscle rigidity is often heterogeneous and can be “lead-pipe” or cogwheeling, but may be absent. Autonomic dysfunction in NMS may include hypertension, orthostatic hypotension, labile blood pressure, tachycardia, tachypnea, sialorrhea, diaphoresis, skin pallor, and urinary incontinence. Neurological dysfunction may consist of tremor, myoclonus, focal dystonias, dysphagia, dysarthria, opisthotonus, oculogyric crisis, and dyskinesias. Altered level of consciousness may range from decreased awareness to coma. CPK levels are elevated in NMS secondary to muscle necrosis from rigidity, hyperthermia, and ischemia. Elevated CPK levels are not proof of NMS, because they may result from agitation, use of physical restraints, and intramuscular injections. Extreme elevation of CPK ($>100,000\text{ U/L}$) constitutes rhabdomyolysis, which may be a consequence of NMS and/or other causes in the medically ill (e.g., sepsis, shock, alcohol). Serial CPK levels decline with the resolution of NMS. Leukocytosis with or without a left shift is common. Complications may include respiratory or renal failure, pulmonary embolus, electrolyte disturbances, and coagulopathy (Caroff and Mann 1993; Pelonero et al. 1998) as well as neuropsychiatric sequelae (Adityanjee et al. 2005).

The differential diagnosis of NMS is large (Table 38–7). Although the vast majority of patients receiving antipsychotics who develop fever and rigidity will be found to have other conditions, the possibility of NMS should be considered because of the importance of promptly withholding antipsychotics. Diagnosis may be guided by the use of an NMS rating scale (Sachdev 2005).

The main interventions in NMS are early diagnosis, rapid cessation of the antipsychotic treatment, and intensive supportive care. Lithium, antipsychotics, and all other dopamine-blocking agents (including antiemetics, metoclopramide, and droperidol) should be discontinued. No specific therapy (e.g., benzodiazepines, dantrolene, or bromocriptine) has been proven superior to other measures (reviewed by Strawn et al. 2007). Meta-analyses of dantrolene therapy of NMS have demonstrated results which vary

TABLE 38–6. Diagnostic criteria for neuroleptic malignant syndrome

Use of dopamine-blocking agents

Antipsychotics
Antiemetics
Droperidol
Metoclopramide

Muscle rigidity

Generalized or localized (tongue, facial muscles)
Elevated creatine phosphokinase

Pyrexia

Mild pyrexia to $>42^{\circ}\text{C}$

Altered level of consciousness

Mild confusion to coma

Autonomic dysfunction

Hypertension, orthostatic hypotension, labile blood pressure, tachycardia, tachypnea, sialorrhea, diaphoresis, skin pallor, and urinary incontinence

from a beneficial effect (Rosenberg and Green 1989) to a higher overall mortality or slower clinical recovery (Reulbach et al. 2007). Most cases of NMS require initial treatment in a medical intensive care unit and should be transferred back to a psychiatric service only after the patient is medically stable. Among patients who recover from NMS, there may be a 30% risk of recurrent episodes following subsequent antipsychotic rechallenge, but the majority of patients who require antipsychotic therapy can be cautiously re-treated at least two weeks after resolution of NMS. Additional information is available from the Neuroleptic Malignant Syndrome Information Service (www.nmsis.org).

Autonomic and cardiovascular. Autonomic side effects result from cholinergic and α_1 -adrenergic blockade, seen more frequently with low-potency typical antipsychotics. Among the atypical agents, the hierarchy for producing hypotension (from greatest risk to least risk) is clozapine $>$ quetiapine $>$ iloperidone (estimated) $>$ risperidone = paliperidone (estimated) $>$ olanzapine = ziprasidone = aripiprazole (estimated) (Tandon 2002; Vanda 2010). Clozapine and quetiapine have been reported to cause tachycardia in 25% and 7% of cases, respectively. Tachycardia occurs in 5% of patients receiving risperidone or olanzapine, and in 2% of ziprasidone patients (Drici and Priori 2007).

QTc prolongation and torsade de pointes. A number of antipsychotics may be associated with QTc interval prolongation and risk for torsade de pointes. Sertindole was never

TABLE 38-7. Differential diagnosis of neuroleptic malignant syndrome

Differential diagnosis	Distinguishing clinical features
Serotonin syndrome	Occurs with combinations of drugs that increase serotonin transmission. Rapid onset over 24 hours; altered mental state, hyperreflexia, spontaneous or inducible clonus, autonomic instability; nausea, vomiting, diarrhea are common. Muscle rigidity present only in very severe form.
Malignant hyperthermia	Occurs after general anesthesia; familial
Lethal catatonia	Similar symptoms but occurs independent of antipsychotic exposure
Heatstroke	Pyrexia, agitation, and confusion. Skin is hot and dry and muscles are flaccid; prior neuroleptic exposure may increase risk for heatstroke
Severe EPS or Parkinson's disease	No fever, leukocytosis, or autonomic changes
Central nervous system infection	Seizures more likely; abnormal CSF
Allergic drug reaction	Rash, urticaria, wheezing, eosinophilia
Toxic encephalopathy, lithium toxicity	No fever; low CPK
Anticholinergic delirium	Dry skin, flaccid muscles, and low CPK
Systemic infection plus severe EPS	May appear identical to neuroleptic malignant syndrome

Note. CPK = creatine phosphokinase; CSF = cerebrospinal fluid; EPS = extrapyramidal symptoms.

Source. Compiled from Haddad and Dursun 2008; Pelonero et al. 1998.

marketed in the United States for this reason, but it is available in Europe with a restrictive label. Ziprasidone, thioridazine, and droperidol carry a black-box warning regarding dose-related QTc prolongation and risk for sudden death. Mean QTc interval prolongation (greatest to least) for antipsychotics is: thioridazine (36 msec) > ziprasidone (21 msec) > quetiapine (15 msec) > paliperidone (12 msec) = risperidone (10 msec) = asenapine (estimated) = iloperidone (9 msec) > olanzapine (6 msec) > haloperidol (5 msec) > aripiprazole (<1 msec) (Citrome 2009; Janssen 2010; Otsuka 2002; Pfizer 2010a; Weber and McCormack 2009). Almost 30% of patients taking thioridazine had a change in QTc of 60 msec, followed by 21% for ziprasidone, 11% for quetiapine, and 4% each for risperidone, olanzapine, and haloperidol. A few subjects receiving thioridazine (10%) or ziprasidone (3%) had a QTc prolongation of 75 msec or greater. Case reports have also associated droperidol and pimozide with QTc prolongation. Controlled trials confirm QTc prolongation with droperidol (Carroll et al. 2002).

Other cardiac side effects. Potentially fatal myocarditis, cardiomyopathy, and heart failure have been reported with clozapine. Estimated rates of clozapine-associated myocarditis range from 1 in 10,000 to 1 in 500. Eighty-five percent of these cases develop during the first 2 months of therapy and may be accompanied by eosinophilia. Clozapine-associated cardiomyopathy has most often occurred in patients younger than 50 years, with dilated cardiomyop-

athy accounting for two-thirds of the cases and one-third of the deaths. Withdrawal of the drug might result in improvement of the cardiomyopathy (Wooltorton 2002). Myocarditis and cardiomyopathy have also been reported in association with chlorpromazine, fluphenazine, risperidone, haloperidol, and quetiapine (Bush and Burgess 2008), but a causal link has not been demonstrated (Coulter et al. 2001).

Endocrine and Metabolic

For a fuller discussion of the endocrine and metabolic effects of antipsychotic drugs, the reader is referred to Chapter 22, "Endocrine and Metabolic Disorders."

Glucose tolerance. Pharmacoepidemiological studies and case reports reveal an association between the use of various atypical antipsychotics and hyperglycemia, new-onset type 2 diabetes, and occasionally ketoacidosis. These effects are not fully understood and are not solely explained by weight gain; schizophrenia is itself a risk factor for type 2 diabetes regardless of treatment. A large retrospective study suggests the risk of new-onset diabetes is greatest with clozapine and declines through olanzapine, quetiapine, and risperidone (E.A. Miller et al. 2005). Other surveys suggest little difference in risk between olanzapine, quetiapine, and risperidone (Lambert et al. 2006). A U.S. consensus statement concluded that hyperglycemia is associated with all marketed atypical antipsychotics but is less with aripiprazole and ziprasidone (American Diabetes

Association et al. 2004). To date, however, the only report of hyperglycemia associated with ziprasidone has been in the context of possible NMS with rhabdomyolysis and pancreatitis (Yang and McNeely 2002). Diabetic ketoacidosis has been reported in association with all atypical antipsychotics, including aripiprazole, except for ziprasidone and paliperidone.

Lipids. Phenothiazines, but not butyrophenones were long ago noted to elevate serum levels of cholesterol and triglycerides. Among atypical antipsychotics, risk of hyperlipidemia is highest with clozapine, olanzapine, and quetiapine, and lowest with risperidone, ziprasidone and aripiprazole (Meyer and Koro 2004). Serum triglycerides usually peak in the first year of therapy.

Hyperprolactinemia. Hyperprolactinemia is relatively common, especially with high-potency typical antipsychotics, risperidone, and paliperidone, and can result in amenorrhea or irregular menses, galactorrhea, gynecomastia, sexual dysfunction, and osteoporosis. Risperidone and paliperidone (Melkersson 2006) often elevate prolactin levels; clozapine, quetiapine, olanzapine, and ziprasidone are regarded as prolactin-sparing; aripiprazole decreases prolactin levels (Haddad and Sharma 2007).

Weight gain. All currently marketed antipsychotics (with the possible exception of ziprasidone and aripiprazole) are associated with weight gain, which may increase health risks (e.g., hypertension, atherosclerosis, type 2 diabetes, cardiovascular disease, and stroke), stigmatization, non-compliance, impairment in quality of life, and social withdrawal. The relative propensity to cause weight gain among the atypical antipsychotics (from greatest to least) is clozapine > olanzapine >> quetiapine > risperidone = paliperidone (estimated) > iloperidone (estimated) > asenapine (estimated) >> aripiprazole > ziprasidone (Citrome 2009; Haddad 2005; Weber and McCormack 2009). Current consensus guidelines for monitoring patients receiving atypical antipsychotics, including monitoring forms and risk criteria, are available from the Center for Quality Assessment and Improvement in Mental Health (www.cqaimh.org/pdf/tool_metabolic.pdf).

Syndrome of inappropriate antidiuretic hormone secretion. SIADH can occur with typical as well as atypical antipsychotics (and some antidepressants and anticonvulsants). SIADH is characterized by a reduced ability to excrete water, resulting in extracellular dilution and hyponatremia. SIADH is distinguished from polydipsia (water intoxication) by urine osmolality, with relatively high

urine osmolality in SIADH versus very low urine osmolality in polydipsia. Common symptoms include weakness, lethargy, headache, anorexia, and weight gain and may progress to confusion, convulsions, coma, and death.

Hematological. Hematological side effects of antipsychotics include agranulocytosis, aplastic anemia, neutropenia, eosinophilia, and thrombocytopenia (reviewed in Flanagan and Dunk 2008). Transient leukopenia and leukocytosis are not uncommon in the first few weeks of therapy and are usually not clinically significant. Agranulocytosis is the most common serious hematological side effect with clozapine, low-potency typical antipsychotics (<0.1%) and olanzapine. Clozapine-associated agranulocytosis occurs in about 0.5%–2.0% of patients, with highest risk in the first 6 months. Clozapine use is through a controlled distribution system dependent on routine assessment of WBC count and absolute neutrophil count (ANC). A WBC count less than 2,000/mm³ or an ANC less than 1,000/mm³ is an indication for immediate cessation of clozapine.

Hepatic. Liver function abnormalities during antipsychotic therapy have long been reported but seldom require drug discontinuation. Mild to moderate elevations in liver aminotransferases and alkaline phosphatase usually occur early in treatment and are unlikely to result in hepatic impairment. Cholestatic jaundice is an idiosyncratic reaction that occurs rarely with phenothiazines.

Allergic, dermatological, and ophthalmological. Dermatological adverse reactions include early allergic rashes, photosensitivity, and skin hyperpigmentation, especially with chlorpromazine. Pigmentary retinopathy occurred in patients taking more than 800 mg/day of thioridazine. Acute angle closure glaucoma may occur in patients with a physiologically narrow anterior chamber angle who take anticholinergic medications.

Sexual. Antipsychotics may cause sexual dysfunction, in some cases related to their causing hyperprolactinemia (see also Chapter 22, "Endocrine and Metabolic Disorders," and Chapter 16, "Sexual Dysfunction").

Toxicity/overdose. Generally, antipsychotic overdose is associated with low morbidity and mortality. Most patients who have taken an antipsychotic overdose remain asymptomatic or develop mild sedation within 1–2 hours, but particular antipsychotics can cause serious cardiac effects (e.g., QTc prolongation from ziprasidone or thioridazine) or neurotoxicity (e.g., clozapine-induced seizures), especially in medically vulnerable patients.

Drug interactions. Most antipsychotic drugs have sedating, hypotensive, anticholinergic, antiarrhythmic, and seizure threshold-lowering properties. Predictable drug interactions may occur when combining antipsychotics with other drugs also possessing these characteristics. For example, antipsychotics may strongly potentiate the sedative effects of other CNS depressants, and anticholinergic antipsychotics will have additive adverse effects with other anticholinergic drugs. Antipsychotics may greatly enhance the hypotensive effects of antihypertensive agents. Low-potency antipsychotics and ziprasidone should be avoided in patients receiving other drugs with type 1A antiarrhythmic (quinidine-like) properties.

Many antipsychotics, including aripiprazole, clozapine, olanzapine, risperidone, and asenapine, are prone to pharmacokinetic drug interactions because of the limited number of CYP isozymes involved in their metabolism (see Table 38-2).

Anxiolytics and Sedative-Hypnotics

Benzodiazepines have long been considered the cornerstone of pharmacotherapy for anxiety and insomnia. Alternatives include buspirone for anxiety and the nonbenzodiazepine hypnotics eszopiclone, zopiclone, zolpidem, zaleplon, and ramelteon (a melatonin receptor agonist). These newer agents appear to have less tolerance and abuse potential and fewer adverse effects than benzodiazepines. Chloral hydrate has been used as a sedative-hypnotic since 1869, but because dependence occurs rapidly and withdrawal can be fatal, its use has greatly declined. Chloral hydrate is no longer FDA-approved for use in the United States.

Benzodiazepines

Benzodiazepines commonly cause dose-related CNS adverse effects but rarely affect organ systems other than the respiratory system, although in cirrhosis they may precipitate hepatic encephalopathy.

Central nervous system. Acute adverse CNS effects, including sedation, fatigue and weakness, ataxia, slurred speech, confusion, and memory impairment, are common, especially in older individuals and the medically ill. When used for the treatment of insomnia, long-half-life benzodiazepines are more likely to cause daytime sedation and cognitive impairment than short-half-life drugs. The elderly and patients with brain injury are also susceptible to benzodiazepine-induced behavioral disinhibition resulting in excitement, aggression, and paradoxical rage (Mancuso et al. 2004).

Physical tolerance often develops with chronic use of benzodiazepines, and some therapeutic effects (not anxiolysis) and adverse effects (sedation and psychomotor im-

pairment) may diminish (O'Brien 2005). Studies suggest little or no long-term cognitive deterioration following chronic benzodiazepine use in the elderly (Bierman et al. 2007; McAndrews et al. 2003).

Respiratory. Benzodiazepines decrease the central respiratory response to hypoxia. Benzodiazepines differ in their ability to cause respiratory depression (Cohn 1983; Guilleminault 1990), with long-acting agents such as flurazepam (Dolly and Block 1982; Mendelson et al. 1981) and nitrazepam (Model 1973; Sanger and Zivkovic 1992) having the most pronounced effects. These drugs can cause apnea when used alone or in combination with other CNS depressants, most commonly alcohol (Guilleminault 1990; Mendelson et al. 1981). The respiratory depressant effects of benzodiazepines may become clinically significant in individuals with preexisting respiratory disorders, such as chronic obstructive pulmonary disease (COPD) (Clarke and Lyons 1977; Model 1973) or sleep apnea (Mendelson et al. 1981), or in those with seizure disorders (which also can cause respiratory depression).

The incidence of respiratory depression associated with benzodiazepine treatment of seizure disorder ranges from 10.6% for lorazepam in adults (Alldredge et al. 2001) to 14% in children treated mainly with lorazepam (W.A. Stewart et al. 2002) and 9%–20% for children treated with diazepam (Appleton et al. 1995; Norris et al. 1999). Benzodiazepines should be used with caution in patients with compromised respiratory function or seizure disorders. Use in patients with obstructive sleep apnea is potentially fatal (Dolly and Block 1982; see also Chapter 15, "Sleep Disorders").

Drug interactions. Additive CNS depressant effects, including respiratory depression, result from the combination of benzodiazepines and other CNS depressants, including alcohol.

Many benzodiazepines, including alprazolam, bromazepam, clonazepam, diazepam, midazolam, and triazolam, undergo hepatic and intestinal metabolism mediated by CYP3A4. Significant inhibitors of CYP3A4 may reduce the elimination of these benzodiazepines, whereas CYP3A4 inducers can increase their hepatic metabolism (see Table 38-2). Oxazepam, lorazepam, and temazepam are eliminated primarily by conjugation and renal excretion and thus may be less problematic in patients with hepatic impairment.

Toxicity/overdose. Benzodiazepines have a wide margin of safety; death from overdose is rare unless part of a poly-drug overdose. Overdose may result in sedation, ataxia, slurred speech, confusion, seizures, respiratory depression, and coma. Treatment includes removal of any unabsorbed drug from the stomach (gastric lavage or emesis) followed

by supportive therapy. The benzodiazepine antagonist flumazenil can also be used but may cause seizures.

Sudden discontinuation of benzodiazepines may result in severe withdrawal symptoms, including anxiety, agitation, dysphoria, anorexia, insomnia, sweating, vomiting, diarrhea, abdominal cramps, ataxia, psychosis, and seizures. The intensity of withdrawal symptoms is greater with higher doses, prolonged treatment, abrupt discontinuation, and short-half-life benzodiazepines. Patients should be gradually withdrawn from benzodiazepines; this is especially crucial for those with a history of seizure disorder. Withdrawal from short-half-life agents can be facilitated by switching to a long-half-life agent before tapering.

Nonbenzodiazepine Sedatives (Eszopiclone, Zopiclone, Zolpidem, Zaleplon, and Ramelteon)

Eszopiclone, zopiclone, zolpidem, and zaleplon are very well tolerated short-half-life hypnotics with very few dose-related adverse effects. Adverse effects of eszopiclone and zopiclone include bitter taste, dry mouth, difficulty arising in the morning, sleepiness, nausea, and nightmares (Allain et al. 1991; Najib 2006). Clinical trials of zaleplon report adverse effects comparable to those seen with placebo (Hedner et al. 2000). Zolpidem's adverse effects include CNS (dizziness, drowsiness, and headache) and gastrointestinal (nausea) effects (Krystal et al. 2008). Tolerance to the hypnotic effects of these agents occurs less frequently than with benzodiazepines, and they may be useful for treatment of rebound insomnia associated with benzodiazepine withdrawal (Pat-Horenczyk et al. 1998). Mild withdrawal symptoms have been reported in a small number of patients after discontinuation of zolpidem (Elie et al. 1999) and zopiclone (Bianchi and Musch 1990). These agents have less abuse potential than benzodiazepines (Wagner and Wagner 2000).

Ramelteon, a melatonin agonist FDA approved for insomnia, demonstrated efficacy for insomnia, with no next-morning residual effects, an adverse-effect profile similar to that of placebo, and no withdrawal symptoms upon discontinuation in a 6-month controlled clinical trial (Mayer et al. 2009).

Reports of complex sleep behaviors (e.g., sleep driving, sleep cooking, sleep eating, sleep conversations, sleep sex) in individuals taking these nonbenzodiazepine sedatives has prompted the FDA to require new safety warnings in product information. Although such reports are rare, the majority have been associated with zolpidem (Dolder and Nelson 2008).

Respiratory. Unlike benzodiazepines, typical doses of zolpidem, zopiclone, eszopiclone, and ramelteon have no significant effect on respiratory drive and central control

of breathing in healthy subjects or patients with mild to moderate COPD (Girault et al. 1996; Kryger et al. 2007; Muir et al. 1990; Rosenberg et al. 2007). However, at high doses, zolpidem has been reported to cause respiratory depression (Cirignotta et al. 1988). A preliminary trial of zaleplon suggested an absence of significant respiratory effects (George 2000). Ramelteon did not worsen sleep apnea when administered to subjects with mild to moderate obstructive sleep apnea (Kryger et al. 2007).

Drug interactions. Ramelteon is oxidatively metabolized primarily by CYP1A2, with a much lesser contribution by CYP3A4. Fluvoxamine, a potent CYP1A2 inhibitor, has been reported to increase blood levels of ramelteon by 70-fold and area under the curve (AUC) by 190-fold (Takeda 2010). Ramelteon should not be used in combination with CYP1A2 inhibitors (e.g., fluvoxamine) or CYP1A2 inducers (e.g., rifampicin; see Table 38–2 for a listing). Coadministration with strong CYP3A4 inhibitors (e.g., conazole antifungals, macrolide antibiotics, grapefruit juice) should also be avoided.

Toxicity/overdose. Fatal overdose of zolpidem is rare. A review of zolpidem ($n = 5,842$) and zaleplon ($n = 467$) overdoses identified 2 deaths with zolpidem and no fatalities with zaleplon (Forrester 2006). In a survey of 344 cases of intentional acute zolpidem overdose, death occurred in 6% of the cases but could not be directly linked to zolpidem because of multiple drug involvement (Garnier et al. 1994). Symptoms of intentional overdose of zolpidem and zaleplon are similar and include drowsiness, slurred speech, ataxia, vomiting, and coma. Treatment is generally limited to supportive measures and/or gastric lavage. Symptoms of toxicity rapidly subside in most cases (Garnier et al. 1994).

Fatal overdose with zopiclone has been reported but, as with zolpidem, appears rare (Boniface and Russell 1996; Bramness et al. 2001).

Buspirone

Buspirone is a well-tolerated anxiolytic with no apparent effects on cognitive function or seizure threshold. Buspirone has little or no potential for physiological or psychological tolerance and so has no abuse liability or withdrawal syndrome on discontinuation. Dizziness, drowsiness, nervousness, nausea, and headache are the most frequent adverse effects and occur in about 5%–10% of patients. Adverse effects appear to be dose and age-related and diminish with continued therapy. Unlike benzodiazepines, buspirone does not potentiate the effects of alcohol (Seppala et al. 1982) or suppress respiration (Garner et al. 1989). Buspirone does not exhibit cross-tolerance with benzodiazepines and so cannot be used to manage benzodiazepine with-

drawal. Buspirone stimulates prolactin secretion in a dose-related manner, but the clinical significance of this effect is uncertain. Menstrual irregularities and galactorrhea have occasionally been reported, but their relation to buspirone is unclear.

Drug interactions. Case reports suggest that buspirone may very rarely precipitate serotonin syndrome when used in combination with St. John's wort (Dannawi 2002) or SSRIs (G.H. Manos 2000). Buspirone should not be combined with drugs possessing MAOI activity (see Table 38-2 for list).

Buspirone undergoes hepatic and intestinal metabolism mediated by CYP3A4, so interactions are similar to those described earlier for benzodiazepines. Oral absorption of buspirone is greatly limited (~4%) by intestinal P-gp. Coadministration with drugs which inhibit P-gp (e.g., macrolide antibiotics; see Table 38-2) can increase buspirone bioavailability manyfold (5 to 10 times) and possibly cause symptoms of overdose.

Toxicity/overdose. No fatalities have been reported from buspirone overdose. Overdose symptoms include nausea, vomiting, drowsiness, miosis, and gastric distention. Treatment includes removal of any unabsorbed drug from the stomach (gastric lavage or emesis), followed by supportive therapy.

Psychostimulants

Psychostimulants are used in the treatment of attention-deficit/hyperactivity disorder (ADHD), narcolepsy, depression, apathy, and analgesia augmentation in the medically ill. The well-established psychostimulant medications include methylphenidate, dexamethylphenidate, and amphetamines (a mixture of amphetamine salts; dextroamphetamine). Pemoline has been withdrawn in many regions due to potentially fatal hepatotoxicity.

Newer compounds include atomoxetine (a specific norepinephrine reuptake inhibitor) and lisdexamfetamine, an amphetamine prodrug, for ADHD (Gibson et al. 2006) and modafinil and armodafinil for excessive sleepiness due to narcolepsy, shift work sleep disorder and obstructive sleep apnea. Modafinil and armodafinil have demonstrated efficacy for excessive daytime sleepiness accompanying obstructive sleep apnea (Black and Hirshkowitz 2005; Roth et al. 2008). Modafinil improves fatigue and cognition accompanying multiple sclerosis (Lange et al. 2009).

Methylphenidate, Dexamethylphenidate, and Amphetamines

Common adverse effects include CNS (insomnia, headache, nervousness, and social withdrawal) and gastrointes-

tinal (stomachache and anorexia) symptoms. Adverse effects are generally mild and diminish with continued treatment, adjustment of dose, or dose timing. Lisdexamfetamine has a longer duration of action than dextroamphetamine but otherwise has similar therapeutic and adverse effects (Cowles 2009).

Although psychostimulants may suppress appetite, this does not tend to occur with the low doses used in medically ill patients (Masand et al. 1991). In healthy adults, methylphenidate (≤ 30 mg) and dextroamphetamine (≤ 15 mg) did not significantly alter heart rate or blood pressure (Martin et al. 1971). However, psychostimulants can cause elevated heart rate and blood pressure, palpitations, hypertension, hypotension, and cardiac arrhythmias when taken at doses higher than those routinely used in the medically ill. In a review of side effects associated with methylphenidate therapy in children with ADHD, methylphenidate increased heart rate by 3–10 beats/minute and blood pressure by 3.3–8.0 mm Hg systolic and 1.5–14.0 mm Hg diastolic (Rapport and Moffitt 2002). Dexamethylphenidate and methylphenidate have similar therapeutic and adverse effects.

Drug interactions. Psychostimulants may interact with sympathomimetics and MAOIs (including selegiline), resulting in headache, arrhythmias, hypertensive crisis, and hyperpyrexia. Psychostimulants should not be administered with MAOIs or within 14 days of their discontinuation. Despite the paucity of empirical evidence regarding TCA-stimulant metabolic interactions, warning statements are included in many drug manuals. One review of the effects of stimulants on the pharmacokinetics of desipramine in children found no statistically or clinically significant interaction regardless of age, gender, or type of stimulant (L.G. Cohen et al. 1999). Several reports suggest that methylphenidate may interact pharmacodynamically with TCAs to cause increased anxiety, irritability, agitation, and aggression. Symptoms subsided on drug discontinuation (Grob and Coyle 1986; Gwirtsman et al. 1994; Markowitz and Patrick 2001).

Higher doses of psychostimulants may also reduce the therapeutic effectiveness of antihypertensive medications. When psychostimulants are used concurrently with beta-blockers, the excessive alpha-adrenergic activity may cause hypertension, reflex bradycardia, and possible heart block.

Toxicity/overdose. Symptoms of overdose include cardiovascular (flushing, palpitations, hypertension, arrhythmias, and tachycardia), CNS (delirium, euphoria, hyperreflexia, and psychosis), and autonomic (hyperpyrexia and sweating) effects. Treatment is primarily supportive. Any unabsorbed drug should be removed from the stomach

(gastric lavage or emesis). A short-acting sedative may be needed in patients with severe intoxication.

Modafinil, Armodafinil, and Atomoxetine

Modafinil, armodafinil (the active R-enantiomer of modafinil), and atomoxetine have adverse-effect profiles different from those of other psychostimulants and do not have their same abuse potential. Modafinil's adverse effects include delayed sleep onset, nausea, and rhinitis (U.S. Modafinil in Narcolepsy Multicenter Study Group 2000). Palpitations, tachycardia, hypertension, excitation, and aggression have also been infrequently observed. Modafinil has been associated in rare cases with chest pain, palpitations, dyspnea, and transient ischemic T wave changes in association with mitral valve prolapse or left ventricular hypertrophy. Modafinil does not cause appetite reduction (Rugino and Copley 2001). Serious skin rash and possible Stevens-Johnson syndrome have been observed in modafinil trials and may occur with armodafinil (Cephalon 2010). Modafinil and armodafinil have similar therapeutic and adverse effects.

Atomoxetine side effects reported in clinical trials included insomnia, nausea, dry mouth, constipation, dizziness, decreased appetite, urinary hesitancy, sexual dysfunction, and palpitations (Adler et al. 2009; Eli Lilly 2010a).

Elimination of atomoxetine, modafinil, and armodafinil is reduced in patients with hepatic impairment. Atomoxetine dose should be reduced by 50% in patients with moderate hepatic impairment and by 75% in those with severe hepatic impairment (Eli Lilly 2010a). In patients with severe hepatic impairment, modafinil and armodafinil dose should be reduced by 50% (McEvoy 2008). Blood levels of modafinil acid, a modafinil metabolite, increase ninefold in patients with severe renal insufficiency, but its effects are unknown.

Drug interactions. Atomoxetine is a potent inhibitor of CYP2D6 and is primarily eliminated through metabolism by CYP2D6 (see Table 38-2). Atomoxetine may increase the toxicity of other coadministered narrow-therapeutic-index medications primarily metabolized by CYP2D6.

Modafinil and armodafinil are moderate inducers of CYP3A4 and moderate inhibitors of CYP2C19 (Darwish et al. 2008). Drug interaction data for modafinil and armodafinil are limited. Clinical studies suggest that significant metabolic drug interactions are most likely with compounds, such as ethinylestradiol and triazolam, that undergo significant gastrointestinal CYP3A4-mediated first-pass metabolism (Robertson and Hellriegel 2003; Robertson et al. 2002). Modafinil-clozapine interactions have been the subject of two case reports, one showing an increase in clozapine level (Dequardo 2002) and the other

showing a decrease in clozapine's therapeutic effect (Narendran et al. 2002).

Like other psychostimulants, atomoxetine, modafinil, and armodafinil should not be administered to patients receiving MAOIs or within 14 days of MAOI withdrawal.

Cognitive Enhancers

The currently approved treatments for dementia of the Alzheimer's type are cholinesterase inhibitors, including tacrine, donepezil, rivastigmine, and galantamine, and the N-methyl-D-aspartate (NMDA) receptor antagonist memantine.

Cholinesterase Inhibitors

Tacrine is now rarely prescribed because of frequent reversible hepatotoxicity (Watkins et al. 1994). Other mainstream cholinesterase inhibitors are well tolerated; most of their adverse effects are mild, dose-related, and gastrointestinal in nature (nausea, vomiting, and diarrhea), as expected from procholinergic agents. Gastrointestinal side effects can be minimized by slow dose titration and administration with food. Adequate hydration reduces nausea. Procholinergic properties increase vagotonic and bronchoconstrictor effects. These agents should be used with caution in patients with cardiac conduction abnormalities or a history of asthma or obstructive pulmonary disease.

Agent-specific side effects include muscle cramps and insomnia with donepezil and anorexia with rivastigmine and galantamine.

Overdose. Overdose of cholinesterase inhibitors can cause a potentially fatal cholinergic crisis, with bradycardia, hypotension, muscle weakness, nausea, vomiting, respiratory depression, sialorrhea, diaphoresis, and seizures. Treatment is with atropine (1–2 mg intravenously, repeat as required) and supportive care.

Drug interactions. Donepezil and galantamine are metabolized by CYP2D6 and CYP3A4 isozymes but are not associated with any clinically important CYP-mediated pharmacokinetic interactions (reviewed in Jann et al. 2002). Rivastigmine is metabolized primarily by esterase-mediated hydrolysis and has been shown not to interact with CYP isozymes in vitro (Grossberg 2002).

Cholinesterase inhibitors do, however, have the potential to exacerbate the effects of other cholinesterase inhibitors (e.g., physostigmine) or cholinomimetic agents (e.g., bethanechol). Cholinesterase inhibitors prolong the duration of action of the depolarizing neuromuscular blocking agent succinylcholine (suxamethonium) by inhibiting metabolism of succinylcholine by plasma cholinesterase and increasing acetylcholine-mediated neuromuscular depo-

larization (Crowe and Collins 2003). In contrast, the cholinesterase inhibitor-mediated increase in acetylcholine levels antagonizes the actions of nondepolarizing neuromuscular blockers (e.g., atracurium, mivacurium) (Baruah et al. 2008). Cholinesterase inhibitors should be discontinued several weeks before surgery (Russell 2009).

Many prescription and nonprescription drugs possess anticholinergic activity that may impair cognitive function. In addition to those drug classes commonly recognized as having anticholinergic effects, such as antiparkinsonian agents, antispasmodics, TCAs, low-potency antipsychotics, and antihistamines, many individual drugs from unrelated drug classes also have these effects. Drugs with anticholinergic properties may decrease the effect of cognitive enhancers. In a study of long-term care residents, 21% of those receiving acetylcholinesterase inhibitors were receiving concurrent medications with anticholinergic activity (J.L. Mann et al. 2003). The use of anticholinergic agents in a patient with compromised cognitive function should be minimized. A partial listing of drugs with significant CNS anticholinergic effects is presented in Table 38–8. Conversely, cholinesterase inhibitors may have a countertherapeutic effect in those patients receiving anticholinergic medication for medical conditions.

NMDA Receptor Antagonists

Memantine has been shown in a meta-analysis of controlled long-term trials in patients with Alzheimer's disease to be well tolerated, with an adverse-effect profile similar to that of placebo (Farlow et al. 2008). Memantine has no effect on respiration and is generally benign in patients with cardiovascular disease, although it may rarely cause bradycardia (Gallini et al. 2008). Memantine is primarily renally eliminated and requires reduced dosage in patients with moderate renal impairment.

Drug interactions. Memantine has no significant interactions with other drugs.

Alternative Routes of Administration

Psychotropic medications are usually delivered orally, but this may not represent the best administration route or even be possible for many patients. Oral administration of medications may be difficult in the medically compromised including: patients with severe nausea or vomiting, dysphagia, severe malabsorption; unconscious or uncooperative patients; and patients unable to take medications by mouth. Alternative nonoral routes of administration include intravenous, intramuscular, subcutaneous, sublingual/buccal, rectal, topical or transdermal, and intranasal.

The potential advantages of nonoral administration of psychotropics include guaranteed compliance, providing options for those patients who cannot take oral medications, and potential pharmacokinetic advantages such as greater bioavailability, bypassing first-pass hepatic metabolism, and potential reduction in toxic metabolites or adverse effects. Intravenous delivery can be controlled from very rapid to slow infusion with 100% bioavailability and rapid drug distribution. Intramuscular administration provides fast absorption, avoidance of first-pass metabolism and ensured compliance, but bioavailability is often less than 100% because of drug retention or metabolism by local tissues. Sublingual/buccal routes have rapid absorption and good bioavailability for small lipid-soluble drugs. Drugs absorbed sublingually avoid first-pass metabolism and may have fewer gastrointestinal adverse effects. Significant sublingual/buccal absorption of oral liquids or oral disintegrating tablets cannot be assumed and must be evaluated on a drug-by-drug basis. Rectal absorption is often incomplete and erratic, but in comparison with oral administration, first-pass metabolism is reduced by about 50% (reviewed by van Hoogdalem et al. 1991a, 1991b). Transdermal drug delivery bypasses the gut, avoids first-pass metabolism, reduces gastrointestinal adverse effects, and is unaffected by food intake. Continuous drug delivery from a transdermal patch reduces the peak to trough fluctuation of drug levels produced by oral dosing and provides near-constant plasma drug levels, even for short-half-life drugs, over longer dosing intervals. The intranasal route has been suggested as the best alternative to parenteral injections for rapid systemic drug delivery. However, there are no approved intranasal formulations of psychotropic medications.

Many formulations discussed are commercially available, although not necessarily in the United States or Canada. The Lundbeck Institute provides an international database of approved psychotropic formulations (www.psychotropics.dk) that may help to locate their sources. Customized formulations are reported for a few agents. Caution is indicated when using a medication for which adequate studies of safety and efficacy regarding parenteral administration are lacking.

Antidepressants

Few antidepressants are available for parenteral administration. Intravenous clomipramine, amitriptyline, imipramine, maprotiline, doxepin, viloxazine, trazodone, and citalopram have been studied or widely used, mainly in Europe. None are currently available in the United States or Canada. Intravenous mirtazapine (15 mg/day) was found to be well tolerated and effective in two small uncontrolled trials in moderately to severely depressed inpatients (Kon-

TABLE 38–8. Common drugs with significant anticholinergic effects

Antidepressants		Antiparkinsonian agents		Antispasmodics	
Tertiary amine TCAs	+++	Amantadine	++	Atropine	+++

Note. Risk of anticholinergic adverse effects at therapeutic doses: +++, high; ++, medium; +, low. Risk is increased in the elderly and with multiple agents with anticholinergic activity.

Source. Compiled from Bezchlibnyk-Butler et al. 2007; Cancelli et al. 2009; Chew et al. 2008; McEvoy 2008; Repchinsky 2009; Rudolph et al. 2008.

stantinidis et al. 2002; Muhlbacher et al. 2006). Citalopram is the only SSRI available for parenteral administration. To date, open and double-blind randomized, controlled clinical trials have shown citalopram infusion followed by oral citalopram (Kasper and Muller-Spahn 2002) or escitalopram (Schmitt et al. 2006) to be effective and well tolerated for severe depression. However, the safety and efficacy of in-

travenous antidepressants in the medically ill is uncertain because studies to date have been performed only in medically healthy patients.

No antidepressants are currently marketed in a rectal preparation including enema, foam, semisolid suppository, or gelatin capsules. However, several antidepressants, including trazodone, amitriptyline, imipramine, and clomi-

pramine, have been compounded as rectal suppositories with anecdotal reports of success in depression (Koelle and Dimsdale 1998; Mirassou 1998). Therapeutic serum levels of doxepin were produced in 3 of 4 cancer patients following rectal insertion of oral capsules (Storey and Trumble 1992). The rectal bioavailability of fluoxetine oral capsules, administered rectally, was only 15% of oral administration but was reasonably well tolerated in 7 healthy subjects (Tetter et al. 2005). With an appropriate dosage adjustment, rectal administration of antidepressants may be feasible in patients who cannot take oral medications. Serum drug levels (if available) and clinical response should guide dosage.

The MAOI selegiline, available in a transdermal patch, is the only nonoral antidepressant formulation approved in the United States. The antidepressant dose of oral selegiline requires dietary tyramine restriction because of clinically significant inhibition of intestinal MAO-A. By avoiding intestinal exposure to selegiline, transdermal administration reduces intestinal MAO-A inhibition and the need for dietary tyramine restrictions at doses of 6 mg/day or less, as well as circumventing first-pass metabolism to provide higher plasma levels and reduced metabolite formation. Short-term (8-week; Feiger et al. 2006) and long-term (52-week; Amsterdam and Bodkin 2006) placebo-controlled, double-blind clinical trials have demonstrated antidepressant efficacy, with adverse effects similar to those of placebo, except for application-site reactions and insomnia. An oral disintegrating tablet of selegiline, designed for buccal absorption, has been approved in the United States for Parkinson's disease (Valeant 2010). There are no reports of its use for the treatment of depression.

Transdermal amitriptyline was reported to be well absorbed and effective in a case report (Scott et al. 1999) but showed no significant systemic absorption in a small open trial (Lynch et al. 2005). This variability may be due to use of different transdermal formulations.

Sublingual administration of fluoxetine oral solution produced therapeutic plasma levels of fluoxetine plus norfluoxetine and improved depressive symptoms in two medically compromised patients with depression (Pakurek and Pasol 1999).

Mirtazapine is available in an oral disintegrating tablet for gut absorption, but the extent of sublingual/buccal absorption from this formulation is unknown.

Anxiolytics and Sedative-Hypnotics

Internationally, many benzodiazepines are available in intravenous, intramuscular, rectal, sublingual, and intranasal preparations. Injectable forms of diazepam, lorazepam, and midazolam and diazepam rectal gel are marketed in the United States and Canada. Sublingual lorazepam is available in Canada. Intravenous benzodiazepines are com-

monly used to treat status epilepticus or to calm severely agitated patients. Compared with diazepam, lorazepam pharmacokinetics after intravenous administration are more predictable. Because intravenous lorazepam redistributes more slowly from the CNS to peripheral tissues than diazepam or midazolam, it has a longer duration of effect after a single dose. Midazolam is a short-acting, water-soluble benzodiazepine frequently used in preoperative sedation, induction and maintenance of anesthesia, anxiolysis, and the treatment of status epilepticus. Midazolam's onset of action following intravenous administration is usually within 1–5 minutes, and the action lasts usually less than 2 hours. Intravenous flunitrazepam (Rohypnol), available in Europe and Japan, has been used for severe insomnia (Matsuo and Morita 2007) and for the treatment and the prevention of alcohol withdrawal (Pycha et al. 1993). Intravenous benzodiazepine administration should always occur in a setting where there is ready access to personnel and equipment necessary for respiratory resuscitation.

Injectable forms of lorazepam, midazolam, and diazepam are available for intramuscular delivery. For behavioral emergencies, lorazepam is the preferred agent because it is readily absorbed and has no active metabolites. Midazolam is also rapidly absorbed after intramuscular administration, with an onset of action between 5 and 15 minutes. Intermittent or sustained continuous subcutaneous infusion of injectable midazolam is reported for management of delirium, especially in a palliative care setting (Bottomley and Hanks 1990). Intramuscular diazepam is not recommended because of its erratic absorption (Rey et al. 1999).

Sublingual benzodiazepines are often used to control anxiety in patients undergoing dental procedures. Only lorazepam in Canada and temazepam in Europe (Russell et al. 1988) are marketed in a sublingual form, although several benzodiazepines, including alprazolam, triazolam, prazepam, midazolam, clonazepam, diazepam, flunitrazepam, and lormetazepam have been administered sublingually using commercial nonsublingual formulations (such as oral tablets) or custom preparations. Pharmacokinetic studies comparing sublingual administration of oral tablets against intramuscular administration suggest slightly slower sublingual drug absorption but similar bioavailability.

Rectal administration of benzodiazepines is useful for the acute management of seizures in children. Diazepam is available as a rectal gel for use when other routes are not readily available. A pharmacokinetic study of a parenteral solution of lorazepam administered rectally to healthy adults describes average bioavailability of 80% but with considerable variation in the rate and extent of absorption (Graves et al. 1987). Other benzodiazepines, such as clonaz-

epam, triazolam, and midazolam, have also been administered rectally. Although rectal benzodiazepine absorption is rapid, it is not always reliable because rectal bioavailability is highly variable and the onset of action is delayed (Rey et al. 1999). Since lorazepam may be given intravenously, intramuscularly, or sublingually, there is little need for rectal administration of benzodiazepines in adults.

Other routes of administration for benzodiazepines include intrathecal and nasal midazolam. Intrathecal midazolam has been used principally for adjunctive pain management and has been found to be safe and effective in a variety of settings (Duncan et al. 2007). While no benzodiazepines are available in intranasal formulations, intranasal formulations of midazolam and lorazepam sprays have been reported to be effective with rapid absorption and high bioavailability (Bjorkman et al. 1997; Wermeling et al. 2006).

Two sublingual formulations of zolpidem, a nonbenzodiazepine hypnotic, have recently been approved in the United States: a sublingual tablet and an oral spray. In a clinical study, the sublingual tablet produced significantly earlier sleep initiation than the oral preparation (Staner et al. 2010). The sublingual spray has been demonstrated to provide more rapid systemic absorption of zolpidem than the oral formulation (NovaDel 2010).

Antipsychotics

The atypical antipsychotics aripiprazole, olanzapine, and ziprasidone and many typical agents are available as short-acting intramuscular preparations. Haloperidol has been given intravenously and subcutaneously. Long-acting intramuscular depot formulations for risperidone, olanzapine, paliperidone, haloperidol, and fluphenazine are available in the United States. In Canada, long-acting depot formulations of risperidone, fluphenazine, haloperidol, flupenthixol, pipotiazine, and zuclopenthixol are approved. Olanzapine is the only atypical antipsychotic available in oral, short-acting intramuscular and depot intramuscular formulations.

Intravenous agents are usually reserved for acute agitation in which a rapid onset of effect is desirable. Droperidol is FDA approved for use as an intravenous anesthetic adjunct (but not for psychiatric conditions) but has been used for rapid tranquilization in the medical/surgical setting. Droperidol causes dose-dependent prolongation of the QTc interval and has been withdrawn from the United Kingdom and received a black-box warning in North America. Although haloperidol is not approved by the FDA for intravenous use, it is often administered intravenously in medical inpatient settings, especially for delirium, aggression, or mania. The FDA recommends electrocardiogram monitoring for QT prolongation and arrhythmia if halo-

peridol is administered intravenously. High doses of haloperidol, up to 1,000 mg daily, in patients with severe delirium have been reported to have minimal effects on heart rate, respiratory rate, blood pressure, and pulmonary artery pressure, with minimal EPS (Levenson 1995; Stern 1985).

Intramuscular antipsychotic formulations can be categorized on the basis of their pharmacokinetic features: short-acting preparations and long-acting depot preparations. Long-acting antipsychotics are typically used as antipsychotic maintenance treatment to ensure adherence and to eliminate bioavailability problems. Short-acting antipsychotics are usually used in acute management of delirium, psychosis, mania, or aggression (see Chapter 5, "Delirium"; Chapter 7, "Aggression and Violence"; and Chapter 10, "Psychosis, Catatonia, and Mania," for further discussion). Haloperidol is the most common (and least costly) intramuscularly administered antipsychotic in medical settings. However, acute parenteral administration of high-potency antipsychotics such as haloperidol is associated with more dystonia and other EPS. In patients with existing extrapyramidal disorders, an intramuscular antipsychotic other than haloperidol would be preferred. Parenteral administration of low-potency agents may cause more hypotension and lowered seizure threshold.

Intramuscular forms of atypical antipsychotics are less likely to cause acute dystonia and akathisia than haloperidol (Currier and Medori 2006; Zimbroff 2008), but there has been much less experience using them in the medically ill, and they are considerably more expensive. Haloperidol, but none of the atypical antipsychotics, can be mixed with a benzodiazepine in the same syringe. Ziprasidone and aripiprazole can be administered in conjunction with an intramuscular benzodiazepine, but concurrent intramuscular olanzapine with a parenteral benzodiazepine is not recommended because of excessive sedation and cardiorespiratory depression (Eli Lilly 2010b). Ziprasidone (oral or intramuscular) is contraindicated in patients with a known history of QT prolongation (including congenital long QT syndrome) or cardiac arrhythmias, with recent acute myocardial infarction, or with uncompensated heart failure, and caution should be used when coadministering ziprasidone with other drugs that prolong the QT interval (Pfizer 2010a). Intramuscular ziprasidone has not been systematically studied in patients with significant hepatic or renal impairment. Intramuscular olanzapine is recommended for the management of agitation in patients with schizophrenia, bipolar mania, or dementia. At this time, there are no data on intramuscular ziprasidone or olanzapine in the management of agitation in medically ill patients without an underlying psychiatric condition, so caution is advised.

Asenapine, recently FDA approved, is the only antipsychotic available in a sublingual preparation; it is not avail-

able in other delivery forms at this time. Oral disintegrating tablets, designed to deliver drug for intestinal absorption, are available for most atypical agents. Sublingual absorption of olanzapine oral disintegrating tablet has been studied in healthy volunteers (Markowitz et al. 2006). Sublingual administration resulted in a similar extent and rate of drug absorption compared with regular administration of the oral disintegrating tablet and faster absorption than the standard oral tablet. Sublingual/buccal absorption of oral disintegrating tablets for other antipsychotics has not been reported.

Subcutaneous administration of haloperidol and methotrimeprazine (available in Canada and Europe) and fluphenazine (Health Canada-approved for subcutaneous administration) can be used to manage terminal restlessness and for nausea/vomiting in palliative care patients. Loxapine has also been used subcutaneously in the palliative care setting. Most other phenothiazines are too irritating for subcutaneous injection.

Psychostimulants

Transdermal methylphenidate was approved for children in 2006 in the United States. The patch is worn for 9 hours but provides therapeutic effect through 12 hours. Several patch doses are available and the duration of effect can be modified by early removal of the patch (M.J. Manos et al. 2007). In children with ADHD, the adverse-effect profile is similar to that of a placebo patch (McGough et al. 2006). A placebo-controlled comparison of transdermal methylphenidate and the osmotic-release oral capsule in children revealed similar treatment efficacy for the active formulations but a higher incidence of tics and anorexia for transdermal methylphenidate (Findling et al. 2008). No clinical trials of transdermal methylphenidate in adults with serious medical illness have been published.

Although no other nonoral forms of psychostimulants are available, custom preparations are described. Dextroamphetamine has been administered intravenously to human subjects in research but not clinically (C.L. Ernst and Goldberg 2002). There is one published case report of 5-mg dextroamphetamine suppositories compounded by a pharmacy for treating depressed mood in a woman with gastrointestinal obstruction (Holmes et al. 1994).

Mood Stabilizers/Anticonvulsants

Mood stabilizers that have been administered intravenously include lithium carbonate and valproate. Because lithium is not metabolized, parenteral administration has fewer potential pharmacokinetic advantages than for other psychotropics. Parenteral lithium has rarely been used in the treatment of psychiatric disorders but has been used as a possible treatment in thyroid storm. Lithium was admin-

istered intraperitoneally in patients on continuous ambulatory peritoneal dialysis (Flynn et al. 1987). Lithium carbonate is not approved by the FDA for parenteral use, and there is not enough clinical experience or data to recommend its use by nonenteral routes.

Valproate has been available in parenteral form (Depacon) in Europe for more than 18 years and was approved by the FDA in the United States in 1997 (it was discontinued in Canada in 2004). Valproate is the only mood stabilizer, apart from several atypical antipsychotics, with an approved parenteral formulation where case reports exist for its use in psychiatric conditions (Norton 2001; Norton and Quarles 2000; Regenold and Prasad 2001). The intravenous solution, prepared in dextrose, saline, or lactated Ringer's solution, should not be infused at more than 20 mg/minute, with the dosage reduced in the elderly and in those with organic brain syndromes. The infusion does not require cardiac monitoring and causes no significant risk of orthostatic hypotension (Norton 2001). There are no randomized controlled trials documenting its safety and efficacy for psychiatric disorders.

Several studies report that rectal administration of carbamazepine, lamotrigine, and topiramate provides acceptable bioavailability and tolerability. Carbamazepine has been rectally administered as a solution (Neuvonen and Tokola 1987) and as a crushed tablet in a gelatin capsule (Storey and Trumble 1992), attaining therapeutic blood levels in some, but not all, patients. Rectal preparations of lamotrigine and topiramate have been prepared from oral formulations. Compared with oral dosing, rectal lamotrigine had reduced bioavailability (approximately 50%) leading to lower drug levels and slower absorption (Birnbbaum et al. 2001), while blood levels were identical after rectal topiramate (Conway et al. 2003). Provided relative bioavailability is considered, rectal administration of an aqueous suspension of these tablets may be acceptable. Rectal absorption of other anticonvulsants including oxcarbazepine, gabapentin, felbamate, and phenytoin is not reliable (Clemens et al. 2007). Oxcarbazepine is available as an oral suspension, but its rectal administration achieved only 10% of the oral bioavailability for the parent drug or active metabolite (Clemens et al. 2007). Thus, rectal delivery is not an appropriate route for oxcarbazepine.

Cholinesterase Inhibitors

Rivastigmine, as a transdermal patch, is the only cognitive enhancer available in a nonoral formulation. The rivastigmine patch is dosed daily and provides less fluctuating plasma levels than the twice-daily oral capsules or solution. The patch provides greater bioavailability but with slower absorption, which reduces peak drug levels by 20%. This more consistent drug exposure might improve effi-

cacy, but this remains to be investigated. The incidence of nausea and vomiting declined from 33% with the oral form to 20% with the patch (Lefevre et al. 2008).

Complementary Medicines

Surveys suggest that approximately 20% of U.S. adults have used herbal medicines and nonherbal dietary supplements within the past year (Barnes et al. 2004), often without disclosing their use. Many people assume that complementary medicines are “naturally” safe, and they combine complementary and conventional therapies, believing that the combination will be more effective (Eisenberg et al. 2001). This raises concerns about the appropriate therapeutic use, contraindications, adverse effects, and drug interactions of herbal and nonherbal drugs. Patients with chronic disease may be especially vulnerable to adverse effects from herbal medicines because of compromised organ function and polypharmacy with conventional agents.

Recently, the FDA Office of Nutritional Products, Labeling, and Dietary Supplements (www.cfsan.fda.gov/~dms/supplmnt.html) and Health Canada, Office of Natural Health Products (www.hc-sc.gc.ca/dhp-mps/prodnatur/), have moved to provide a regulatory framework to encourage good manufacturing practice and adverse-effect reporting for natural health products (Bent 2008; Morrow 2008). However, the FDA does not require efficacy or safety data for products marketed as dietary supplements.

The lack of government oversight and regulation has complicated attempts to assess the safety of herbal medicines. Manufacturers are not required to standardize the concentration of active ingredients or even to identify them (Chandler 2000; De Smet 2002). Herbal preparations may contain several plant species used under a single name (Chandler 2000) and may be adulterated with unlisted pharmacological agents, pesticides, and heavy metals, including cadmium, lead, mercury, or arsenic (Crone and Wise 1998; Saper et al. 2008). Drugs such as anti-inflammatory agents, steroids, diuretics, antihistamines, sildenafil-like compounds, and benzodiazepines may be intentionally added to the herbal product for therapeutic effect (G.M. Miller and Stripp 2007; Woollorton 2003).

Contraindications, major adverse effects, and significant drug interactions for those herbal medicines and nonherbal dietary supplements commonly used for neuropsychiatric symptoms are summarized in the following subsections, derived from available reviews (Ang-Lee et al. 2001; Bent and Ko 2004; Brazier and Levine 2003; Chandler 2000; De Smet 2002; C.L. Ernst and Goldberg 2002; E. Ernst 2003; Gardiner et al. 2008; Gurley et al. 2008; Hu et al. 2005; Mahady et al. 2008; Tracy and Kingston 2007).

Selected Herbal Medicines

Black Cohosh

Purported use. Menopausal symptoms

Pharmacological effects and drug interactions. Black cohosh binds to estrogen receptors and lowers levels of luteinizing hormone. It is contraindicated in pregnancy and lactation and should be avoided by women with estrogen-dependent tumors. Hepatotoxicity has prompted the FDA to require a cautionary notice on black cohosh products.

Feverfew

Purported use. Migraine prophylaxis, anti-inflammatory

Pharmacological effects and drug interactions. Used as an abortifacient in animals, feverfew is contraindicated in pregnancy in humans. It inhibits platelet activation factor and may prolong bleeding time. Risk is increased with drugs known to increase bleeding times, such as anticoagulants, NSAIDs, SSRIs, and platelet inhibitors. Allergic reactions are common. Withdrawal syndrome (anxiety, fatigue, joint ache) may occur on sudden discontinuation.

Ginkgo Biloba

Purported use. Ginkgo biloba improves peripheral and CNS blood flow and has been used for ischemia associated with peripheral artery disease and vascular dementia.

Pharmacological effects and drug interactions. Ginkgo biloba inhibits platelet activation factor and prolongs bleeding time. It carries an increased risk for bleeding disorders when used with drugs known to increase bleeding times (anticoagulants, NSAIDs, SSRIs, platelet inhibitors). Intracerebral and intraocular hemorrhages have been reported, and it may cause palpitations. Seizures have been reported in children, and efficacy of anticonvulsants may be reduced. The ginkgo biloba fruit, including the seeds, is poisonous and very allergenic. Ingestion of the fruit has resulted in loss of consciousness, seizures, and death, with a mortality rate of 27%. Ingestion of fruit also causes contact dermatitis of mucous membranes. Ginkgo biloba should be discontinued at least 2 days before surgery.

Ginseng

Purported use. Ginseng is promoted as a physical, mental, and sexual tonic, immunostimulant, and mood enhancer.

Pharmacological effects and drug interactions. Ginseng possesses estrogenic activity; it is contraindicated in patients with estrogen receptor-positive breast cancer. It may cause estrogen-related bleeding disorders (vaginal bleed-

ing) and breast nodules. Sympathomimetic activity may cause tachycardia, hypertension, nervousness, agitation, mania, and headache. It also has hypoglycemic and antiplatelet aggregation properties. Ginseng may reduce the effects of loop diuretics (furosemide), antihypertensives, anxiolytics, antidepressants, mood stabilizers, and antiestrogens. It inhibits platelet activation factor and prolongs bleeding time. Ginseng increases the risk of bleeding disorders with drugs known to increase bleeding times (anticoagulants, NSAIDs, SSRIs, platelet inhibitors). Risk is increased in patients with diabetes, hypertension, anxiety disorders, and bipolar disorder or those using estrogen therapy, antiestrogen therapy, or anticoagulants. Long-term use may result in "ginseng abuse syndrome" with symptoms including hypertension, nervousness, insomnia, skin eruptions, diarrhea, and tremor. A withdrawal syndrome (hypotension, weakness, tremor) may occur upon discontinuation. Ginseng should be discontinued at least 7 days before surgery.

Kava Kava

Purported use. Anxiolytic, sedative

Pharmacological effects and drug interactions. Kava kava exerts effects on several neurotransmitter systems, including gamma-aminobutyric acid (GABA), norepinephrine, and dopamine, and should not be used with antipsychotics and drugs used to treat Parkinson's disease. It potentiates the effects of CNS depressants, such as barbiturates, benzodiazepines, and alcohol. Dermopathy is common with heavy use. Antithrombotic action may prolong bleeding time. Risk is increased with drugs known to increase bleeding times. Kava kava is also hallucinogenic. Sale of kava has been banned in many jurisdictions because of several incidents of fatal hepatotoxicity. Kavalactones, the proposed active constituents of kava, inhibit major CYP enzymes and may cause interactions with concurrent medications. Kava kava should be discontinued at least 24 hours before surgery.

Ma Huang (Ephedra)

Purported use. Weight loss, stimulant

Pharmacological effects and drug interactions. Ma huang is an indirect sympathomimetic; it contains ephedrine and pseudoephedrine, which cause release of epinephrine and norepinephrine. Excessive sympathetic stimulation can lead to dizziness, headache, decreased appetite, gastrointestinal distress, irregular heartbeat, tachycardia, hypertension, insomnia, flushing, seizures, stroke, and death. Drug interactions include increased risk of cardiac arrhythmia

with cardiac glycosides and antiarrhythmics; reduced effects of antihypertensives, beta-blockers, sedative-hypnotics, and anesthetics; hypertensive crisis with MAOIs; and increased stimulant effects with theophylline and caffeine. Several ephedra-related deaths have occurred. The FDA banned the sale of ephedra in 2004.

St. John's Wort

Purported use. Antidepressant for mild to moderate depression, sedative

Pharmacological effects and drug interactions. St. John's wort increases serotonin and norepinephrine activity, which may cause sinus tachycardia and gastrointestinal distress and may exacerbate bipolar disorder, causing mania. Photosensitizing properties may cause sun-induced skin rash, neuropathy, and possibly increased incidence of cataracts, and may exacerbate photosensitivity due to tetracycline, piroxicam, and phenothiazines. St. John's wort induces CYP3A4 and has the potential to interact with medications metabolized by this enzyme to lower drug levels and decrease therapeutic effect (see Table 38-2). It induces P-gp drug efflux systems, reducing bioavailability and systemic exposure to several drugs, including digoxin, cyclosporine, and TCAs. St. John's wort may induce serotonin syndrome in combination with other serotonergic drugs. It should be discontinued at least 5 days before surgery.

Valerian

Purported use. Sedative, short-term treatment of insomnia, anxiolytic

Pharmacological effects and drug interactions. Tolerance to valerian may develop and lead to withdrawal effects with abrupt discontinuation following prolonged use. Withdrawal effects are similar to benzodiazepine withdrawal and can be managed with benzodiazepines. Valerian potentiates the sedative effects of CNS depressants.

Yohimbe, Yohimbine

Purported use. Aphrodisiac, stimulant

Pharmacological effects and drug interactions. Yohimbine, an α_2 antagonist, has indirect sympathomimetic activity. Adverse effects include insomnia, anxiety, panic attacks, hallucinations, hypertension, tachycardia, nausea, and vomiting. It should be avoided in patients with hypertension, sleep disorders, anxiety disorders, and psychosis. Yohimbine exacerbates the CNS and autonomic effects of stimulants and TCAs. It should be discontinued at least 2 days before surgery.

Selected Nonherbal Supplements

DHEA (Dehydroepiandrosterone)

Purported use. Depression, postmenopausal osteoporosis, systemic lupus erythematosus, erectile dysfunction, multiple sclerosis, dementia

Pharmacological effects and drug interactions. DHEA is an endogenous anabolic steroid that may undergo conversion in vivo to testosterone or androstenedione followed by conversion to estriol, estrone, and estradiol. DHEA may cause weight gain, voice change, hirsutism, and menstrual irregularities in females and gynecomastia and prostatic hypertrophy in males. DHEA is contraindicated in patients who have liver dysfunction, prostate cancer, or hormone-dependent diseases such as estrogen-dependent breast cancer. DHEA may inhibit CYP3A4.

Gamma-Hydroxybutyrate (GHB or Sodium Oxybate), Gamma-Butyrolactone, and 1,4-Butanediol

Purported use. Narcolepsy, recreational fast-acting hypnotic

Pharmacological effects and drug interactions. GHB is a partial agonist at GABA_B receptors with fast-onset hypnotic action. Gamma-butyrolactone and 1,4-butanediol are metabolized to GHB in vivo. Adverse effects include nystagmus, ataxia, apnea, sedation, dizziness, and respiratory depression. Coma, bradycardia, and death can result. Psychiatric side effects of GHB include hallucinations, delusions, agitation, confusion, and euphoria. A withdrawal syndrome (consisting of anxiety, insomnia, tremor, muscle cramps) has been observed. GHB is approved in the United States and Canada for narcolepsy under a controlled prescription program, but it is a banned drug in many other jurisdictions. Its precursors, gamma-butyrolactone and 1,4-butanediol, are industrial solvents and are available as street drugs (see also Chapter 17, “Substance-Related Disorders”).

S-Adenosyl-L-Methionine (SAME)

Purported use. Depression, osteoarthritis, chronic liver disease

Pharmacological effects and drug interactions. SAME is the principal endogenous methyl donor for methylation reactions. Adverse effects include nausea, vomiting, and diarrhea. SAME may increase anxiety and restlessness in patients with depression and mania and hypomania in patients with bipolar disorder. Serotonin syndrome has been reported. Risk is increased in patients with bipolar disorder, patients with movement disorders, or patients taking serotonergic drugs.

Psychotropic Drug Use in the Medically Ill

Psychosomatic medicine specialists routinely prescribe and advise other physicians regarding the use of psychotropic medications in patients with multiple complex medical problems. This gives rise to many issues regarding changes in pharmacokinetics and pharmacodynamics as previously outlined in this chapter. This section outlines clinical recommendations for the use of psychotropic medications in specific medical/surgical populations.

Gastrointestinal Disorders

Hepatic Disease

Psychopharmacological concerns in patients with liver disease largely center on pharmacokinetic changes brought about by the disease (discussed earlier in this chapter). Acute hepatitis usually does not require dose alteration of psychotropics, but chronic hepatitis may require dosage adjustment depending on the severity of liver dysfunction. In patients with cirrhosis, drug dose will require significant modification. The severity of liver disease can be approximated using the Child-Pugh scoring system (see Chapter 20, “Gastrointestinal Disorders”). All plasma proteins are synthesized in the liver, so protein binding is altered in liver disease. The main clinical effect of chronically decreased protein binding is on the interpretation of blood levels (see discussion in the “Distribution” subsection under “Pharmacokinetics in the Medically Ill” at the beginning of this chapter). When prescribing hepatically metabolized psychotropic drugs to patients with impaired hepatic function, it is prudent to reduce the initial dose and titrate more slowly, to carefully monitor for clinical response and side effects, and to choose drugs with a wide therapeutic index. Table 38-9 lists recommendations regarding dosing of psychotropics in patients with hepatic disease.

Antidepressants. Most antidepressants undergo extensive phase I hepatic oxidative metabolism and should be dosed according to the recommendations described. Anticholinergic TCAs may exacerbate hepatic encephalopathy in susceptible individuals via intestinal stasis and central anticholinergic effects. The use of newer antidepressants in patients with hepatic disease has received very little study. Citalopram, paroxetine, sertraline, and fluoxetine have all been used safely in patients with hepatitis C, usually in the context of interferon-alpha treatment (Hauser et al. 2002; Kraus et al. 2008; Raison et al. 2007; Sammut et al. 2002; Schramm et al. 2000).

Hepatotoxicity is a known rare side effect of many antidepressants, but nefazodone has a higher reported inci-

TABLE 38–9. Selected psychotropic drugs in hepatic insufficiency (HI)**Antidepressants**

MAOIs	Potentially hepatotoxic. No dosing guidelines.
SSRIs	Extensively metabolized. Decreased clearance and prolonged half-life. Initial dose should be reduced 50% and subsequent increments at longer intervals than usual. Target doses are typically substantially lower than usual.
TCAs	Extensively metabolized. Potentially serious hepatic effects. No dosing guidelines.
Bupropion	Extensively metabolized; decreased clearance. In even mild cirrhosis, use at reduced dose and/or frequency. In severe cirrhosis, dose should not exceed 75 mg daily for conventional tablets, or 100 mg daily or 150 mg every other day for sustained-release formulations.
Desvenlafaxine	Primarily metabolized by conjugation. No adjustment in starting dose necessary in HI. Dosage should not exceed 100 mg/day in severe HI.
Duloxetine	Extensively metabolized; reduced metabolism and elimination. Do not use in patients with any HI.
Mirtazapine	Extensively metabolized; decreased clearance. No dosing guidelines.
Nefazodone	May cause hepatic failure. Avoid use in patients with active liver disease.
Selegiline	Extensively metabolized; caution in HI. No dosing guidelines.
Trazodone	Extensively metabolized. No dosing guidelines.
Venlafaxine	Decreased clearance of venlafaxine and its active metabolite O-desmethylvenlafaxine. Dosage should be reduced by 50% in mild to moderate HI per manufacturer.

Atypical antipsychotics

Asenapine	No dosage adjustment required in mild to moderate HI. Not recommended in patients with severe HI per manufacturer.
Aripiprazole	Extensively metabolized. No dosage adjustment required in mild to severe HI per manufacturer.
Clozapine	Extensively metabolized. Clozapine should be discontinued in patients with marked transaminase elevations or jaundice. No dosing guidelines.
Iloperidone	Extensively metabolized. Pharmacokinetics in mild or moderate HI are unknown. Not recommended in patients with HI per manufacturer.
Olanzapine	Extensively metabolized. Periodic assessment of transaminases is recommended. No dosage adjustment needed per manufacturer.
Paliperidone	Primarily renally excreted. No dosage adjustment required in mild to moderate HI. No dosing guidelines in severe HI.
Quetiapine	Extensively metabolized; clearance decreased 30%. Start at 25 mg/day; increase by 25–50 mg daily.
Risperidone	Extensively metabolized; free fraction increased 35%. Starting dosage and dose increments not to exceed 0.5 mg bid. Increases over 1.5 mg bid should be made at intervals of ≥ 1 week.
Ziprasidone	Extensively metabolized; increased half-life and serum level in mild to moderate HI. In spite of this, manufacturer recommends no dosage adjustment.

Conventional antipsychotics

Haloperidol et al.	All metabolized in the liver. No specific dosing recommendations. Phenothiazines (e.g., thioridazine, trifluoperazine) should be avoided. If nonphenothiazines are used, dosage should be reduced and titration should proceed more slowly than usual.
--------------------	---

Anxiolytic and sedative-hypnotic drugs

Alprazolam	Decreased metabolism and increased half-life. Dosage should be reduced by 50%. Avoid use in patients with cirrhosis.
Buspirone	Extensively metabolized; half-life may be prolonged. Reduce dose and frequency in mild to moderate cirrhosis. Do not use in patients with severe impairment.
Chlordiazepoxide, clonazepam, diazepam, flurazepam, triazolam	Extensively metabolized; reduced clearance and prolonged half-life. Avoid use if possible.

TABLE 38-9. Selected psychotropic drugs in hepatic insufficiency (HI) (continued)

Lorazepam, oxazepam, temazepam	Metabolized by conjugation; clearance not affected. No dosage adjustment needed. Lorazepam is the preferred choice.
Ramelteon	Extensively metabolized. Exposure to ramelteon increased 4-fold in mild HI and 10-fold in moderate HI. Use with caution in patients with moderate HI. Not recommended in severe HI.
Zaleplon, zolpidem	Metabolized in the liver. Reduced clearance. Usual ceiling dose is 5 mg. Not recommended in severe HI.
Eszopiclone, zopiclone	Metabolized in liver. No dosage adjustment for mild to moderate HI. Reduce dose by 50% in severe HI.

Mood stabilizers/anticonvulsants

Carbamazepine	Extensively metabolized. Perform baseline liver function tests and periodic evaluations during therapy. Discontinue for active liver disease or aggravation of liver dysfunction. No dosing guidelines.
Oxcarbazepine	Manufacturer states that no dosage adjustment is needed in mild to moderate HI.
Gabapentin	Renally excreted; not appreciably metabolized. No dosage adjustment needed.
Lamotrigine	Initial, escalation, and maintenance dosages should be reduced by 50% in moderate HI (Child-Pugh B) and by 75% in severe HI (Child-Pugh C).
Lithium	Renally excreted; not metabolized. Dosage adjustment depends on fluid status.
Pregabalin	Renally excreted; not appreciably metabolized. No dosage adjustment recommended.
Topiramate	Reduced clearance. No dosing guidelines.
Valproate	Extensively metabolized; reduced clearance and increased half-life. Reduce dosage, monitor liver function tests frequently, especially in first 6 months of therapy. Avoid in patients with substantial hepatic dysfunction. Use with caution in patients with prior history of hepatic disease.

Cholinesterase inhibitors and memantine

Donepezil	Mildly reduced clearance in cirrhosis. No specific recommendations for dose adjustment.
Galantamine	Use with caution in mild to moderate HI. Dose should not exceed 16 mg daily in moderate HI (Child-Pugh 7-9). Use not recommended in severe HI (Child-Pugh 10-15).
Rivastigmine	Clearance reduced 60%-65% in mild to moderate HI, but dose adjustment may not be necessary.
Memantine	Primarily renally eliminated. No dosage adjustment expected in HI per manufacturer.

Central nervous system stimulants

Atomoxetine	Extensively metabolized; reduce initial and target dose by 50% in moderate HI and 75% in severe HI as per manufacturer.
Methylphenidate	Unclear association with hepatotoxicity, particularly when coadministered with other adrenergic drugs. No dosing guidelines.
Armodafinil, modafinil	Decreased clearance. Reduce dose by 50% in severe HI.

Note. MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

Source. Compiled from Crone et al. 2006; Jacobson 2002; Monti and Pandi-Perumal 2007; and manufacturer's product information.

dence than other current antidepressants and thus should be avoided in patients with preexisting hepatic disease (Carvajal Garcia-Pando et al. 2002; D.E. Stewart 2002). As a general guideline, minor elevations in transaminases are common and usually benign. Elevation of aspartate transaminase (AST) or alanine transaminase (ALT) levels of two to three times baseline or two times normal is significant, and any elevation of alkaline phosphatase (ALP) or bilirubin may be significant.

Antipsychotics. Although very little has been written about the use of antipsychotics in individuals with liver

failure, haloperidol remains the most commonly chosen antipsychotic agent for patients with hepatic disease. Chlorpromazine should be avoided because of its greater risk for hepatotoxicity. Low-potency typical antipsychotic medications, which are more anticholinergic than high-potency typical agents, may precipitate hepatic encephalopathy in patients with cirrhosis (as previously described for TCAs). Hepatotoxicity from atypical antipsychotics is rare, and agents in this class remain viable alternatives. All antipsychotics except paliperidone and aripiprazole require dosage reduction in patients with hepatic insufficiency.

Anxiolytics and sedative-hypnotics. Most benzodiazepines are metabolized by phase I processes, and liver disease affects phase I processes significantly more than phase II processes. For this reason, the preferred benzodiazepines for any patient with liver disease are lorazepam, oxazepam, and temazepam because they are metabolized by phase II conjugation. All benzodiazepines should be avoided in patients at risk for developing hepatic encephalopathy because they may precipitate its onset. When their use cannot be avoided (e.g., alcohol withdrawal in a patient with cirrhosis), lorazepam, oxazepam, and temazepam are preferred, with vigilant monitoring of changes in mental status.

Mood stabilizers/anticonvulsants. Because of the risk of hepatotoxicity, carbamazepine and valproate are relatively contraindicated in patients with preexisting liver disease. If either of these agents is used, reduce dose and monitor liver function regularly, especially during the first 6 months of therapy. Gabapentin is renally excreted and does not require dosage adjustment in patients with hepatic disease. Lithium, although renally excreted, may require dosage adjustment and close monitoring secondary to fluctuating fluid balance in patients with liver disease accompanied by ascites (secondary hyperaldosteronism). Lithium pharmacokinetics is also influenced by diuretics for treatment of ascites (see discussion of lithium drug interactions, above). Oxcarbazepine's manufacturer states that no disease adjustment is needed for patients with mild to moderate hepatic insufficiency. Lamotrigine dose should be reduced according to the severity of hepatic impairment. There are no current dosing recommendations for topiramate.

Cholinesterase inhibitors and memantine. Donepezil clearance may be reduced in cirrhosis, but there are no specific dosing recommendations for hepatic insufficiency. Galantamine should be used with caution in patients with mild to moderate hepatic insufficiency, and its dose should not exceed 16 mg daily in patients with a Child-Pugh Score of 7–9 (see Chapter 20, "Gastrointestinal Disorders"). Rivastigmine clearance may be reduced by 60%–65% in patients with mild to moderate hepatic insufficiency, and dosing should be guided by monitoring efficacy and tolerability. Memantine is mainly renally eliminated and requires no dosage reduction in hepatic insufficiency.

Psychostimulants. There are no specific dosing recommendations for methylphenidate. Modafinil and armodafinil clearance is reduced in hepatic insufficiency, and its dosage should be reduced by 50% in patients with severe hepatic insufficiency. For atomoxetine, initial and target doses should be reduced by 50% and 75% of the normal

dose for patients with moderate and severe hepatic impairment, respectively (Eli Lilly 2010a).

Gastrointestinal Bleeding

Antidepressants. SSRIs have hemorrhagic potential by interfering with serotonin-induced platelet aggregation through depletion of platelet serotonin stores. The absolute effects are modest and about equal to low-dose ibuprofen. Cohort studies confirm an increased risk of upper gastrointestinal bleeding (3.6-fold), especially with concurrent NSAID or acetylsalicylic acid (ASA; aspirin) use (12-fold) (Dalton et al. 2003; Turner et al. 2007). Concurrent use of SSRIs and warfarin increased the risk of clinically relevant nongastrointestinal bleeding in patients receiving warfarin (3.5-fold) (Wallerstedt et al. 2009). Risk also increases in the presence of medical conditions, such as thrombocytopenia or clotting disorders, which predispose to prolonged bleeding time (see Chapter 24, "Hematology," for a more complete discussion).

Cholinesterase inhibitors. Increased cholinergic activity is expected to increase gastric acid secretion, thereby increasing risk of peptic ulcers. Therefore, caution is warranted when using cholinesterase inhibitors in patients who are at increased risk of developing ulcers or who are receiving NSAIDs.

Drug-Induced Pancreatitis

Several psychotropic agents are infrequently associated with drug-induced pancreatitis. Risk may be elevated in patients with AIDS/HIV, cancer, Crohn's disease, cystic fibrosis, or alcohol abuse or those on multiple medications. Symptoms usually resolve with prompt discontinuation of medication. Among psychotropics, valproate is most frequently associated with acute pancreatitis with an incidence of 0.0025%. Although transient asymptomatic hyperamylasemia occurs in 20% of adult valproate patients, it is unrelated to risk of pancreatitis (Gerstner et al. 2007). Anticonvulsant drug-induced pancreatitis is also infrequently reported with carbamazepine, lamotrigine, topiramate, levetiracetam, and vigabatrin (Zaccara et al. 2007). Antipsychotic-induced pancreatitis, usually occurring within 6 months of starting therapy, has been reported with clozapine and olanzapine, and less often with risperidone and haloperidol (Koller et al. 2003). Mirtazapine, and less frequently bupropion, venlafaxine, and SSRIs may also cause antidepressant-induced pancreatitis (Hussain and Burke 2008; Spigset et al. 2003).

Following recovery from drug-induced pancreatitis, the offending drug should not be re-instituted; use of a drug from a different class is preferred (Dhir et al. 2007).

Other Gastrointestinal Disorders

Many diseases can cause malabsorption. Depending on the type of malabsorption syndrome and the mechanism involved, varied effects on pharmacokinetics may be observed. In general, however, orally administered drugs may be poorly absorbed in the presence of malabsorption syndromes. In patients with delayed gastric emptying (due to diabetes mellitus, atrophic gastritis, gastric cancer, pyloric stenosis, pancreatitis, gastric ulcer, or drug effects), absorption rate may be slowed resulting in a delay in the onset of the medication's therapeutic effect. The effects of gastric dysfunction on drug absorption, including reduced gastric acidity and reduced gastric emptying, are complex (see Gubbins and Bertch 1991; Parsons 1977). For non-enteric-coated preparations, increased gastric emptying is likely to increase the rate of drug absorption, and conversely, delayed gastric emptying will slow the rate of drug absorption. However, because of the large intestinal surface area, overall absorption is not likely to change significantly. Similarly, for most drugs, reduced gastric acidity is unlikely to significantly affect the extent of absorption. For enteric-coated preparations, however, reduced gastric acidity increases the rate of drug absorption because dissolution of the preparation will occur in the stomach. The rate and extent of absorption of drugs, such as clorazepate, that require gastric acid-induced hydrolysis for conversion to the active form (desmethyldiazepam in the case of clorazepate) are impaired by agents, and presumably disease states, that reduce gastric acidity (Greenblatt et al. 1978; Parsons 1977). Anticholinergic drugs should be avoided in patients with gastroparesis, constipation, or ulcerative colitis. SSRIs may be undesirable in patients with increased gastric motility or diarrhea. When conditions or disease states may significantly alter oral drug absorption, an alternate route of drug administration should be considered (see "Alternative Routes of Administration" subsection earlier in this chapter).

Renal Disease

Although most psychotropic drugs do not depend on the kidney for excretion, renal failure may alter drug pharmacokinetics including changes in absorption, distribution, and protein binding (discussed earlier in this chapter). Despite the complexity of pharmacokinetic changes in renal failure, most psychotropics, other than lithium, gabapentin, pregabalin, memantine, paliperidone, paroxetine, desvenlafaxine, topiramate, and venlafaxine, do not require drastic dosage adjustment. However, many problems associated with use of psychotropics in patients with end-stage renal disease (ESRD) are related to comorbid illnesses rather than to the renal failure per se. Specific dosing

guidelines based on creatinine clearance are not available for most psychotropics, but many clinicians use the rule of "two-thirds"—that is, for patients with renal insufficiency, use two-thirds of the dose (except for drugs listed above) used for patients with normal renal function.

Because most psychotropics are lipophilic compounds with large volumes of distribution, they are not dialyzable. Only lithium, gabapentin, pregabalin, valproate, topiramate, and levetiracetam are removed by dialysis. Significant fluid shifts occur during and several hours after each hemodialysis treatment, making dialysis patients more prone to orthostasis. Hence, drugs that frequently cause orthostatic hypotension should ideally be avoided.

Table 38-10 provides recommendations for dosing psychotropics in patients with renal disease.

Antidepressants

Virtually all antidepressants may be used in patients with renal failure, although the greatest experience is with the TCAs. However, patients with ESRD tend to be more sensitive to the side effects of TCAs, including sedation, anticholinergic toxicity, and orthostatic hypotension. Hydroxylated metabolites have been shown to be markedly elevated in patients with ESRD and may be responsible for some TCA side effects. Nortriptyline is considered the preferred TCA because its blood levels correlate well with clinical effect, and the "therapeutic window" is the same in renal failure patients as in physically healthy patients. Limited data are available on the use of newer antidepressants in patients with renal failure. Some evidence suggests that dosage adjustments may not be needed for citalopram and fluoxetine in those with ESRD. However, the half-life of venlafaxine is prolonged in renal insufficiency; its clearance is reduced by over 50% in patients undergoing dialysis. Desvenlafaxine undergoes significant renal elimination requiring dosage reduction in moderate and severe renal impairment. Paroxetine clearance is also reduced in renal insufficiency. Because most antidepressants are metabolized by the liver and excreted by the kidney, initial dosage reduction of all antidepressants is reasonable as a way to reduce the possibility that potentially active metabolites will accumulate.

Antipsychotics

All antipsychotics may be used in patients with renal failure, however, paliperidone clearance is significantly decreased in all degrees of renal impairment requiring a reduction in initial and target dose. Difficulties arise from the complications of renal failure and dialysis or from the chronic disease causing renal failure (e.g., diabetes). For example, patients with ESRD who also have diabetic autonomic neuropathy will be at higher risk for drug side ef-

TABLE 38–10. Psychotropic drugs in renal insufficiency (RI)^a**Antidepressants**

MAOIs	May accumulate in RI.
TCAs	Water-soluble active metabolites may accumulate. No recommended dosage adjustments.
Most SSRIs	Mild to moderate RI: no dosage adjustment needed. Severe RI: may need to reduce dosage or lengthen dosing interval.
Paroxetine	Mild RI: no dosage adjustment needed. Moderate RI: 50%–75% of usual dose. Severe RI: initial dosage of 10 mg/day; increase as needed by 10 mg at weekly intervals to a maximum dosage of 40 mg/day. Controlled-release formulation: initial dose of 12.5 mg/day; increase if needed by 12.5 mg at weekly intervals to a maximum of 50 mg/day.
Bupropion	Water-soluble active metabolites may accumulate. Reduce initial dosage.
Desvenlafaxine	Approximately 45% of desvenlafaxine is excreted unchanged in urine. No dosage adjustment is required in mild RI. Dosage should not exceed 50 mg/day in moderate RI, or 50 mg every other day in severe RI, per manufacturer.
Duloxetine	Mild RI: population CPK analyses suggest no significant effect on apparent clearance. No data regarding use in moderate to severe RI. Not recommended for patients with end-stage renal disease.
Mirtazapine	Moderate RI: clearance decreased by 30%. Severe RI: clearance decreased by 50%.
Nefazodone	No dosage adjustment needed.
Trazodone	Mild RI: use with caution. No data regarding use in moderate to severe RI.
Selegiline	Active metabolite (methamphetamine) renally eliminated. Use with caution in renal impairment. No dosing guidelines.
Venlafaxine	Mild to moderate RI: 75% of usual dose. Severe RI: 50% of usual dose. Hemodialysis patients should have dosage reduced by 50% and receive dose after dialysis session.

Atypical antipsychotics

Asenapine, aripiprazole, clozapine, olanzapine, quetiapine	No dosage adjustment needed.
Iloperidone	Dosage adjustment not needed in mild to moderate RI, per manufacturer. No recommendations for dosing in severe RI.
Paliperidone	Clearance decreased in RI. For mild impairment, start at 3 mg/day, increasing to a maximum of 6 mg/day. For moderate to severe impairment start at 1.5 mg/day, increasing to 3 mg/day, as tolerated.
Risperidone	Clearance decreased in RI. Initiate therapy at 0.25–0.5 mg bid. Increase beyond 1.5 mg should be made at intervals of at least 7 days.
Ziprasidone	No recommendations made regarding dosage adjustment.

Conventional antipsychotics

Haloperidol et al.	No dosage adjustment needed.
--------------------	------------------------------

Anxiolytics and sedative-hypnotics

Most benzodiazepines	No dosage adjustment needed.
Chlordiazepoxide	Severe RI: 50% of usual dose.
Buspirone	Use in severe RI not recommended.
Ramelteon	No dosage adjustment needed.
Zaleplon	Mild to moderate RI: no dosage adjustment needed. Severe RI not adequately studied.
Zolpidem	Dosage adjustment may not be needed in RI.
Eszopiclone, zopiclone	No dosage adjustment needed.

TABLE 38–10. Psychotropic drugs in renal insufficiency (RI)^a (continued)**Mood stabilizers/anticonvulsants**

Carbamazepine	Severe RI: 75% of usual dose.
Gabapentin	Cl _{cr} >60 mL/min: 1,200 mg/day (400 mg tid). Cl _{cr} 30–60 mL/min: 600 mg/day (300 mg bid). Cl _{cr} 15–30 mL/min: 300 mg/day. Cl _{cr} <15 mL/min: 150 mg/day (300 mg every other day). Hemodialysis: 300–400 mg loading dose to patients who have never received gabapentin, then 200–300 mg after each dialysis session.
Lamotrigine	Reduced dose may be effective in significant RI.
Lithium	Moderate RI: 50%–75% of usual dose. Hemodialysis: supplemental dose of 300 mg once after each dialysis session.
Oxcarbazepine	Initiate therapy at 300 mg/day (50% of usual starting dose).
Pregabalin	Cl _{cr} 30–60 mL/min: 50% of usual dosage. Cl _{cr} 15–30 mL/min: 25% of usual dosage. Cl _{cr} <15 mL/min: 12.5% of usual dosage. Hemodialysis: supplemental dose may be needed after every 4-hour dialysis. See manufacturer's recommendations.
Topiramate	Mild RI: 100% of usual dosage. Moderate RI: 50% of usual dosage. Severe RI: 25% of usual dosage. Supplemental dose may be needed after hemodialysis.
Valproate	No dosage adjustment needed in RI, but valproate level measurements are misleading.

Cholinesterase inhibitors and memantine

Donepezil	Limited data suggest no dosage adjustment needed.
Galantamine	Moderate RI: maximum dose 16 mg/day. Severe RI: use not recommended.
Rivastigmine	Dosage adjustment not recommended.
Memantine	Extensive renal elimination. No dosage reduction needed in mild to moderate RI. Reduce dose to 5 mg bid in severe RI.

Central nervous system stimulants

Atomoxetine	No dosage adjustment needed.
Methylphenidate	No dosage adjustment needed.
Armodafinil, modafinil	No dosage adjustment needed.

Antiparkinsonian agents

Amantadine	Cl _{cr} 80 mL/min: 100 mg twice daily. Cl _{cr} 60 mL/min: alternating daily doses of 100 mg once daily and 100 mg twice daily. Cl _{cr} 40 mL/min: 100 mg/day. Cl _{cr} 30 mL/min: 200 mg twice weekly. Cl _{cr} 20 mL/min: 100 mg three times weekly. Cl _{cr} 10 mL/min: alternating weekly doses of 100 mg once weekly and 200 mg once weekly. Hemodialysis: 200 mg once weekly.
Pramipexole	90% renal elimination: clearance of pramipexole is 75% lower in severe RI (Cl _{cr} 20 mL/min) and 60% lower in patients with moderate RI (Cl _{cr} 40 mL/min) compared with healthy volunteers. Interval between titration steps should be increased to 14 days in restless legs syndrome (RLS) patients with severe or moderate RI (Cl _{cr} 20–60 mL/min).

Note. Cl_{cr} = creatinine clearance; CPK = creatine phosphokinase; MAOIs = monoamine oxidase inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

^aMild RI is >50 mL/min; moderate RI is 10–50 mL/min; severe RI is <10 mL/min.

Source. Compiled from L.M. Cohen et al. 2004; Crone et al. 2006; Jacobson 2002; Periclou et al. 2006; and manufacturer's product information.

fects, including postural hypotension and bladder, gastrointestinal, and sexual dysfunction.

Anxiolytics and Sedative-Hypnotics

Virtually all sedative-hypnotics can be used in patients with renal failure with the exception of barbiturates. Barbiturates should be avoided because they may increase osteomalacia and because of excessive sedation. Preferred benzodiazepines include those with inactive metabolites such as lorazepam and oxazepam. Even so, the half-lives of lorazepam and oxazepam may almost quadruple in patients with ESRD, and dosage reduction is required. Other benzodiazepines with inactive metabolites include clonazepam and temazepam, but less is known about changes in their half-lives in ESRD.

Mood Stabilizers/Anticonvulsants

Lithium is almost entirely excreted by the kidneys. It is contraindicated in patients with acute renal failure, but not in those with chronic renal failure. For patients with stable partial renal insufficiency, dose conservatively and monitor renal function frequently. For patients on dialysis, lithium is completely dialyzed and may be given as a single oral dose (300–600 mg) following hemodialysis treatment. Lithium levels should not be checked until at least 2–3 hours after dialysis, because re-equilibration from tissue stores occurs in the immediate postdialytic period. For patients on peritoneal dialysis, lithium can be given in the dialysate. Dosage adjustment recommendations based on creatinine clearance are available for gabapentin, lithium, pregabalin, topiramate, and carbamazepine (Jacobson 2002).

Cholinesterase Inhibitors and Memantine

It appears, from the limited data available, that dosage adjustment of donepezil is not required. As in patients without renal disease, rivastigmine dose should be titrated according to efficacy and individual tolerability. Galantamine should be used cautiously in patients with moderate renal insufficiency; according to the manufacturer, its use in patients with severe renal insufficiency is not recommended. Memantine undergoes extensive renal elimination requiring a dosage reduction in severe renal insufficiency.

Psychostimulants

No specific dosing recommendations are currently available for psychostimulants.

Cardiovascular Disease

Potential adverse cardiovascular effects of psychotropics include orthostatic hypotension, conduction disturbances, and arrhythmias (see also Chapter 18, “Heart Disease”).

Orthostatic hypotension can be a serious problem for many debilitated patients, aggravated by dehydration, with increased morbidity resulting in patients with poor tissue perfusion and leading to injuries due to falls (fractures, subdural hematomas).

Antidepressants

The safety of antidepressant drugs in patients with cardiac disease is extensively reviewed by Alvarez and Pickworth (2003) and Taylor (2008). In summary, patients most at risk for developing cardiac side effects include those with unstable coronary artery disease (especially recent myocardial infarction), conduction abnormalities, orthostatic hypotension, and congestive heart failure (Taylor 2008). Although there are more studies of TCAs than of other antidepressants in cardiac patients, the SSRIs have been studied in the largest number of patients.

Tricyclic antidepressants. The TCAs have been shown to be relatively safe for short-term treatment of patients with stable ischemic heart disease, previous myocardial infarction, and congestive heart failure. Long-term safety has not been studied. In healthy individuals, the cardiovascular complications from TCAs administered at therapeutic levels are largely limited to orthostatic hypotension (Glassman 1984). In patients with heart disease, the cardiovascular risks become clinically significant. TCAs are more likely to cause orthostatic hypotension in patients with impairment in left ventricular function but are relatively safe to use in most patients with congestive heart failure. Caution is required if the patient has symptomatic orthostatic hypotension or markedly reduced cardiac ejection fraction. Nortriptyline is considered the safest TCA in patients with congestive heart failure because it is least likely to cause orthostasis (Roose et al. 1981) and has little to no effect on cardiac ejection fraction (Giardina et al. 1985; Roose et al. 1986).

All TCAs have quinidine-like Type 1A antiarrhythmic properties that delay cardiac conduction and increase heart rate. In healthy individuals, this is usually not clinically significant. Patients with existing conduction delays (e.g., bundle branch block) may have clinically relevant deleterious effects on conduction time. In patients with bundle branch block (especially those with second-degree heart block), dissociative (third-degree) atrioventricular heart block may develop. Some calcium channel blockers (diltiazem and verapamil, but not nifedipine) may also slow atrioventricular conduction, making their combination with TCAs more dangerous.

The quinidine-like effect of TCAs prolongs the QTc interval, which may lead to the potentially fatal arrhythmia torsade de pointes. Patients at particular risk include those

with preexisting familial long QTc syndrome or who develop undue QTc prolongation during treatment with TCAs (or other QTc-prolonging drugs including antipsychotics and antimicrobials). An electrocardiogram is indicated for patients treated with TCAs who have a family history of sudden death or syncope or a personal history of angina, syncope, myocardial infarction, congestive heart failure, arrhythmias, hypokalemia, hypomagnesemia, or other significant cardiac risk factors (Vieweg 2002). TCAs are not recommended in patients with existing conduction disturbances, however, if necessary, a cardiology consultation should be sought prior to the use of TCAs in these patients.

Wolff-Parkinson-White syndrome, or atrioventricular nodal reentrant tachycardia, affects approximately 0.15%–0.2% of the general population. Of these individuals, 60%–70% have no other evidence of heart disease. In some, more serious and potentially life-threatening abnormal rhythms may develop. The most common of these is atrial fibrillation. Quinidine-like drugs given to patients with atrial flutter-fibrillation may lead to ventricular tachycardia or fibrillation. All patients with Wolff-Parkinson-White syndrome should be evaluated by a cardiologist prior to considering TCA treatment.

Newer antidepressants. SSRIs are currently considered the safest antidepressants in patients with cardiac disease. Cardiovascular effects of SSRIs include modest slowing of heart rate, minimal effects on blood pressure (rare hypotension) or conduction, and no effects on ventricular function (Taylor 2008; Vieweg et al. 2006). Venlafaxine, desvenlafaxine, and duloxetine may increase supine diastolic blood pressure through their noradrenergic effects. Although trazodone is considered safe, it causes orthostatic hypotension not infrequently and, rarely, premature ventricular contractions and ventricular tachycardia (Winkler et al. 2006). Bupropion may elevate blood pressure, but other cardiovascular effects are generally rare. Bupropion has been used safely in patients with conduction disease and left ventricular dysfunction (Roose et al. 1991). Mirtazapine has been studied in patients with post-myocardial infarction depressive disorder and found to have no significant cardiac effects (Honig et al. 2007).

Antipsychotics

Antipsychotics causing orthostatic hypotension, including low-potency antipsychotics, clozapine, and quetiapine, should be avoided in patients with congestive heart failure. Because olanzapine and high-potency typical antipsychotics such as haloperidol cause orthostasis far less frequently, they can usually be used safely even during acute unstable cardiac disease.

Patients with preexisting intraventricular conduction delays are at increased risk of heart block when given antipsychotics with quinidine-like properties such as thioridazine. Although the cardiovascular risks with antipsychotics may vary, pimozide, thioridazine, mesoridazine, droperidol, sertindole, ziprasidone, and quetiapine carry the highest risk for prolonging the QTc interval and causing torsade de pointes. Other atypical antipsychotics and haloperidol appear to demonstrate the least risk for prolonging the QTc interval. Although haloperidol has caused QTc prolongation and torsade de pointes, especially when parenterally administered at a high dosage (>100 mg/day), it is generally accepted to be minimally cardiotoxic. It is prudent to obtain an electrocardiogram for any patient at increased cardiac risk when prescribed an antipsychotic drug, and especially for those drugs associated with a significantly increased risk of QTc prolongation (ziprasidone, quetiapine, droperidol, mesoridazine, thioridazine, pimozide, high-dose intravenous haloperidol).

Anxiolytics and Sedative-Hypnotics

Generally, benzodiazepines are free of cardiovascular effects. Their safety has been documented even in the immediate post-myocardial infarction period (Risch et al. 1982). However, rapid intravenous administration may cause hypotension. Buspirone is essentially free of cardiovascular effects. Zolpidem has been reported to be without effect on systolic blood pressure or heart rate in healthy human volunteers (McCann et al. 1993). To date, there are no reports of the cardiovascular effects of zopiclone, eszopiclone, zaleplon, or ramelteon.

Mood Stabilizers/Anticonvulsants

The cardiac effects of lithium at nontoxic levels are generally insignificant; there may be nonspecific electrocardiographic changes, which are usually benign. Lithium uncommonly causes sinus node dysfunction or first-degree atrioventricular block (Dasgupta and Jefferson 1990) and QTc prolongation (van Noord et al. 2009) and should be used cautiously in patients at risk. For patients with congestive heart failure, reduced doses are required secondary to decreased lithium clearance. However, lithium is difficult to use in these patients because of salt restriction and coadministration of diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers. Valproate is safe to use in patients with cardiovascular disease. Carbamazepine is more cardiotoxic and has been associated with the development of atrioventricular conduction disturbances (Chong et al. 2001). Before carbamazepine is prescribed, a baseline electrocardiogram should be obtained in patients at risk, and alternative therapy should be considered if there is evidence of heart block or atrioven-

tricular conduction delay. Lamotrigine has been associated with clinically insignificant prolongation of the PR interval. Caution is warranted with other mood stabilizers because they have not been systematically studied in patients with cardiac disease.

Cholinesterase Inhibitors and Memantine

Cholinesterase inhibitors may have vagotonic effects on the heart (e.g., bradycardia). This effect may be of particular concern in patients with “sick sinus syndrome” or other supraventricular conduction abnormalities. Cholinesterase inhibitors should be avoided in patients with most cardiac conduction abnormalities and those with unexplained syncopal episodes. Memantine is generally benign in patients with cardiovascular disease, but it may rarely cause bradycardia (Gallini et al. 2008).

Psychostimulants

Methylphenidate and dextroamphetamine in low doses have no significant cardiovascular effects, including no effect on blood pressure or heart rate. While safe use has been described in many cardiac patients, including those with congestive heart failure, coronary artery disease, arrhythmias, and hypertension (Masand and Tesar 1996), use of these stimulants in patients with structural cardiac abnormalities, cardiomyopathy, coronary artery disease or serious rhythm abnormalities is contraindicated according to FDA-approved product monographs.

There are no studies of the cardiovascular effects of modafinil, armodafinil, or atomoxetine in cardiac patients. Modafinil increased blood pressure more than placebo in obstructive sleep apnea patients subjected to mental and physical stress (Heitmann et al. 1999). In noncardiac patients, cardiovascular adverse effects of atomoxetine are restricted to small increases in heart rate and blood pressure with no prolongation of the QT interval (Wernicke et al. 2003).

Because stimulants can increase heart rate and blood pressure, it would seem prudent to use caution when prescribing stimulants to patients with underlying medical conditions that might be compromised by increases in heart rate or blood pressure.

Central Nervous System Disease

Cerebrovascular Disease

The most common problems encountered when prescribing psychotropics to patients with cerebrovascular disease include lowered threshold for CNS side effects, orthostatic hypotension, and comorbid disorders (e.g., cardiac disease, diabetes).

Antidepressants. Poststroke depression is a common neuropsychiatric complication of stroke in up to one-half of patients (see also Chapter 8, “Depression,” and Chapter 32, “Neurology and Neurosurgery”). Antidepressant prophylaxis of poststroke depression has been studied in several meta-analyses. Chen et al. (2007) suggested that SSRIs and TCAs are effective in reducing the incidence of poststroke depression by more than 50%, especially in patients with ischemic stroke. Many, but not all (Hackett et al. 2005), analyses support a beneficial prophylactic effect for antidepressants in poststroke depression. Treatment of existing poststroke depression has been most studied with nortriptyline, trazodone, fluoxetine, sertraline, citalopram, and escitalopram, with favorable therapeutic effects in those patients able to tolerate these medications. Mirtazapine, venlafaxine, and milnacipran are also reportedly of benefit (Tharwani et al. 2007). Evidence for the safety and efficacy of desvenlafaxine and duloxetine in poststroke patients is lacking.

Antipsychotics. Concerns of an increased risk of cerebrovascular events (stroke, transient ischemic attack), including fatalities, arose from analysis of four placebo-controlled trials of risperidone in elderly patients with dementia-related psychosis (Health Canada 2002). Further pharmacovigilance suggested an increased risk of cerebrovascular events with all atypical antipsychotics prompting Britain’s Committee on Safety of Medicines in 2004 to recommend against use of atypical antipsychotics in dementia patients. In 2005, the FDA ordered a black-box warning for all atypical antipsychotics of an increased risk of death in elderly patients with dementia-related psychosis. Recent studies suggest that all antipsychotics (both typical and atypical agents) are associated with an increased risk of stroke in the elderly. A large cohort study identified risk of stroke as greater for elderly users of phenothiazines (5.8-fold), butyrophenones (3.6-fold), and atypical agents (2.5-fold) than for elderly nonusers (Sacchetti et al. 2008). An increase in stroke incidence was also observed in a within-person case series examining the risk of stroke while taking an antipsychotic drug. For elderly patients, the risk of stroke increased while taking antipsychotics 2.3-fold for atypical agents and 1.7-fold for typical agents. The presence of dementia approximately doubled the risk of stroke for each drug class (Douglas and Smeeth 2008). To date, identified risk factors that may predispose to cerebrovascular adverse events are limited to age greater than 80 years, antipsychotic use, and presence of dementia, although other factors—including sedation, concomitant use of benzodiazepines, and the presence of pulmonary conditions (e.g., pneumonia with or without aspiration)—have been suggested.

Psychostimulants. Psychostimulants offer an alternative in treating poststroke depression, but poststroke patients may be more sensitive to their side effects. Hence, psychostimulants should be initiated at a very low dose and gradually increased as necessary (Masand and Tesar 1996).

Seizures

Psychotropics that may lower seizure threshold at normal doses primarily pose a risk in patients with untreated (or undertreated) seizure disorder.

Antidepressants. Seizure disorder patients are frequently prescribed psychotropic medications, including antidepressants, because of high psychiatric comorbidity. Naturally, the use of antidepressants in these patients raises concerns over the possibility of increased seizure risk. Studies estimating seizure risk are difficult to interpret because of methodological limitations and confounding factors. TCAs consistently increase seizure risk a small amount. An analysis of FDA Phase II and Phase III clinical trials suggests that in comparison with placebo, SSRIs and SNRIs actually lower the incidence of seizure by more than 50% (Alper et al. 2007). Risk of seizures with the sustained-release (SR) formulation of bupropion (dosage of 450 mg/day) is comparable to that with SSRIs but is elevated at dosages greater than 450 mg/day. Bupropion immediate release (IR) has a greater risk of seizures than bupropion SR. The use of bupropion in patients with preexisting seizure disorder, or in patients who may be at higher risk for developing seizures (e.g., in bulimia), warrants caution, especially with the IR form.

Antipsychotics. Low-potency typical antipsychotics, especially at high dose ($\geq 1,000$ mg/day chlorpromazine), and clozapine have higher reported risk of seizures and should be avoided in patients with existing seizure disorders. Seizures have been reported with most antipsychotics; however, haloperidol and risperidone (and likely paliperidone) have the lowest rate of seizures, followed by quetiapine, then olanzapine and low-potency typical antipsychotics with an intermediate risk (Alldredge 1999; Alper et al. 2007). Generally, antipsychotic seizure risk increases with sedating effect.

Cholinesterase inhibitors and memantine. Cholinomimetics may reduce the seizure threshold, and seizures have been reported during clinical trials with all cholinesterase inhibitors. However, seizure activity may also be a manifestation of Alzheimer's disease. Donepezil has been reported to increase seizure frequency in patients with epilepsy (Fisher et al. 2001). The risk-benefit ratio of cholinesterase treatment for patients with seizures must be carefully eval-

uated. Memantine may lower seizure threshold but clinical trials do not suggest an increase in seizure risk (Forest 2010).

Psychostimulants. Many physicians believe that psychostimulants can lower seizure threshold, but evidence is lacking. One study of traumatic brain injury patients with post-traumatic seizures concluded that methylphenidate can be safely used even in those at high risk for seizures (Wroblewski et al. 1992). A small number of patients may experience an increase in seizure frequency when they are treated with psychostimulants. If seizure frequency rises, the drug should be discontinued. A review of pharmaceutical company databases suggests that atomoxetine does not increase the risk of seizures in ADHD (Wernicke et al. 2007a).

Migraine Headache

Antidepressants. Many patients with migraine headaches take triptans, which are potent 5-HT_{1B/1D} receptor agonists. Antidepressants are also frequently prescribed for migraine prophylaxis or comorbid depression. Risk of serotonin syndrome with antidepressant and triptan coadministration is quite rare, with only a few cases reported (Gardner and Lynd 1998). Triptan use does not contraindicate the use of serotonergic antidepressants. The triptans vary widely in their potential for pharmacokinetic interactions (Dodick and Martin 2004). Some triptans, including sumatriptan, rizatriptan, and zolmitriptan, are metabolized by MAO and should not be used during MAOI therapy (including selegiline) or within 2 weeks of MAOI discontinuation (McEvoy 2008). Almotriptan, eletriptan, frovatriptan, and naratriptan are eliminated primarily through metabolism by CYP enzymes and/or renal elimination and thus can be more safely used in conjunction with MAOIs.

Parkinsonism

For additional discussion of use of medications in patients with Parkinson's disease, see Chapter 32, "Neurology and Neurosurgery."

Antidepressants. Double-blind studies of imipramine, nortriptyline, desipramine, and bupropion demonstrate antidepressant efficacy with no change in Parkinson's disease symptoms. The anticholinergic effects of TCAs may even be therapeutic for parkinsonism.

There is a theoretical concern that serotonergic antidepressants could worsen parkinsonism through serotonin-mediated inhibition of nigrostriatal dopamine release—this effect occurs rarely (Richard et al. 1999). In a retrospective analysis of patients with Parkinson's disease stabilized on L-dopa, initiation of an SSRI was no more likely to re-

sult in a change in antiparkinsonian medication dose than initiation of any other antidepressant class including TCAs, venlafaxine, bupropion, or mirtazapine (Arbouw et al. 2007). The clinical efficacy of antidepressants for Parkinson's disease depression has been studied in few controlled antidepressant drug trials. Placebo-controlled trials suggest nortriptyline, desipramine, and citalopram (Devos et al. 2008) but not paroxetine (Menza et al. 2009) or sertraline (Wermuth et al. 1998) to be superior to placebo for the treatment of Parkinson's-related depression. TCAs may be more efficacious but less tolerable than SSRIs for depression in Parkinson's disease.

Early reports suggest that mirtazapine may reduce tremor (Gordon et al. 2002; Pact and Giduz 1999). Selegiline, a highly selective MAO-B inhibitor at doses used in the treatment of Parkinson's disease, is another antidepressant option, but it loses selectivity at the oral doses required for antidepressant efficacy and so requires standard MAOI precautions.

Antipsychotics. The major concern regarding antipsychotic use in Parkinson's disease is the degree of dopamine D₂ receptor blockade—especially with high-potency typical antipsychotics—potentially aggravating the disease. Clozapine is the only atypical antipsychotic demonstrated in a number of controlled trials in patients with Parkinson's disease to be effective against psychosis without aggravating the disease (reviewed in Frieling et al. 2007), and it may even be beneficial in reducing tremor (Parkinson Study Group 1999). In two placebo-controlled trials, quetiapine was well tolerated but failed to demonstrate efficacy. Olanzapine was without therapeutic effect but increased EPS in four controlled trials.

To date, case reports and open-label studies suggest that aripiprazole and ziprasidone may be effective for psychosis in Parkinson's disease and well tolerated (Gomez-Esteban et al. 2005; Lopez-Meza et al. 2005; Schonfeldt-Lecuona and Connemann 2004), but controlled trials are needed to confirm these results.

Cholinesterase inhibitors. Cholinesterase inhibitors are currently the most promising alternative to antipsychotics for the treatment of psychosis in Parkinson's disease. Rivastigmine, in both an open-label study and a placebo-controlled trial involving 188 patients with Parkinson's disease and visual hallucinations, exhibited efficacy without increased EPS (Burn et al. 2006). Although case studies suggest an improvement in psychosis with donepezil, results from two controlled clinical trials are less encouraging; donepezil was not significantly better than placebo (Aarsland et al. 2002; Ravina et al. 2005).

Dementia With Lewy Bodies

Antipsychotics. Patients with dementia with Lewy bodies typically present with extreme sensitivity to EPS of antipsychotics—an important consideration when prescribing antipsychotics for the treatment of hallucinations, delusions, and/or agitation in patients with dementia. No randomized controlled trials of antipsychotics in patients with dementia with Lewy bodies exist. Overall, atypical antipsychotics are probably safer than typical antipsychotics but should be used at very low doses.

Cholinesterase inhibitors. Patients with Lewy body dementia (see Chapter 6, "Dementia") typically present with cognitive, behavioral, and psychiatric symptoms. Cholinesterase inhibitors are now considered by many to be first-line therapy for dementia with Lewy bodies. A review of open-label trials of donepezil and galantamine and a placebo-controlled trial of rivastigmine concluded that all three cholinesterase inhibitors significantly improve cognitive and psychiatric symptoms in patients with this condition (Bhasin et al. 2007). More recent case-control studies and open-label trials support these conclusions for galantamine (Edwards et al. 2007) and rivastigmine (Rozzini et al. 2007). A placebo-controlled trial of all three agents is necessary to identify the most efficacious and tolerable cholinesterase inhibitor for Lewy body dementia.

Endocrine Disease

Diabetes Mellitus

Antidepressants. Elevated catecholamine levels increase serum glucose levels while reducing both insulin release and insulin sensitivity. In contrast, increases in serotonergic function seem to increase sensitivity to insulin and reduce serum glucose. Thus, in this light, SSRIs may be preferred agents in patients with diabetes because of their minimal effects on glucose metabolism. However, in diabetic neuropathic pain, SNRIs are more effective at lower doses than SSRIs, perhaps because both catecholamines and serotonin have been implicated in pain pathways (Goodnick 2001). First-line pharmacological treatments for diabetic neuropathic pain include TCAs, SNRIs, and the anticonvulsants gabapentin and pregabalin (Zin et al. 2008), which appear to be of comparable efficacy (Chou et al. 2009; Quilici et al. 2009). Duloxetine, venlafaxine, desvenlafaxine, and milnacipran have fewer side effects than TCAs.

Antipsychotics. An assessment of relative risks of particular antipsychotics in diabetes should include the risks of weight gain, glucose intolerance, and hyperlipidemia. Where these factors are of concern it is generally agreed

that clozapine and olanzapine should be avoided. Weight gain is minimal for ziprasidone and aripiprazole (Haddad 2005). Clozapine, olanzapine, quetiapine, and risperidone on rare occasions have precipitated diabetic ketoacidosis. Current consensus guidelines for monitoring patients receiving atypical antipsychotics, including monitoring forms and risk criteria, are available from the Center for Quality Assessment and Improvement in Mental Health (www.cqaimh.org/pdf/tool_metabolic.pdf).

Obesity

Antidepressants. Many patients receiving antidepressants experience weight gain. The proportion of patients who gained at least 7% of their body weight over 1 year of treatment was greatest for mirtazapine (26%), less for SSRIs (16%–19%) and similar to placebo for venlafaxine, duloxetine (at doses ≤ 60 mg/day), nefazodone, and bupropion (Papakostas 2008).

Antipsychotics. Almost all antipsychotics can cause weight gain, but they vary in their propensity to cause this effect. There is some controversy as to who is more likely to gain weight on antipsychotics—those at normal weight to begin with or those who are already obese. Nevertheless, in patients who are already obese, weight-neutral antipsychotics such as ziprasidone and aripiprazole are sensible as preferred agents.

Anticonvulsants. Many anticonvulsants are associated with significant weight changes with long-term treatment for epilepsy. Weight gain has been reported for gabapentin (57% of patients gain $>5\%$ baseline weight), pregabalin (11% of patients gain $>7\%$ baseline weight), valproate (average weight gain 3%–8% of baseline weight), and possibly carbamazepine. Lamotrigine, levetiracetam, and phenytoin are weight neutral. Felbamate, topiramate, and zonisamide are associated with weight loss (Ben-Menachem 2007; Biton et al. 2001; Privitera et al. 2003).

Lipids

Antidepressants. Several antidepressants, including mirtazapine, paroxetine, and sertraline, are reported to increase low-density lipoprotein cholesterol (LDL-C), especially in women (Le Melleo et al. 2004). Generally, lipid disruptions are most likely with antidepressants associated with weight gain (McIntyre et al. 2006).

Antipsychotics. Phenothiazines, clozapine, olanzapine, and quetiapine are known to elevate serum triglyceride levels and thus should be avoided in patients with hypertriglyceridemia or hypercholesterolemia.

Respiratory Disease

For additional discussion of use of medications in patients with respiratory disease, see Chapter 19, “Lung Disease.”

Antidepressants

Antidepressants generally do not cause problems in patients with respiratory disease. However, MAOIs are problematic in asthmatic patients because of their potential to interact with epinephrine and other sympathomimetic medications. Use of antidepressants with anticholinergic properties is of theoretical benefit because of their mild bronchodilator effect. Cyclic antidepressants, SSRIs, and other newer antidepressants have little to no effect on respiratory function.

Anxiolytics and Sedative-Hypnotics

The respiratory depressant effects of all benzodiazepines are well established; most of these agents can significantly reduce the ventilatory response to hypoxia. This may precipitate respiratory failure in a patient with marginal respiratory reserve. Patients with moderate-to-severe COPD are at risk for carbon dioxide retention with long-acting benzodiazepines, even at relatively low doses. However, benzodiazepines should not automatically be rejected for use in patients with COPD. Anxiety can often reduce respiratory efficiency, and benzodiazepines may actually improve respiratory status in some patients, especially those with asthma or emphysema (“pink puffers”) (Mitchell-Heggs et al. 1980). Patients with severe bronchitis (“blue bloaters”) or severe restrictive lung disease are the most vulnerable to the adverse effects of benzodiazepines. Intermediate-acting agents (e.g., oxazepam, temazepam, lorazepam) have fewer respiratory depressant effects and are the benzodiazepines of first choice for anxiolysis in patients with COPD. For patients with severe COPD, baseline assessment of blood gases and pulmonary consultation may be necessary in deciding whether benzodiazepines are appropriate for use. Oximetry is likely adequate for ongoing monitoring of the patient’s clinical status during benzodiazepine use unless the patient is a known CO_2 retainer, in which case blood gases are more appropriate. Benzodiazepines are currently contraindicated in individuals with sleep apnea.

Controlled trials with the short-acting nonbenzodiazepine hypnotics zopiclone, eszopiclone, zolpidem, and zaleplon suggest that they may be safely used in selected patients who have mild to moderate COPD without daytime hypercapnia (George 2000). Zopiclone and zolpidem have been found to have no significant effects on ventilatory drive or central control of breathing in patients with mild to moderate COPD (Girault et al. 1996; Ranlov and Nielsen 1987). Zopiclone has been studied in patients with upper airway resistance syndrome and has no adverse effects on

sleep architecture, respiratory parameters during sleep, and daytime sleepiness (Lofaso et al. 1997). Ramelteon, a melatonin agonist, is a recently introduced hypnotic that reduces sleep latency. Ramelteon has been shown in controlled clinical trials to be safe in patients with mild to moderate COPD (Kryger et al. 2008) and moderate to severe COPD (Kryger et al. 2009) without effect on arterial oxygen saturation. Further study is needed to better define the risk-benefit ratio of hypnotics in patients with COPD.

Buspirone is potentially a safer anxiolytic in pulmonary patients because it does not depress respiration in patients with COPD (Argyropoulou et al. 1993). It also does not adversely affect sleep apnea (Mendelson et al. 1991). In the one open-label study of buspirone in subjects with severe lung disease, none of the subjects showed deterioration in respiratory function or increased carbon dioxide retention (Craven and Sutherland 1991). In patients with COPD, a double-blind study demonstrated no adverse effects on respiratory measures but also failed to show clinical benefit (Singh et al. 1993). Although buspirone does not adversely affect pulmonary function, its limitations are its potency and delayed therapeutic effect (Robinson and Levenson 2000).

Antipsychotics

Antipsychotics may be helpful in pulmonary patients who are incapacitated by extreme panic and dyspnea that mutually exacerbate each other. Most typical and atypical antipsychotics can be used in patients with chronic respiratory disease. Uncommon but serious concerns include the provocation of laryngeal dystonia and development of tardive dyskinesia affecting respiratory musculature. Low-potency typical antipsychotics may have some additional bronchodilatory effects because of their anticholinergic properties. Clozapine has been associated with respiratory arrest and depression as well as allergic asthma (Lieberman and Safferman 1992; Stoppe et al. 1992).

Cholinesterase Inhibitors and Memantine

Because acetylcholine is a potent mediator of bronchoconstriction, cholinesterase inhibitors should be used with caution in patients with a history of asthma or obstructive pulmonary disease. Memantine has no effect on respiration and can be used safely in patients with COPD.

Cancer

For additional discussion of use of medications in patients with cancer, see Chapter 23, "Oncology."

Antidepressants

Serotonin-enhancing antidepressants elevate prolactin levels, and hyperprolactinemia has been associated with

increased risk of postmenopausal breast cancer. However, several recent large population-based case-control surveys reported no association between the risk of breast cancer and the use of antidepressants overall, or by antidepressant class or individual agent (Chien et al. 2006; Coogan et al. 2005; Fulton-Kehoe et al. 2006). Similar methodologies identified no evidence of increased risk of ovarian cancer with antidepressants in general or for SSRIs (Moorman et al. 2005). SSRI use did not increase the risk of prostate cancer (Tamim et al. 2008) and was related to a decreased risk of lung (Toh et al. 2007) and colorectal cancer (Xu et al. 2006).

Antipsychotics

Both increased and decreased rates of cancer in patients taking (mostly typical) antipsychotics have been reported in a number of epidemiological studies (Dalton et al. 2006; Hippisley-Cox et al. 2007; Mortensen 1987). No findings have been clearly replicated. Risperidone, and possibly its major metabolite paliperidone, may be associated with pituitary tumors according to a retrospective pharmacovigilance review of the U.S. FDA Adverse Event Reporting System database (Szarfman et al. 2006). Studies to date do not support withholding antipsychotics based on fear of increasing cancer risk. It would seem prudent to avoid risperidone and paliperidone in patients with present or past history of pituitary endocrine tumors.

Anxiolytics and Mood Stabilizers/Anticonvulsants

Benzodiazepines, and the mood stabilizers lithium, valproate, and lamotrigine are not associated with increased cancer risk. Carbamazepine carcinogenicity has not been studied in humans.

HIV/AIDS

See Chapter 28, "HIV/AIDS," and reviews by Repetto and Petitto (2008) and Robinson and Qaqish (2002) for further discussion of the use of psychotropics in patients with HIV/AIDS.

Psychotropic Drug Use During Pregnancy and Breast-Feeding

For additional discussion of the issues regarding medication use by pregnant or breast-feeding women, including consideration of the risks of withholding medication, see Chapter 33, "Obstetrics and Gynecology." Current information on drug use in pregnancy and breast-feeding is available through the Motherisk program (www.motherisk.org). Patient information handouts on medication use during pregnancy and breast-feeding can be obtained

from the Organization of Teratology Information Specialists (www.otispregnancy.org).

Pregnancy

Fetal exposure to medications is common, especially during the first trimester. Because approximately 50%–65% of all pregnancies in the United States are unplanned (Koren et al. 1998; Rosenfeld and Everett 1996), the fetus may be exposed to a variety of drugs during the first trimester before the mother is aware of her pregnancy. Even during an established pregnancy, surveys estimate that 80% of women take prescription medications and 21%–33% are exposed to psychotropic drugs (Barki et al. 1998; Doering and Stewart 1978). For any woman of childbearing age, all drugs should be considered for their safety in pregnancy and breast-feeding. Risks for teratogenicity have been identified for lithium, carbamazepine, valproate, phenytoin, benzodiazepines, and paroxetine.

Fetal risks associated with drug use during pregnancy include teratogenicity, direct toxicity, perinatal effects, and possible long-term effects on behavior and development. Known and possible risks of pharmacotherapy, however, must be balanced against the risks to the fetus from withholding therapy. Exacerbation of the mother's psychiatric illness may endanger the fetus in utero through maternal self-harm, suicide, malnutrition, lack of proper prenatal care, or excessive exposure to risks through impulsivity, delusions, disorientation, or denial of the pregnancy. Treatments for psychotic and bipolar disorders in severely ill patients should not be discontinued during pregnancy because of the fetal risks associated with the high incidence of relapse (Viguera et al. 2007).

Physiological changes associated with pregnancy alter drug pharmacokinetics and complicate therapy. In general, drug levels decline during pregnancy because of increases in renal elimination, volume of distribution, and cardiac output (R.M. Ward 1995, 1996). Over the course of the pregnancy, lithium clearance doubles (Schou et al. 1973) and TCA elimination increases 1.6 times (Wisner et al. 1993).

Drug levels should be monitored during the pregnancy, and dosage should be adjusted to maintain a therapeutic response consistent with the lowest effective dose. However, with the decline in albumin levels during pregnancy, therapeutic drug monitoring results may be misleading unless methods selective for unbound drug are used (see discussion in the "Distribution" subsection under "Pharmacokinetics in the Medically Ill" at the beginning of this chapter). During the early postpartum period, these physiological changes reverse. As maternal drug elimination returns to normal, any dosage adjustment required during pregnancy should be gradually reversed.

At parturition, the delivery of maternal drug to the neonate is discontinued and neonatal withdrawal symptoms may appear. Neonatal benzodiazepine withdrawal symptoms include irritability, tremor, diarrhea, vomiting, hypertonicity, and high-pitched crying (Rementeria and Bhatt 1977). Symptoms of TCA withdrawal in neonates include irritability, abdominal cramps, insomnia, tachycardia, tachypnea, and cyanosis. SSRIs have also been associated with a neonatal withdrawal syndrome (irritability, constant crying, shivering, increased tonus, eating and sleeping difficulties, and convulsions) (Klinger and Merlob 2008). When possible, tapering and discontinuation of benzodiazepines and TCAs over a few weeks before delivery has been recommended to prevent neonatal withdrawal (L.J. Miller 1991, 1994), but this must be balanced against the risk of postpartum depression. Discontinued medications should be reinstated postpartum.

Neonates exposed to SSRIs and SNRIs late in the third trimester have developed complications requiring prolonged hospitalization, respiratory support, and tube feeding. Such complications can arise immediately upon delivery. Reported clinical findings have included respiratory distress, cyanosis, apnea, seizures, temperature instability, feeding difficulty, vomiting, hypoglycemia, hypotonia, hyperreflexia, tremor, jitteriness, irritability, and constant crying (Nordeng et al. 2001). These features are consistent with either a direct toxic effect of SSRIs and SNRIs or possibly a drug discontinuation syndrome. Before making the decision to treat a pregnant woman with an antidepressant during the third trimester, the physician should carefully consider the potential risks and benefits of treatment.

Breast-Feeding

During the postpartum period, women are at risk for the development of depression, mania, or psychosis. More than 60% of mothers breast-feed their infants (Llewellyn and Stowe 1998), and many will wish to do so while taking psychotropic medications. If informed that a medication is incompatible with breast-feeding, a mother may covertly breast-feed and discontinue her medication. Recurrence of the psychiatric disorder not only is dangerous for the mother but may place the infant at greater risk than that posed by breast-feeding while the mother is taking medication.

Unfortunately, case reports are the only source of information on adverse psychotropic effects during breast-feeding; there are no clinical trials of drug effects in breast-fed infants. With a few exceptions, psychotropic drugs seem to be relatively safe in breast-feeding (Menon 2008; Rubin et al. 2004).

Risks of Psychotropic Drug Use During Pregnancy and Breast-Feeding

The use of medications during pregnancy and breast-feeding, including the risks, benefits, and treatment alternatives, must be discussed with the patient. Failure to fully inform may result in the patient discontinuing treatment because of excessive fear of risk to the fetus or neonate.

Increasing evidence suggests that most psychotropic medications are safe in pregnancy and breast-feeding. However, there are concerns about the anticonvulsant mood stabilizers, lithium, low-potency antipsychotics, paroxetine, and benzodiazepines. Concerns about psychotropic drug use in pregnancy and breast-feeding are listed below (American Academy of Pediatrics Committee on Drugs 2000; C.L. Ernst and Goldberg 2002; Gentile 2008; Gjere 2001; Jain and Lacy 2005; Menon 2008; Rubin et al. 2004; R. K. Ward and Zamorski 2002).

Antipsychotics

Pregnancy. *Typical agents*—Not associated with any evidence of teratogenic, behavioral, emotional, or cognitive abnormalities.

Low-potency drugs—Can cause neonatal tachycardia, gastrointestinal dysfunction, sedation, and hypotension for a few days after birth. Best avoided so as to minimize anticholinergic, hypotensive, and antihistaminic effects.

High-potency drugs—Preferred despite the risk of fetal EPS. Incidence of fetal EPS (hyperactivity, hyperreflexia, abnormal movements, tremor, hand flapping, and crying that may persist for several months) is dose related.

Atypical agents—Limited evidence from cohort studies suggests no evidence of increased risk of malformations for olanzapine, risperidone, and quetiapine (McKenna et al. 2005). Antipsychotic use increases the risk of gestational diabetes (Reis and Kallen 2008).

Depot preparations—Avoid because of long duration of action.

Breast-feeding. Compatibility of antipsychotics with breast-feeding is unknown. Clozapine may be of concern because of possible agranulocytosis, sedation, and seizures (Iqbal et al. 2001). Sedating drugs such as chlorpromazine may produce drowsiness and lethargy in the infant. Monitor the neonate for antipsychotic side effects such as sedation, muscle rigidity, or tremor (Gentile 2008).

Antidepressants

Pregnancy. *TCA*s—Not associated with evidence of teratogenic effects. Avoid maprotiline because of increased maternal seizure risk. Neonatal TCA withdrawal symptoms include seizures, irritability, abdominal cramps, insomnia,

tachycardia, tachypnea, and cyanosis. Desipramine is the recommended TCA because of low anticholinergic effects.

SSRIs/SNRIs—Paroxetine has been associated with a risk of cardiovascular birth defects by the FDA and Health Canada (U.S. Food and Drug Administration 2005), although this has been disputed (Einarson et al. 2008). Fluoxetine is not associated with teratogenic effects. Other SSRIs/SNRIs do not appear to be teratogenic from limited human data. Infants exposed to SSRIs in late pregnancy may have an increased risk for persistent pulmonary hypertension (Chambers et al. 2006).

Bupropion—Early reports from the GlaxoSmithKline bupropion pregnancy registry suggested an increase in cardiovascular malformations in infants exposed to bupropion during the first trimester. More recent analysis of data from this registry do not support a teratogenic effect for first-trimester exposure to bupropion (Cole et al. 2007).

MAOIs—Avoid because of hypotensive effects and potential for drug and food interactions.

Breast-feeding. Compatibility with breast-feeding is unknown. Sedating drugs such as doxepin, fluoxetine, and trazodone may cause neonatal lethargy. Limited case reports suggest that SSRIs are relatively safe. Data for SNRIs, mirtazapine and bupropion are too limited for recommendations.

Antiparkinsonian Agents

Pregnancy. *Anticholinergics*—Not recommended for the treatment of EPS during pregnancy. Associated with increased risk of congenital anomalies, complications of pregnancy, and neonatal adverse effects (Gjere 2001). Akathisia can be treated during pregnancy with propranolol or atenolol.

Breast-feeding. Anticholinergic drugs and amantadine are not classified.

Mood Stabilizers/Anticonvulsants

Pregnancy. *Lithium*—Teratogenic potential is less than earlier thought. First-trimester exposure associated with a 10-fold increase in Ebstein's anomaly, a rare (1 in 20,000) cardiovascular malformation. Cardiac ultrasonography at 16–18 weeks, neonatal electrocardiogram, and monitoring the infant for the first 10 days for lithium toxicity are recommended. Regular monitoring of serum lithium levels is required during pregnancy (every 4 weeks early in pregnancy; weekly in the latter half) (Jain and Lacy 2005; Menon 2008).

Carbamazepine and valproate—Associated with neural tube defects—carbamazepine (~1%) and valproate (~1% to

2%)—and fetal hydantoin syndrome (facial dysmorphism, cleft lip and palate, cardiac defects and digit hypoplasia). Valproate is relatively contraindicated during pregnancy. Screening for neural tube defects (amniocentesis and serum alpha-fetoprotein) before week 20 is advised. To minimize risk, all women of childbearing age should consume 0.4 mg folate daily. Women taking valproate or carbamazepine should supplement with 4 mg folate daily when planning to start pregnancy. Carbamazepine and valproate may cause transient vitamin K deficiency, resulting in neonatal clotting disorders. This risk can be minimized by supplementing with 20 mg oral vitamin K daily from week 36 to delivery, plus 1 mg intramuscularly to the newborn (Jain and Lacy 2005; Menon 2008).

Gabapentin, lamotrigine, topiramate—Insufficient human data for recommendation. There is evidence of fetal toxicity (gabapentin) and teratogenicity (topiramate) in animal studies. Lamotrigine decreases folate in rats; consider folate supplementation (see previous item).

Breast-feeding. Carbamazepine and valproate are compatible with breast-feeding; monitor for possible neonatal thrombocytopenia and hepatotoxicity. Avoid breast-feeding if patient is taking lithium. High levels of lithium are present in breast milk, and therapeutic serum levels are found in breast-fed infants (Chaudron and Jefferson 2000), with reports of neonatal electrocardiographic changes and hypotonia (C.L. Ernst and Goldberg 2002). Gabapentin is excreted into breast milk at near 100% of maternal levels; avoid breast-feeding if possible. For lamotrigine and topiramate, compatibility with breast-feeding is unknown. Lamotrigine may be of concern.

Anxiolytics and Sedative-Hypnotics

Pregnancy. *Benzodiazepines*—May be associated with a twofold increase in orofacial clefts. Neonatal benzodiazepine withdrawal (irritability, tremor, diarrhea, vomiting, hypertonicity, and high-pitched crying) may occur. “Floppy infant syndrome” is characterized by lethargy, hypothermia, respiratory depression, and feeding difficulties.

Other anxiolytics/sedatives—Insufficient data for recommendation.

Breast-feeding. Compatibility with breast-feeding is unknown. Sedating drugs may cause neonatal lethargy. Short half-life agents with no active metabolites (e.g., oxazepam or lorazepam) may be preferred. Buspirone, zaleplon, zopiclone, and eszopiclone achieve high concentrations in breast milk and are contraindicated in breast-feeding. Zolpidem is hydrophilic and compatible with breast-feeding.

General Guidelines for Psychotropic Drug Use in Pregnancy and Breast-Feeding

General guidelines for psychotropic drug use in pregnancy and breast-feeding (adapted from Fait et al. 2002; Newport et al. 2002; R.K. Ward and Zamorski 2002) include the following:

1. For any woman of childbearing age, carefully select all drugs for their safety in pregnancy and breast-feeding.
2. Remember that the benefit of any medication to the mother must outweigh the risk to the fetus.
3. Discuss with the mother the risks and benefits of using psychotropic medications while pregnant or breast-feeding.
4. Avoid all drugs during pregnancy and breast-feeding if possible, including over-the-counter and herbal medicines.
5. Use the lowest effective dose.
6. Prefer monotherapy to combination therapy.
7. Select established drugs with known effects in pregnancy and breast-feeding rather than agents with little supporting data.
8. Select medications for minimum teratogenic and behavioral toxicity.
9. Monitor clinical response and drug levels where possible during pregnancy. Adjust dosage as necessary to maintain therapeutic effect. At delivery, slowly return drug dose to prepregnancy levels.
10. Minimize drug exposure for the nursing infant by instructing the mother to take medication just after breast-feeding or before the infant is due for a long sleep (American Academy of Pediatrics 2001). SSRI levels peak in breast milk at 8–9 hours postdose. Infant exposure can be minimized if the milk during this period is “pumped and dumped” (Newport et al. 2002).
11. Consider electroconvulsive therapy for treatment of depression and especially for psychotic depression.

Conclusion

Rapid developments in medical care in general, and psychopharmacology in particular, challenge clinicians to remain current with new agents, new indications for established agents, and potential pharmacokinetic and pharmacodynamic interactions in a polypharmacy environment, which also includes over-the-counter and herbal preparations. In this chapter the many key considerations relevant to the use of psychopharmacological agents in complex medically ill patients and during pregnancy and lactation have been discussed. Detailed adverse effects, toxicities,

drug interactions, and alternate administration routes for each major psychotherapeutic drug class have been described. Where possible, the use of Internet resources provides access to the most up-to-date information. Many of these Internet sources are cited in the References below, and their general use as a means of following developments in this area is encouraged.

Psychotherapy

Elsbeth Guthrie, M.B., Ch.B., M.R.C.Psych., M.Sc., M.D.

The heartbeat of therapy is a process of learning how to go on becoming a person together with others. That learning never ends.

R.F. Hobson 1985, p. xii

THE TERM *PSYCHOTHERAPY* has a very broad meaning. At its heart, however, it implies the intent to help another person or persons through the medium of an interpersonal professional relationship. People usually seek or are referred for therapy because they are distressed or are struggling to cope with some major life problem or difficulty. Physical illness is scary, stressful, and at times unimaginably difficult to bear. What must it be like to be told that the tremor you have developed is the first sign of Parkinson's disease, or that the cough that will not go away has been confirmed as lung cancer?

This chapter focuses on the role of psychological treatments in physical illness and is divided into two parts. In the first part, psychological approaches to helping people cope with physical illness are discussed, and in the second part, evidence for the effectiveness of psychological treatments in physical illness is reviewed. In this textbook there are separate chapters on psychological treatments and pharmacotherapy. The two, however, are commonly used together to good effect, particularly in people with physical illness, and it is usually helpful when considering psychological treatment to also consider the potential benefits of pharmacological interventions. This will be discussed further in relation to collaborative and stepped-care models (see later in chapter).

Psychological Approaches to Helping People Cope With Physical Illness

Rationale for Psychological Therapies in Physical Illness

Many people find it difficult to cope or adapt to physical illness, but given time and the right environment, most manage this process without the need to seek professional help. Approximately 10% of medically ill patients require specific psychiatric treatment (Royal College of Physicians and Royal College of Psychiatrists 2003). Although certain forms of physical illness (e.g., terminal cancer) carry huge emotional burdens, people's individual perceptions of their illness have a powerful influence on how they cope with the illness and how emotionally stressful they find it. At a very basic human level, physical illness can be understood as a threat to the self (Cassell 1982), and it can "attack" the very heart of who we are as people and human beings. For example, physical illness can interfere with our ability to work, parent, make love, socialize, and take part in sports, music, and other creative activities. It can threaten our body image, our physical independence, and our ability to care for ourselves. It can undermine and destabilize us—and, of course, in its most extreme form, threaten our very existence.

Minute Particulars of the Patient's Story of Illness

Whatever the modality of therapy, the starting point for most therapies involving patients with physical illness is a detailed account of the person's own illness story. Most people "need" to tell their story, retell it and reshape it, and finally, hopefully, make peace with it. William Blake wrote, "He who would do good to another must do it in the Minute Particulars: General Good is the plea of the scoundrel, hypocrite and flatterer, for Art and Science cannot exist but in minutely organized particulars" (William Blake, *Jerusalem* III, 55:60–68).

It is through the exploration of the "minute particulars" of the person's illness that a real sharing and understanding of the person's suffering emerges. At its best, this process can foster a deep and positive therapeutic alliance with the client, which can provide a springboard for further work involving any therapeutic modality. In itself it can bring relief from suffering, an understanding of the self and of the experience of illness, and a sense of mastery and empowerment.

Necessary Adaptations

Participation in any form of meaningful psychotherapy requires an individual to be able to concentrate during the therapy and to recall and think about the therapy in between sessions. In structured therapies, there is an explicit expectation that homework will be carried out between sessions. However, physical illness may prevent some people from participating in psychological treatments because they are too physically unwell. It is hard to concentrate in therapy if one is nauseous or exhausted or is very short of breath. It may also be physically difficult for some people to attend psychotherapy sessions because of problems with mobility or transport. Sessions may have to be rescheduled or fitted around other medical commitments (e.g., investigations, renal dialysis). The duration of sessions may have to be modified or breaks in therapy accommodated because of relapses in the person's illness or participation in challenging treatment regimes.

It is often appropriate for the therapist to involve other members of the patient's family in the therapeutic process, particularly if they have a role as a care provider. It may also be important for the therapist to liaise with other members of the health care team and to spend time with the patient discussing relationships with nursing, medical, and other professional staff.

Therapists who work in medical settings need to have an understanding of the illnesses the patients they see are suffering from and the kinds of investigations and treatment that patients are likely to experience. This will involve spending time with other health professionals and patients on medical or surgical units or in the community setting.

Therapists vary in their competence, and more competent therapists produce better outcomes than less competent ones (Barber et al. 2006). There is some evidence for cognitive-behavioral therapy (CBT) that use of so-called concrete CBT techniques (e.g., establish the session agenda, set homework tasks, or help clients identify and modify negative automatic thoughts) is associated with good outcomes (DeRubeis and Feeley 1990). In relational therapies, better outcomes have been associated with therapists who can repair ruptures in the alliance (Bennett and Parry 2004).

In the medical setting, it may be particularly important that therapists have a high level of competence because of the complexity of patients' problems and the need for the adaptations described above, which are required when working with people who have both physical and mental illness.

Although there are many different types of psychological treatment, three main approaches will be described in this chapter: basic supportive techniques, and problem solving, relational therapies, and cognitive-behavioral therapies.

Supportive and Problem-Solving Approaches

Health care professionals play a key role in helping people adjust to illness and may prevent the development of long-term distress by a sensitive and judicious approach. This should involve establishing a trusting relationship with the patient based on warmth and a genuine desire to help. Fear and uncertainty can be reduced by providing individuals with clear information. This may need to be repeated on several occasions, and it is important to convey the right amount of information so that individuals are not overwhelmed. The information should be presented in an authoritative but jargon-free manner. There should be a continual process of checking out what the person knows and doesn't know and what they want to know. The health professional should be guided by the person's responses and tailor the information accordingly. The health professional should be optimistic but realistic and avoid false reassurance.

There should be a collaborative approach to treatment so that patients themselves can make most of the decisions about their treatment. However, sometimes patients want doctors to play a more active, authoritative role in decision making, as was found in women attending clinics for breast cancer (Wright et al. 2004). This emphasizes the need to find out what different people want and tailor responses accordingly.

If possible, patients should be given emotional space to voice their fears and uncertainties about their illness or reflect on loss and explore ways of coping. This is rarely possible in busy hospital clinics or ward settings, but it should

be an ideal to which all health professionals aspire. Any opportunity to foster beliefs in the controllability of the disease process will help the patient feel more empowered and less vulnerable. Involvement of patients' families in the treatment process is crucial, as illness affects the whole family and not just the individual with the illness.

Positive reassurance can be very helpful but must be based on and grow out of the physician's understanding of the patient's anxiety. The physician should explore any fears and not presume that he or she knows why the patient is asking without asking. Facile, nonspecific reassurance can undermine the therapeutic relationship, because the patient is likely to feel that the physician is out of touch with and not really interested in what he or she is actually feeling. Knowing, not presuming, the patient's specific fears leads the physician to appropriate therapeutic interventions.

The spiritual and cultural dimensions of peoples' lives are often overlooked by busy health professionals. Many religious organizations offer support and help for people at times of adversity, and other forms of cultural support may be available for certain groups of patients (e.g., gay men who are HIV positive).

Managing Uncertainty and Breaking Bad News

Physicians and other health professionals play a key role in providing patients and relatives with information. Often, information that is painful, difficult, and upsetting has to be conveyed. Common mistakes when giving bad news are to provide too little information about prognosis and to fail to explore people's concerns, fears, and associated feelings. Patients thus remain preoccupied with their fears and fail to take on board anything positive that the health professional has told them. Professionals also mistakenly think that once they have told a patient something, he or she will retain the information and will not need to be told again. However, people often need to be told something several times before they are able to assimilate the information.

People's responses to bad news are highly variable and unpredictable. There may be a whole range of emotions from extreme distress to utter blankness and denial. Two of the key principles of giving bad news well are 1) to tailor the information to what the patient wishes and is able and ready to hear and 2) to give enough time to the process. It is important to give the patient and his or her family members time to take in the information, without provoking denial or overwhelming distress. The physician should check out from the patient what he or she wants to know and in how much detail and tailor responses accordingly. A third principle is to acknowledge distress, to explore reasons for it, and to check that the patients would like to continue the discussion. Further guidelines on communicating risk and

uncertainty and breaking bad news are provided in Chapter 2 of *The Psychological Care of Medical Patients: A Practical Guide*, 2nd Edition (Royal College of Physicians and Royal College of Psychiatrists 2003).

Illness Narratives

Writing about emotionally charged experiences in comparison with emotionally neutral topics appears to have a beneficial and cathartic effect (Pennebaker and Seagal 1999). Expressive writing has been shown to promote good health with beneficial outcomes on reported physical health, psychological well-being, physiological functioning, and general functioning (Smyth 1998).

Patients with chronic illness (either asthma or rheumatoid arthritis) also appear to benefit from being asked to write about an emotionally stressful experience (Stone et al. 2000). An interesting study involving women with early-stage breast cancer found that women who were rated low in avoidance found writing about "their deepest thoughts and feelings about breast cancer" to be very beneficial, and they reported significantly reduced physical symptoms over a 3-month follow-up period (Stanton et al. 2002). However, women who were rated high in avoidance gained greater benefit from writing about "positive thoughts and feelings about their experience of breast cancer." This suggests that although emotional writing may not be helpful for all people, it may be a simple and beneficial strategy for some people who are struggling to cope with physical illness. Emotional writing may be helpful because it enables people to express things that they cannot put into words (Bolton 2008).

Use of narratives has also been taken to a deeper level to help patients make sense of their depression in the context of physical illness (Viederman and Perry 1980). In this approach, the psychiatrist, after eliciting the patient's illness and life history, presents a statement that places the patient's physical illness in the context of his or her life trajectory and demonstrates the psychodynamic logic of the patient's depression (or other psychological response).

Counseling

There are many different forms of counseling, ranging from the imparting of information (educational counseling) to quite intensive psychotherapeutic interventions. One of the most common forms of therapeutic counseling is person-centered counseling. This is nondirective counseling in which emphasis is placed on the development of a personal relationship in which an individual can talk openly and freely about his or her problems. The counselor employs specific skills, such as warmth, empathy, and attentive listening. Counseling involves skilled use of non-specific psychotherapeutic techniques.

Counseling is widely employed in health service settings to help people adjust better to illness. There are relatively few controlled evaluations of the benefits of counseling in relation to physical illness. An exception is in the field of cancer, where there have been several evaluations by different research groups of the effects of counseling (Christensen 1983; Maguire et al. 1980, 1983). A recent systematic review of psychosocial interventions for anxiety and depression in adult cancer patients concluded that interventions involving counseling can be currently recommended for improving patients' general functional ability or quality of life, degree of depression, and interpersonal relationships (Jacobsen and Jim 2008). However, the review noted the general poor methodological quality of many studies. Counseling has been shown to be helpful for improving the psychological status of persons with systemic lupus erythematosus (Maisiak et al. 1996).

Hypnosis

Hypnosis has been used as a treatment for medical conditions for more than 300 years. There is no consensus view as to what exactly hypnosis is, but it involves the induction of a state of mind in which a person's normal critical nature is bypassed, allowing for acceptance of suggestions. In hypnosis used for the treatment of medical conditions, suggestions are made to the patient, while he or she is hypnotized, about the patient's bodily state, which hopefully results in an improvement in function or a reduction in pain. The role of hypnosis in contemporary medicine has been reviewed by Stewart (2005). The best evidence for hypnotherapy in the field of liaison psychiatry comes from work in relation to irritable bowel syndrome (Whorwell et al. 1984). Hypnotherapy for irritable bowel syndrome is gut directed. The treatment involves the induction of a hypnotic trance using progressive relaxation and other induction procedures to deepen the hypnotic state. This is followed by suggestions, imagery, and other techniques appropriate to the individual, such as inducing warmth through the patient's hands on the abdomen, directed toward control and normalization of gut function, in addition to relevant ego-strengthening interventions. Patients are given one-to-one treatment over several weeks and also asked to practice skills on a daily basis using an autohypnosis tape. This kind of treatment can also be delivered in a group format.

Problem-Solving Therapy

Problem-solving therapy improves individuals' abilities to cope with stressful life difficulties. It has three main steps: 1) symptoms and problems are identified, and the two are linked together; 2) the problems are defined and clarified; and 3) strategies are developed in a collaborative fashion

with the patient to help solve the problems in a systematic way. The overall intention is to break problems down into very small components which then become easier to tackle and solve. Problem solving has been employed in a pure form to treat depression or other problems in primary care. It is a relatively brief intervention, with one of the earliest studies involving six sessions and a total contact time of less than 4 hours (Hawton and Kirk 1989).

Problem-solving therapy has been used to help patients with cancer (Nezu et al. 2003) and has also been incorporated into more complex treatment interventions involving stepped-care models for treating depression or collaborative care models.

Self-Management Programs

Self-management programs or chronic care models are becoming increasingly popular for patients with chronic illness. They consist of a structured primary care-based framework aimed at improving the self-care and management of patients with chronic illnesses. Most include proactive involvement and support from care managers or case workers, with an emphasis on patient education, psychosocial support, and promotion of self-management strategies and skills. A meta-analysis of data from 112 studies involving interventions to improve self-care for chronic illness (e.g., asthma, diabetes, congestive heart failure, and depression) concluded that interventions that contain at least one element of a chronic care model improve clinical outcomes and quality of life for patients with chronic illness (Tsai et al. 2005).

Supportive-Expressive Therapies and Support Groups

A variety of different kinds of supportive therapy groups have been used in the psychosocial treatment for patients with cancer, and several randomized investigations have shown positive effects on psychosocial adjustment (Cain et al. 1986; Edmonds et al. 1999; Fawzy et al. 1990, 1993; Spiegel et al. 1981), trauma symptoms (Classen et al. 2009), physical status (Fawzy et al. 1990, 1993; Spiegel et al. 1981), and survival (Cunningham et al. 1998; Fawzy et al. 1993; Spiegel et al. 1989). The effects on survival are controversial and have not been replicated by other researchers (Goodwin et al. 2001), although the positive effects on emotional adjustment seem robust.

The group therapeutic approaches that have received most attention are those employing supportive-expressive group therapy, which is an unstructured but quite intensive and existentially based treatment (Spiegel and Glafkides 1983). The rationale for the existential orientation presumes that living with a terminal illness amplifies existential concerns of death, meaning, freedom, and isolation. Thus, one aim of the group intervention is to give

patients an opportunity to discuss these concerns. The treatment strategy is to facilitate discussion of issues that are uppermost in patients' minds rather than imposing the topics to be discussed, although the group experience can be quite challenging and intensive.

The supportive–expressive group–based approach should not be confused with supportive–expressive therapy, which is a short-term psychodynamic treatment and is discussed under “Relational Therapies” below.

Relational Therapies

A broad group of therapies have in common a model of human development and the mind in which the nature and quality of human interpersonal relationships play a key role in the maintenance of “emotional homeostasis.” Close interpersonal relationships can either be a source of stress or act as a buffer against adversity to provide emotional support and foster resilience. The earliest relationship, that between mother and infant or main caregiver and infant, is crucially important in shaping identity, cognitive function, and the ability to regulate and control feelings. As adults, the bonds that we form with others help us to maintain our sense of “self.” If the bonds break down or become noxious, this may precipitate anxiety and depression. Relational therapies are based on the premise that feelings, thoughts, and relationships are intimately tied up with each other. How we feel and think about others affects how we behave toward them, and this, in turn, affects how we feel about ourselves.

A variety of different theories and models of development, including psychodynamic, attachment, and interpersonal, link together previous relationship experiences, current relationship experiences, and emotions and coping. Individuals with a history of childhood adversity have an increased likelihood of both emotional and physical problems as adults. People with certain kinds of insecure attachment styles find physical illness more difficult to manage than those with secure attachment and may default on medical appointments or find it more difficult to establish trusting relationships with health professionals (Ciechanowski et al. 2004).

Physical illness is a threat to the self, and nearly all aspects of being physically ill impact the interpersonal domain. At a very deep level, some people construe their illness as a personal attack on themselves, asking “Why me?” At other levels, physical illness can put an immense strain on families and their relationships. Severe or chronic physical illness often changes people and forces them to reappraise themselves and their relationships. Issues of loss—for example, fears of loss or dying, fears of becoming dependent and a burden on others, fears of having to cope alone—are extremely common in the physically ill and can

be addressed by relational therapies (see also Chapter 4, “Psychological Responses to Illness”).

Interpersonal Therapy

Interpersonal therapy (IPT) was developed at Yale University in the late 1960s as a time-limited treatment for depression (Klerman et al. 1984). The basic underlying assumption of the treatment approach is that there is a relationship between the onset and recurrence of a depressive episode and a person's social and interpersonal relationships at the time. The model was influenced by the work of Sullivan (1953) and Bowlby (1969).

There are three stages of development in IPT when it is used to treat depression. In the first phase, depression is diagnosed and explained to the patient so there is a clear understanding of the nature of the condition and its symptoms. An interpersonal inventory is compiled that lists all of the patient's relationships, and the main problem areas are identified. Problem areas are classified into four groups: grief, role transitions, role disputes, and interpersonal deficits.

During the intermediate sessions of therapy, the therapist and client work on a specific problem area. If this is grief, treatment includes facilitating the grieving process, helping the client accept difficult or painful feelings, and exploring ways of replacing lost relationships. If the problem is a role transition, treatment is focused on helping the client give up the old role, accepting feelings of loss about this, and acquiring skills and support in the new role the client has to take on (e.g., becoming a parent). If the problem area is a role dispute, the focus of the treatment is about gaining a better understanding of the nature of the dispute and exploring ways that it could be resolved. If the problem area is an interpersonal deficit or deficits, the focus of the treatment is to gain a better understanding of the nature of the deficit and any problems the client has with the way he or she interacts and communicates with people. Attempts are made to try to modify these problematic interactions using a variety of techniques, including role-play.

In the final part of the therapy, the therapist works to consolidate the client's gains and addresses the termination of therapy, with a focus on strategies that can prevent the depression from recurring.

IPT has a solid evidence base, with a recent systematic review concluding that it is an effective treatment for depression, superior to placebo and comparable to antidepressants (de Mello et al. 2005). IPT has been modified to treat depression in a variety of different settings with different populations (e.g., maintenance therapy for recurrent depression, bipolar disorder, eating disorders, anxiety disorders, borderline personality disorders, postpartum de-

pression, and depression in developing countries) (Weissman 2006).

Several elements of IPT are highly relevant to the general medical setting and to patients who have emotional difficulties secondary to physical illness. In particular, grief (e.g., loss of a body part) and role transition (e.g., having to change from being an active and healthy person to someone who is confined to a wheelchair) are extremely common problem areas. IPT has been used to good effect to treat depression in HIV-positive patients (Markowitz et al. 1995), and it has also been adapted for the treatment of posttraumatic stress disorder, which is common in some medical settings. Two small studies of telephone IPT have been published (Badger et al. 2005; Donnelly et al. 2000), in which IPT was used to help alleviate emotional distress in cancer patients and their spouses.

IPT has also been adapted for use in hypochondriasis (Stuart and Noyes 2005). In this condition, the therapy has been adapted to focus on the interpersonal consequences of being preoccupied with physical illness.

Psychodynamic Interpersonal Therapy ***(“Conversational Model” Therapy)***

This form of treatment has been developed by Hobson (1985), a psychiatrist and psychotherapist. Psychodynamic interpersonal therapy (PIT) combines elements of psychodynamic and interpersonal therapies. It places greater emphasis on the patient–therapist relationship as a tool for resolving interpersonal issues than does IPT, and there is less emphasis on the interpretation of transference than in psychodynamic therapies. One of the central tenets of PIT is the importance of human experience and an individual’s sense of self within a personal relationship. Human existence is regarded as being essentially relational, and man is regarded as a “creature of the between.” This applies even to people who live a solitary existence.

The emphasis in the therapy is on getting to know someone, rather than merely knowing *about* them. In the words of Hobson (1985), “In an unrepeatable moment, I hope to respond to my unique client by sharing in an ongoing act of creation, expressing and shaping immediate experience in the making and remaking of a verbal and nonverbal language of feeling. It is not only a matter of ‘knowing about’ someone but also, and mainly, of sharing a language of ‘knowing’” (p. xiii). Hobson believed that the heart of psychotherapy is that of a personal relationship—a meeting between two people and a process of symbolic transformation of self and experience by means of a personal conversation.

The process of symbolic transformation is particularly valuable when using the PIT model with people who have both physical and psychological symptoms (Moorey and

Guthrie 2003). The client and therapist begin by exploring the “minute particulars” of the client’s physical symptom experience. The client is encouraged to explore and describe his or her physical symptoms in great depth, and the therapist assumes an attitude of intense listening, concern, and fascination. It is in the detail of the conversation that metaphors or feeling language emerges, as the client and therapist go deeper and deeper into the client’s physical experience. Expressions such as “off balance,” used to describe neurological symptoms, come to also represent psychological and emotional states of mind. The process is collaborative, gradual, and nonthreatening. The conversation gradually moves from being about physical symptoms to what Hobson (1985) described as a “feeling language.” This process of symbolic transformation leads to a change in the experience of the self and a move toward a greater understanding of the connection between physical and psychological, followed by psychological and emotional change.

Key features of the model include 1) the assumption that the patient’s problems arise from or are exacerbated by disturbances of significant personal relationships; 2) a tentative, encouraging, supportive approach from the therapist, who seeks to develop deeper understanding with the patient through negotiation, exploration of feelings, and use of metaphor; 3) the linkage of the patient’s distress to specific interpersonal problems; and 4) the use of the therapeutic relationship to address problems and test out solutions in the “here and now.” Emphasis is placed on identifying repeated patterns of behavior within relationships that result in conflict and emotional distress. Support and encouragement is provided to the patient to challenge difficult problem areas in relationships and to develop more adaptive ways of coping.

PIT has efficacy comparable to that of cognitive therapy for the treatment of depression (Shapiro et al. 1994) and has been adapted for use in medically unexplained symptoms. PIT has been evaluated in several large randomized controlled trials (RCTs) (Creed et al. 2003; Guthrie et al. 1991; J. Hamilton et al. 2000). It is cost effective, with the costs of therapy being recouped by reductions in health care use in the months posttherapy (Creed et al. 2003; Guthrie et al. 1999). It has also been used after self-harm and was found to result in a reduction in repetition in the subsequent 6 months following the index episode (Guthrie et al. 2001).

Cognitive-Behavioral Therapy

The central tenet of CBT is that emotions, behavior, and cognitions are all interlinked. According to the cognitive model, when a person shows distressing emotions such as anxiety or depression, these emotions are linked to particular beliefs, assumptions, or thoughts. It is assumed that persistent dis-

tress is linked to underlying maladaptive beliefs, which if modified results in a reduction in emotional distress.

In the general medical setting, the way a person thinks about his or her illness or bodily sensations is central to the cognitive model. If, for example, benign sensations are regarded by the person as being symptomatic of disease, several consequences ensue. First, the patient will become emotionally distressed, which may cause further bodily sensations. Second, the patient will pay increased attention to these symptoms and may worry about them more. Third, the types of behaviors the person employs to cope with the symptoms may exacerbate the symptoms rather than relieve them (e.g., rubbing one's chest if it is painful). Fourth, other people, including doctors, may respond to the patient in a way that intensifies, rather than reduces, the patient's concern with disease, attention to bodily sensations, and dysfunctional coping (Sharpe et al. 1992).

This model is applicable to patients with medically unexplained symptoms, but also to patients with medical disease (e.g., concerns about recurrence of a breast lump after previous diagnosis and treatment for breast cancer).

Sensky (2004) has described in detail how CBT has been adapted for use in people with physical illnesses. Crucial to the development of any treatment intervention is an understanding of the patient's model of his or her illness, and a useful model or framework for doing this has been developed by Moss-Morris et al. (2002) in relation to illness perception. This concept was originally developed by Leventhal et al. (1997). Within Leventhal's model, illness representations are considered to be multidimensional, comprising five main components: identity, perceived consequences, timeline, perceived cause, and control/cure (Table 39-1).

A key principle in cognitive therapy is that the patient, rather than the therapist, is the expert in understanding the patient's problems. A detailed understanding of the patient's illness perceptions often leads to identification of maladaptive beliefs and underlying fears or anxieties, which can then be addressed.

CBT is tailored to the individual patient's beliefs and behavior, although certain cognitions are likely to be asso-

ciated with particular presenting symptoms. For example, it is common for patients who experience chest pain to fear that they are going to have a heart attack, and they will become very anxious every time chest pain is experienced.

If someone believes that his chest pain is indicative of a heart attack and repeatedly seeks reassurance every time chest pain is experienced, that reassurance is characteristically short-lived, and the behavior becomes counterproductive. The therapist can address this kind of behavior in the therapy session, particularly if the client develops pain or seeks reassurance from the therapist during the session itself. The therapist can ask the patient to keep a diary between sessions, quantifying at various times the extent of his worry and/or reassurance on a 0–10 scale. Having identified that the behavior is unhelpful and only increases anxiety and worry, patient and therapist can then collaborate to devise ways of managing the problem behavior and beliefs more effectively.

This is done by devising behavioral and/or cognitive experiments aiming to produce more favorable outcomes. Thus, in the above example, a behavioral experiment might be for the patient to delay seeking reassurance about his chest pain for progressively longer periods, to demonstrate that he is able to tolerate the anxiety involved. A cognitive task might be to prepare a statement (and perhaps even to write the statement down on a "cue card") regarding the unhelpful outcomes of reassurance seeking that the patient can remind himself about when he experiences the urge to seek reassurance. Each of these tasks might be rehearsed in the therapy session, so that the patient has some confidence that the possible benefits of carrying out the tasks between sessions outweigh the perceived risks.

In some cases, the entire focus of treatment can remain on the present and the recent past, particularly if the patient experiences symptoms in the "here and now" in the therapy session. However, beliefs that are maladaptive commonly have their origins in the more distant past, particularly during childhood, and when this occurs, it is an appropriate focus in therapy to make links between the present and the past.

TABLE 39-1. Leventhal and colleagues' five components of illness representations

Identity: Label or name given to the condition and the symptoms that go with it.

Cause: Ideas about the perceived cause of the condition (may or may not be based on biomedical evidence).

Timeline: Predictive beliefs about how long the condition will last.

Consequences: Individual beliefs about the consequences of the condition and how these affect people physically and socially.

Curability/controllability: Beliefs about whether the condition can be cured or kept under control.

Source. Leventhal et al. 1997.

TABLE 39-2. Cognitive factors in the assessment of the physically ill

Illness model and illness perception: What is the patient's understanding of his/her illness, and how does this contribute to worry or distress, or to maladaptive behaviors and beliefs?

Personalized formulation of the patient's problem: How can the patient's physical symptoms, emotional response, behavior, and cognitions be linked together in an understandable and meaningful formulation?

Affective disturbance: Is the patient experiencing anxiety, fears, depression, or hopelessness?

Motivation: Prochaska's stages of change model (Prochaska et al. 1994):

Precontemplation—Is the patient avoiding thinking about the consequences of illness?

Contemplation—Is the patient beginning to face that changes have to be made to adapt to the impact of the illness?

Preparation—Is the patient taking steps necessary for action?

Action—Is the patient making the required changes?

Maintenance—Are the changes/adaptations being maintained?

Coping: What are the patient's emotion-focused and problem-focused ways of coping? Which of these are helpful? Which are not helpful?

Life transitions: How is the individual managing the impact of illness on his/her life, and what can be learned from the way he/she has managed previous life transitions?

Influence of others: How are the patient's relationships with doctors and other professionals, family, and friends influenced by the patient's beliefs about his/her illness? Conversely, how do the patient's illness beliefs influence his/her relationships with others?

Resilience: What are the patient's areas of vulnerability in regard to his/her responses to stress? What are his/her strengths?

Source. Adapted from Guthrie and Sensky 2008.

Other cognitive factors in the assessment of the physically ill have been described by Guthrie and Sensky (2008) and are summarized in Table 39-2.

CBT is a recognized treatment for many different psychiatric disorders (Butler et al. 2006). There is a substantial evidence base for CBT, both for the treatment of medically unexplained symptoms and for the treatment of depression in physical illness (Fekete et al. 2007). Both of these areas will be reviewed later in the chapter. Areas for development in the future include computer-delivered CBT (Kaltenthaler et al. 2006) and Internet-based CBT (Cuijpers et al. 2008).

Mindfulness-Based Stress Reduction Interventions

Mindfulness-based stress reduction (MBSR) is a well-defined systematic educational, patient-focused intervention with formal training in mindfulness meditation and its applications in everyday life, which includes managing physical and emotional pain. It was developed by Jon Kabat-Zinn and colleagues at the University of Massachusetts. MBSR has grown rapidly in the medical setting, and MBSR programs are now offered in health care settings around the world. A useful review of its practice in the medical setting has been written by Ott et al. (2006). MBSR programs generally consist of 7–10 weekly group sessions. Each session lasts 1 to 1.5 hours, and in addition there is one silent retreat. Classes include both an educational component and an experiential component. During the

groups, participants are taught meditation fundamentals and practice sitting meditation, awareness of sensations, body scan and mindfulness movement, which they are expected to practice for 45 minutes on a daily basis. During the first class, participants receive an audiotape so they can practice at home for 45 minutes every day. Participants are also encouraged to bring informal mindfulness into day-to-day activities whenever the opportunity arises.

MBSR has been particularly developed in relation to helping patients cope with cancer. Patients with cancer often experience a loss of control and feelings of helplessness. MBSR is a useful skill that can be used by patients to help reduce and cope with stress, promote relaxation, and alleviate physical discomfort and emotional distress. Mindfulness helps patients to take a proactive stance by consciously directing their attention to present-moment experiences.

Bringing attention to the senses is generally unthreatening and easy to experience. Patients are also asked to focus on their breathing during sitting meditation. They may become aware that they are not breathing fully but rather are limiting inspiration to the upper part of the chest, losing the benefit of abdominal breathing. As patients continue to focus on breathing, the breath becomes a familiar focal point, and they are then able to move on and focus on other physical sensations. Even strong physical sensations such as pain can become less intense and less frightening using MBSR.

The body scan enables patients to develop a focused concentrated awareness of the body, moving attention methodically from the toes to the head. Patients become aware of subtle changes which are happening on a moment-to-moment basis, and unpleasant sensations become more tolerable. Mindfulness movement invites a compassionate, ongoing awareness of the body in motion (Ott et al. 2006).

Mindfulness-Based Cognitive Therapy

Mindfulness-based cognitive therapy (MBCT) has been adapted from mindfulness stress reduction program approaches as a treatment for depression (Segal et al. 2002). It includes simple breathing meditations and yoga stretches to help participants become more aware of the present moment, including getting in touch with moment-to-moment changes in the mind and the body. Participants attend eight weekly educational classes where they are taught and practice the techniques of mindfulness meditation, and also listen to tapes at home during the week. MBCT also includes basic education about depression and several exercises from cognitive therapy that show the links between thinking and feeling and how best participants can look after themselves when depression threatens to overwhelm them. These more structured exercises make MBCT different from mindfulness meditation as it is normally taught at retreat centers, but the approach is embedded within and seeks to remain true to the insight meditation tradition.

MBCT helps participants in the classes to see more clearly the patterns of the mind and to learn how to recognize when their mood is beginning to go down. Unlike formal CBT, which seeks to link negative thoughts and mood and then change negative thoughts to lift mood, MBCT encourages participants to “let go” of their thoughts and break the link between negative mood and the negative thinking. Participants develop the capacity to allow distressing mood, thoughts, and sensations to come and go, without having to battle with them. They find that they can stay in touch with the present moment without having to ruminate about the past or worry about the future.

MBCT is rapidly becoming established as a treatment for depression and as a treatment to prevent depression recurring in vulnerable individuals (Teasdale et al. 2000). MBCT reduces overgeneral autobiographical memory, which has been implicated as a potential mediator of self-harm, and MBCT is now being evaluated as a treatment to alleviate suicidal thinking in vulnerable people. Individuals with overgeneralized autobiographical memory present vague, nonspecific memories when asked about their past or ways in the past they have solved problems. Unlike individuals with more specific memory recall, they do not have

a range of specific past experiences from which to draw to attempt to solve current difficulties or problems.

Mindfulness-based therapies have been used to treat a wide range of stress disorders, including chronic pain (Kabat-Zinn et al. 1987), fibromyalgia (Kaplan et al. 1993; Sephton et al. 2007), mood symptoms in cancer (Carlson et al. 2001, 2003; Smith et al. 2005), and depression (Teasdale et al. 2000). A recent systematic review of meditation techniques for medical illness identified 20 RCTs involving a total of 958 subjects (Arias et al. 2006). The reviewers concluded that the strongest evidence for the efficacy of meditative techniques was found for epilepsy, symptoms of premenstrual syndrome, and menopausal symptoms. Benefit was also demonstrated for mood and anxiety disorders, autoimmune illness, and emotional disturbance in neoplastic disease. Ott et al. (2006) identified nine studies in the field of cancer that had used mindfulness meditation, of which four were RCTs and the other five were one-group pretest-posttest design studies. The reviewers concluded that mindfulness interventions showed promising results in the field of cancer but that more RCTs were required before firm conclusions about efficacy could be established. Ledesma and Kumano (2009) recently published a meta-analysis of 10 MBSR studies in the field of cancer which included 4 RCTs and 6 non-RCTs. Three of the 4 RCTs in this latter study were included in the earlier review by Ott et al. (2006). Ledesma and Kumano (2009) computed an effect size (Cohen's d) for change in mental and physical health resulting from MBSR. The effect size for improvement in mental health was moderate ($d=0.48$), whereas the effect size for improvement in physical health was quite small ($d=0.18$).

Organization and Delivery of Psychological Treatments

Although psychological treatments can be offered as stand-alone treatments, they are increasingly delivered as part of a package of care or part of a stepped-care model. This is particularly so for the treatment of depression but applies to many other psychological conditions including medically unexplained symptoms and depression in the context of chronic physical illness.

The stepped-care model involves five different intensities of treatment that are offered to the patient or client according to the severity or complexity of his or her problems. Most patients start at the bottom of this model and progress to the next step only if their symptoms do not improve:

- ♦ Step 1 involves watchful waiting, as many patients who present with symptoms will find that their symptoms resolve spontaneously without requiring any help.

- ♦ Step 2 usually involves some form of guided self-help and may include computerized CBT, psychoeducation, or help from voluntary organizations. Exercise may also be recommended or even prescribed if such treatment is available from a relevant health service organization.
- ♦ Step 3 involves brief psychological therapy (e.g., CBT, counseling, interpersonal therapies) for 6–8 sessions. Antidepressants may be prescribed if there is a previous history of moderate to severe depression.
- ♦ Step 4 involves depression case management, and the patient may be assigned a case manager or key worker. Medication and more intensive psychological treatments may be offered, with care coordinated by the case manager working with the patient's primary care physician.
- ♦ Step 5 is for patients who have not responded to the previous 4 steps. Step 5 may involve crisis intervention services, inpatient treatment, or even more intensive multicomponent treatment packages.

Collaborative care models have five essential elements:

1. Collaborative definition of problems, in which patient-defined problems are identified alongside medical problems diagnosed by health care professionals
2. Focus on specific problems and use of problem-solving techniques
3. Creation of a range of self-management training and support services
4. Provision of active follow-up in which patients are contacted at regular intervals to monitor health status and check and reinforce progress in implementing the care plan
5. Assignment of a case manager who has responsibility for delivering the care plan

Sometimes stepped-care programs are incorporated into collaborative care interventions, as in the Pathways Study (Katon et al. 2004), which tested a complex intervention to treat depression in patients with diabetes. The intervention involved an initial choice of two treatments, either an antidepressant or problem-solving therapy, followed by a stepped-care algorithm in which patients received different types and intensities of treatment according to their observed outcomes. In comparison with usual care, patients who received the complex intervention improved significantly in relation to depression, but there was no impact on glycemic control.

Evidence Base for Psychological Treatments for Specific Conditions

Patients With Medically Unexplained Symptoms or Somatoform Disorders

There is a substantial evidence base for the efficacy and effectiveness of psychological treatments for people with medically unexplained symptoms or somatoform disorders. Most studies have involved patients with specific symptom-defined syndromes, such as chronic fatigue syndrome and irritable bowel syndrome. It remains unclear whether these conditions are discrete entities (W.T. Hamilton et al. 2009) or share a common underlying problem of bodily symptom distress (Fink et al. 2007). There is, however, substantial overlap among the conditions, and psychological approaches that are shown to be helpful for one condition are likely to benefit patients who present with a different symptom pattern but similar psychological concerns.

Psychosocial factors such as depression, anxiety, childhood adversity, stressful life events, and chronic difficulties are common in people who have medically unexplained symptoms that are persistent and severe and who seek treatment. Psychological morbidity is less prevalent in community subjects with medically unexplained symptoms who do not seek treatment. Most studies that have evaluated the efficacy or effectiveness of psychological interventions in patients with medically unexplained symptoms have been carried out on patients in secondary- or tertiary-care settings who have moderate to severe symptoms. There are far fewer primary care-based studies, and these tend to show less substantial treatment effects than studies conducted in secondary-care settings (Raine et al. 2002). A recent systematic review of the efficacy of treatment (pharmacological and nonpharmacological) for fibromyalgia concluded that there was little difference in treatment effects according to whether patients were treated in primary or secondary care (Garcia-Campayo et al. 2008).

Several systematic or critical reviews summarizing the effects of psychological treatment for medically unexplained symptoms or somatoform disorders have been published over the past 10–15 years as the evidence base has been growing. The majority of studies have focused on CBT interventions, although (as discussed earlier in this chapter) other relational therapies have been evaluated and shown to be of benefit in certain conditions, although there are far fewer “non-CBT” studies.

Tables 39–3 through 39–5 summarize the findings of reviews carried out on three common functional somatic syndromes: fibromyalgia, chronic fatigue syndrome, and irritable bowel syndrome. Most of the reviews comment on the variability of the psychological interventions studied

TABLE 39–3. Systematic reviews, critical reviews, and meta-analyses of trials of psychological treatment in fibromyalgia

Authors	Therapy	Type of review	Outcome
Rossy et al. 1999	Pharmacological and nonpharmacological treatment	Meta-analysis (4 studies)	Evidence for benefits for CBT and exercise.
Hadhazy et al. 2000	Mind-body therapies	Systematic review (13 studies)	Moderate evidence that mind-body therapies are more effective for some clinical outcomes than wait list, treatment as usual, or placebo.
Sim and Adams 2002	Nonpharmacological treatment	Systematic review (25 RCTs)	Strong evidence did not emerge for any single intervention. Preliminary support for aerobic exercise.
Van Koulil et al. 2007	CBT and exercise programs	Systematic review (30 studies)	Nonpsychological treatments such as CBT have a limited effect on pain, disability, and mood.
Garcia-Campayo et al. 2008	Pharmacological and nonpharmacological outpatient and inpatient treatments	Meta-analysis (33 RCTs)	Treating fibromyalgia in specialized care centers offers no clear advantages over outpatient treatment.
Häuser et al. 2009	Multicomponent treatments	Meta-analysis (9 RCTs)	Strong evidence that multicomponent treatment has beneficial short-term effects.

Note. CBT=cognitive-behavioral therapy; RCT=randomized controlled trial.

and the diverse population groups included in the RCTs and highlight a variety of methodological concerns, including small numbers and therefore a lack of power, lack of blinded assessments in some trials, and poor quality of randomization procedures. In general, methodological rigor has improved over time, with more recent studies showing evidence of improved methodological quality.

Fibromyalgia

Several different psychological approaches have been evaluated for patients with fibromyalgia, such as multicomponent treatment, CBT, exercise programs, relaxation therapy, and educational interventions. There appears to be evidence for modest effects for these treatments, with the best evidence for multicomponent treatment (at least one educational intervention plus one psychological therapy plus one exercise therapy) rather than specific individual treatments. Multicomponent treatment appears to have beneficial short-term effects on the key symptoms of fibromyalgia, including pain, low physical fitness, and depressive symptoms, but there is little evidence of long-term gain.

Chronic Fatigue Syndrome

There is better evidence for the benefits of CBT for chronic fatigue syndrome, with the most recent meta-analytic re-

view (which included 13 studies) suggesting that CBT is “moderately efficacious” (Malouff et al. 2008). The reviewers also reported a substantial but nonsignificant association between the number of treatment hours and the effect size, which supports the dose-response literature for psychotherapy (i.e., clients tend to show sequential improvements per session, up to 10–16 sessions [Lambert and Ogles 2004]). Malouff et al. (2008) additionally carried out a comparison between treatments with and without cognitive elements and found no evidence that including cognitive components led to a greater effect. In fact, a trend occurred in favor of *not* including cognitive components. This supports the findings of an earlier review of studies employing a variety of different psychological treatment interventions, which reported evidence for the effectiveness of CBT and graded exercise programs (Whiting et al. 2001).

Irritable Bowel Syndrome

The most recent systematic review of treatment interventions for irritable bowel syndrome included the evaluation of the efficacy of antidepressants and psychological therapies (Ford et al. 2009). The reviewers concluded that both antidepressants and psychological therapies were effective in the treatment of irritable bowel syndrome and of comparable efficacy (number needed to treat [NNT]=4 for

Authors	Therapy	Type of review	Outcome
Whiting et al. 2001	Pharmacological and nonpharmacological	Systematic review (36 RCTs, 8 controlled trials)	Mixed results in terms of effectiveness. CBT and graded exercise showed promising results.
Looper and Kirmayer 2002	CBT	Critical review (4 studies)	Positive outcomes in most studies.
Rimes and Chalder 2005	Pharmacological and nonpharmacological	Systematic review	Most promising results were for CBT and graded exercise therapy.
Chambers et al. 2006	Pharmacological and nonpharmacological	Systematic review (70 studies)	Increase in size and quality of evidence base on interventions for CFS/ME. Promising results shown for some behavioral interventions in reducing symptoms of CFS/ME and improving physical functioning.
Malouff et al. 2008	CBT	Meta-analysis (13 RCTs)	Significant difference (Cohen's $d=0.48$) in posttreatment fatigue between CBT and control conditions.

Note. CBT=cognitive-behavioral therapy; ME=myalgic encephalomyelitis; RCT=randomized controlled trial.

both types of treatment), although there was less high-quality evidence for routine use of psychological therapies.

Seven studies included in the Ford et al. (2009) review involved CBT, with an estimated NNT of 3, although there was statistically significant heterogeneity between studies and evidence of funnel plot asymmetry. When some of the smaller studies were removed from the analysis, the beneficial effect of CBT on irritable bowel syndrome symptoms disappeared. There were two studies on hypnotherapy

(NNT=2) and two studies on dynamic therapy (NNT=3.5). Multicomponent treatment was evaluated in three studies (NNT=4).

A previous systematic review of psychological treatments for irritable bowel syndrome by Lackner et al. (2004) identified 10 studies eligible for inclusion in a meta-analysis, involving a total of 185 patients, and reported a number needed to treat of 2. The more recent review by Ford et al. (2009), however, included data on almost 1,300 patients

TABLE 39-5. Systematic reviews, critical reviews, and meta-analyses of trials of psychological treatment in irritable bowel syndrome (IBS)

Authors	Therapy	Type of review	Outcome
Lackner et al. 2004	Psychological treatment	Systematic review and meta-analysis (17 RCTs)	Psychological treatments were effective for IBS (NNT=2).
Blanchard 2005	CBT	Critical review	Good evidence for efficacy of CBT interventions in the short term. Long-term outcome was rarely evaluated.
Wilson et al. 2006	Hypnotherapy	Systematic review (6 controlled/RCT, 12 uncontrolled)	Suggestive evidence of significant benefit.
Ford et al. 2009	Antidepressants and psychological therapies	Systematic review and meta-analysis (32 RCTs)	Antidepressants are effective in the treatment of IBS. There is less high-quality evidence for psychological therapies, although they may be of comparable efficacy. (NNT=4 for both interventions.)

Note. CBT=cognitive-behavioral therapy; NNT=number needed to treat; RCT=randomized controlled trial.

randomly assigned to some form of psychological intervention and employed much more rigorous methods. Ford and colleagues' more conservative estimate of number needed to treat (NNT=4) is probably a better indicator of likely treatment effects but still suggests that psychological treatments have a good evidence base for the treatment of irritable bowel syndrome.

Chronic Pain

Several systematic or meta-analytic reviews of psychological treatment or CBT for chronic pain have been published over the past 20 years. Each review has included different groups of pain patients (e.g., patients with headache and dental pain, with low back pain, with back pain and fibromyalgia). Table 39-6 summarizes the main conclusions from these reviews. Of particular interest, A. Williams and Morley (2009) recently updated an influential review of psychological treatments for persistent pain (excluding headache) that they first published in 1999 (Morley et al. 1999).

The original review identified 25 trials suitable for meta-analysis but commented that most trials were underpowered with small numbers, and some were overcomplex with multiple treatment and control groups (Morley et al. 1999). The authors concluded that CBT, when compared with wait-list control conditions, was associated with significant effect sizes on all domains of measurement (me-

dian effect size across domains=0.5). However, when CBT was compared with other treatments or control conditions across the same range of outcomes, the efficacy of CBT was of a smaller magnitude and limited to fewer outcome measures of pain and coping.

The updated review identified 50 studies suitable for data extraction. Treatments were classified as behavioral treatment (BT) or CBT. The authors found that pain improved with BT and CBT compared with treatment as usual at the assessment immediately posttreatment but not at the follow-up assessment (A. Williams and Morley 2009). Effect sizes were small to medium: 0.18 for CBT (22 studies, >1,200 patients) and 0.48 for BT (8 studies, 564 patients). The authors found no difference between BT or CBT when compared with other active treatment control conditions.

They found a small but positive effect on mood for CBT compared with both treatment as usual conditions and active control conditions, immediately posttreatment (16 trials, 1,001 patients, effect size=0.16) and at follow-up (17 trials, 873 patients, effect size=0.19). They concluded that CBT showed disappointingly small effects on pain and other primary treatment targets (A. Williams and Morley 2009).

The evidence for multidisciplinary interventions as opposed to single-modality treatments for chronic pain

TABLE 39-6. Systematic reviews, critical reviews, and meta-analyses of trials of psychological treatment in chronic pain

Authors	Therapy	Type of review	Outcome
Carroll and Seers 1998	Relaxation	Systematic review (9 RCTs)	Insufficient evidence to confirm that relaxation can reduce chronic pain.
Morley et al. 1999	CBT and BT	Systematic review and meta-analysis (25 RCTs)	Psychological treatments based on CBT are effective. Median effect size across domains was 0.5 for CBT vs. wait-list controls.
Raine et al. 2002	CBT	Systematic review (16 studies)	Sustained improvements in pain, depression, and disability.
Bailey 2002	Psychological treatment	Meta-analysis (146 interventions)	Psychological interventions showed small effects.
Hoffman et al. 2007	Psychosocial interventions	Meta-analysis (22 RCTs)	CBT and self-regulatory treatments were efficacious.
Scascighini et al. 2008	Multidisciplinary treatments	Systematic review (35 RCTs)	Strong evidence for multidisciplinary treatments vs. standard medical treatment for pain.
A. Williams and Morley 2009	Psychological treatments	Systematic review and meta-analysis (62 RCTs)	Effect sizes for pain were small to medium for CBT (0.18) and BT (0.48) vs. treatment as usual immediately posttreatment, although there was no difference at follow-up.

Note. BT=behavior therapy; CBT=cognitive-behavioral therapy; RCT=randomized controlled trial.

seems to be stronger. A minimum standard of multidisciplinary therapy would include the following: specific individual exercising, regular training in relaxation techniques, group therapy led by a clinical psychologist (1.5 hours per week), patient education sessions (once per week), physiotherapy treatments (two per week) for pacing strategies, medical training therapy, and neurophysiology information given by a trained physician (Scascighini et al. 2008).

A recent systematic review of multidisciplinary interventions for chronic pain identified 27 studies involving a total of 2,407 patients (Scascighini et al. 2008). Eighteen of the studies were performed in an outpatient setting, 4 in an inpatient setting, and 4 studies compared inpatient treatment with outpatient treatment. The duration of programs varied, ranging from 4 to 15 weeks for outpatient programs and from 3 to 8 weeks for inpatient programs. Based on available data, the median duration of all treatments was 45 hours. The quality of the trials varied, with many being judged to suffer from a lack of quality of design, execution, or reporting of main outcome variables. The reviewers did not perform a meta-analysis. Fifteen studies comparing multidisciplinary treatment (MDT) versus wait-list control or treatment as usual showed strong evidence (according to the reviewers) for the superiority of MDT. There was moderate evidence that comprehensive inpatient programs were more beneficial than outpatient treatment. There was no evidence that specific treatment variables, such as duration or specific program components, were influential in the success of the intervention.

Somatoform Disorders

There have been relatively few trials involving patients that meet strict criteria for somatoform disorders. Kroenke (2007) recently carried out a critical review of this area and included studies of interventions in somatization disorder, undifferentiated somatoform disorder, hypochondriasis, conversion disorder, pain disorder, and body dysmorphic disorder. Kroenke identified 34 RCTs involving 3,922 patients. He reported that a meta-analysis was not possible because of the small number of trials within each diagnostic category and the wide variability between studies in terms of study design, outcome measures, etc.

Two-thirds of the studies involved somatization disorder ($n=4$ studies) or lower-threshold variants such as abridged somatization disorder ($n=9$) and medically unexplained symptoms ($n=10$). CBT was effective in 11 out of 13 studies, as were antidepressants in a small number (4 out of 5) of studies. Trials involving other treatment modalities showed benefit in 8 out of 16 studies. The other treatments for somatization disorder and its variants were a psychiatric consultation letter to the patient's primary care physician with advice on how to better manage soma-

tizing patients ($n=4$), training of primary care physicians to better manage somatizing patients ($n=3$), non-CBT therapy ($n=2$), a multicomponent nurse care management intervention ($n=1$), aerobic exercise ($n=1$), and writing disclosure ($n=1$). There were two studies of hypnosis and one of paradoxical intention for conversion disorder, and one study of explanatory therapy in hypochondriasis. The most consistent evidence among these other treatments was for a consultation letter to the primary care physician. Kroenke (2007) concluded that CBT is the best-established treatment for a variety of somatoform disorders.

Treatment of Depression in Physical Illness

There is a growing evidence base for the treatment of depression in physical illness using either psychological interventions alone or psychological interventions as part of a package of collaborative care.

Collaborative and Stepped Care

The United Kingdom's National Institute of Clinical Excellence (NICE) recently published a new guideline for the treatment of depression in chronic physical illness (National Institute for Health and Clinical Excellence 2009). In the NICE guideline, 17 trials involving service-led interventions for the treatment of depression in physical illness were identified which provided data on 4,994 participants. Fifteen of the studies assessed the efficacy of collaborative care versus either standard or enhanced standard care (Table 39-7).

There was considerable variation between the different collaborative care interventions, with the complexity of the intervention and treatment components differing among studies. In the stepped-care approaches, participants were given a choice between an antidepressant or a psychological intervention as first-line treatment.

The NICE guideline concluded that there was consistent evidence that collaborative care had small to medium benefits on a range of depression outcomes, including response and remission, when compared with any form of standard care (National Institute for Health and Clinical Excellence 2009). Few conclusions could be drawn regarding the efficacy of collaborative care on improving physical health outcomes. Trials differed in the kind of physical illness from which patients were suffering, and the reporting of physical health outcomes was sparse, with different papers reporting a diverse range of outcomes.

Cognitive-Behavioral Therapy

NICE identified seven trials of individual-based CBT for depression in chronic physical illness (Table 39-8). Following analysis, NICE reported that individual-based CBT had a moderate effect on depression at the end of treatment in

TABLE 39-7. Studies of collaborative care for the treatment of depression in chronic physical illness

comparison with standard care (standardized mean difference [SMD] = -0.55; 95% confidence interval [CI] = -0.97 to -0.13) for people with minor to mild depression. There were no differences between individual-based cognitive and behavioral interventions and counseling for depression at the end of treatment (SMD = -0.13; 95% CI = -0.46 to 0.20).

NICE also reported on group-based CBT interventions and identified 11 studies (Table 39-9). Following analysis, group CBT was found to have a moderate effect on depression at the end of treatment in comparison with standard care (SMD = -0.54; 95% CI = -0.86 to -0.21) for people with mild to moderate depression (National Institute for Health and Clinical Excellence 2009). The quality of evidence was "moderate" for depression because a possible publication bias was identified. There was also high heterogeneity; a sensitivity analysis was performed removing an outlier, which had a large effect on depression at the end of treatment and reduced the effect of the intervention on depression from a moderate to a small effect at the end of treatment (SMD = -0.42; 95% CI = -0.63 to -0.21).

Non-CBT Psychological Therapies

There are relatively few studies of non-CBT treatment for depression in physical illness. Gellis et al. (2008) evaluated problem solving as a treatment for depression in older adults with a range of medical conditions living in a care home. Very positive results on depression following a 6-session intervention were reported.

There have been four trials of IPT. Two of the trials involved patients with HIV (Markowitz et al. 1995; Ransom et al. 2008), one trial involved patients with cardiovascular disease (Lesperance et al. 2007), and one trial involved older adults with general medical illness (Mossey et al. 1996). The results of the trials were mixed. Lesperance et al. (2007) did not find IPT to be superior to clinical management for the treatment of major depression in patients

with cardiovascular disease. Ransom et al. (2008) found a small but statistically nonsignificant effect of IPT in comparison to standard care for patients with HIV, while Markowitz et al. (1995) found IPT to be superior to CBT

for the treatment of depression in HIV and equivalent to counseling. No clear picture emerged for IPT, and further studies are required before its usefulness as a treatment for depression in medical illness can be fully evaluated.

There have been three trials that have included a counseling arm. One involved depressed patients with cancer (Manne et al. 2007), one involved patients with cardiovascular disease (Brown et al. 1993), and one involved patients with multiple sclerosis (Mohr et al. 2005). All three studies compared counseling with individual CBT, and one also compared counseling with a "standard care" control condition. There was no difference between counseling versus standard care, and there was no difference between counseling and CBT for depression over the three studies (SMD = 0.06; 95% CI = -0.16 to 0.27).

Psychological Therapies for Patients With Cancer

Psychosocial care is increasingly being recognized as an essential component of the comprehensive care of the individual with cancer. A wide range of therapies have been evaluated for patients with cancer and include behavioral therapy, cognitive therapy, CBT, communication skills training, counseling, family therapy/counseling, guided imagery, mindfulness therapy, music therapy, problem-solving therapy, psychotherapy, stress management training, support groups, and supportive-expressive group therapy (Jacobsen and Jim 2008).

There have been many systematic reviews published over the past 20 years evaluating the evidence supporting psychosocial treatments for anxiety and depression in patients with cancer. Jacobsen and Jim (2008) recently carried

out a "review of reviews" summarizing findings from 14 previous systematic reviews that had evaluated psychosocial interventions. The studies are shown in Table 39-10, which has been adapted from Jacobsen and Jim (2008).

Thirteen of the 14 studies reached conclusions about the efficacy of psychosocial interventions for depression in cancer patients. Nine out of the 13 reviews reached positive conclusions, with the best evidence for behavioral therapy and counseling/psychotherapy. One of the reviews (Uitterhoeve et al. 2004) specifically evaluated interventions for patients with advanced cancer. These reviewers identified 13 trials and reported that 12 trials evaluating behavior therapy found positive effects on one or more indicators of quality of life (e.g., depression).

Eight of the 14 publications identified offered conclusions about the efficacy of psychosocial interventions for anxiety in cancer patients, with 6 out of the 8 publications reaching positive conclusions.

Jacobsen and Jim (2008) reported that many of the reviews had identified areas of weakness in the evidence base which had important implications for clinical practice. First, few of the studies included men or members of ethnic and racial minority groups. Second, there were inconsistent findings across studies due to differences in type of disease, number and timing of outcome measures, and demographics of patients recruited to the studies. Third, many of the studies were rated as being of poor quality. Finally, relatively few of the studies included patients with clinically significant levels of anxiety and depression, and many people included in the trials may not have been depressed or anxious at all, or suffering from subthreshold symptoms.

TABLE 39-10. Systematic reviews and meta-analyses of psychosocial interventions for anxiety or depression in adults with cancer

Authors	Intervention	Main findings
Devine and Westlake 1995	Psychoeducational care	Positive results for anxiety (Cohen's $d=0.56$; 95% CI = 0.42 to 0.70)
Lovejoy and Matteis 1997	CBT	Knowledge base for CBT for treatment of depression in cancer is in early stages
Bottomley 1998	Pharmacological and psychological	Positive results for depression with individual and groups
Sellick and Crooks 1999	Individual counseling	Magnitude of treatment effects for depression in the 10 studies reviewed were classified as large (5), moderate (2), low (2), and none (1)
Sheard and Maguire 1999	Psychosocial	Anxiety: Cohen's $d=0.42$ (95% CI = 0.08 to 0.74); $d=0.36$ when based on criteria for developing a robust estimate
Luebbert et al. 2001	Relaxation training	Anxiety: Cohen's $d=0.45$ (95% CI = 0.23 to 0.67) Depression: $d=0.54$ (95% CI = 0.30 to 0.78)
Redd et al. 2001	Behavioral interventions for cancer treatment side effects	Four of 5 studies demonstrated beneficial effects on anxiety

TABLE 39–10. Systematic reviews and meta-analyses of psychosocial interventions for anxiety or depression in adults with cancer (continued)

Authors	Intervention	Main findings
Barsevick et al. 2002	Psychoeducational	Positive results for depression reported in 63% of studies reviewed
Newell et al. 2002	Psychosocial	Recommendations for depression were tentatively against 7 strategies, neither for nor against 6 strategies, and tentatively for 0 strategies
Uitterhoeve et al. 2004	Psychosocial	Six of 10 studies showed a significant effect for depression; 1 of 10 studies showed a significant effect for anxiety
Jacobsen et al. 2006	Psychosocial and pharmacological	Forty-one percent of analyses yielded significant results for depression favoring intervention condition; 36% yielded significant results for anxiety favoring intervention condition
Osborn et al. 2006	Psychosocial	Anxiety: Hedges' $g = 1.99$ (95% CI = 0.69 to 3.31) (CBT); $g = -0.02$ (95% CI = -0.36 to 0.31) (psychoeducation)
S. Williams and Dale 2006	Psychosocial and pharmacological	Three of 4 studies showed benefit of intervention in treating depression; 7 of 10 trials showed a benefit of CBT in reducing depression
Rodin et al. 2007	Psychological and pharmacological	Two of 4 studies showed a benefit of psychosocial intervention in reducing depressive symptoms

Note. CBT = cognitive-behavioral therapy; CI = confidence interval; RCT = randomized controlled trial.

Source. Adapted from Jacobsen and Jim 2008.

Conclusion

There is evidence that psychological therapies are beneficial for patients with physical and psychological problems. The best evidence is for CBT, but other therapies are also developing evidence bases. Psychological therapies are particularly helpful for patients with medically unexplained symptoms but have less impact on patients who present with chronic pain, unless the treatments are provided as part of a multicomponent package. Increasingly, psychological treatments are being delivered as components of either stepped-care or collaborative care models. Psychological therapies are often provided in conjunction with pharmacological treatments, particularly if there is poor initial response to psychological treatments alone.

In the coming decade there is likely to be a growth in studies evaluating the role of psychological therapies in chronic illness, particularly in view of the possibility that such treatments may result in reduced health care costs.

Access to appropriate psychological treatment for patients with physical and psychological health problems remains a serious problem in many countries. Improvement in access is unlikely to occur to a significant extent unless psychological therapies are better integrated into physical health care systems, which can be done via liaison psychiatry services or via primary care-based services.

Electroconvulsive Therapy

Keith G. Rasmussen, M.D.

ELECTROCONVULSIVE THERAPY (ECT) is a safe procedure with low mortality rates (Nuttall et al. 2004). Nonetheless, medical comorbidity in ECT patients is so common that the clinician should be familiar with strategies to prevent complications. Management of medically ill patients receiving ECT includes careful pretreatment assessment of medical comorbidity, proper treatment technique, vigilant assessment of the patients' medical status between treatments, and identification and management of treatment-emergent medical complications. Two overriding principles for the ECT clinician are ongoing vigilance and communication. Vigilance refers to the need for the ECT clinician to have a thorough awareness of all significant medical problems the prospective ECT patient has and the results and recommendations of medical tests and consultations. Because ECT fundamentally involves a team approach in patient care, the ECT clinician is the coordinator of the team and must ensure ongoing communication among the various caregivers. For example, if the pre-ECT workup detects cervical spine disease, then the ECT clinician must pass this information on to whoever manages the airway during the treatments. Thus, even though a psychiatrist probably will not determine specialized testing performed before treatments, deliver anesthesia, or manage the airway, the psychiatrist must ensure that the relevant parties are fully informed.

The basic questions covered in this chapter are 1) What are the risks with a particular medical condition during ECT? and 2) How can they be reduced? Ideally, large prospective case series would be available to inform us of morbidity and mortality risks, and controlled trials would inform us about preventive strategies, but both are lacking in this field. We do have case reports and relatively small case series as well as the clinical expertise of experienced ECT practitioners. In this chapter, I review, in an organ system-

based format, the current state of knowledge of ECT risk reduction strategies. It is assumed that all prospective ECT patients will undergo a thorough medical history, review of systems, and physical examination. Laboratory studies, radiological examinations, cardiac testing, and specialty consultation (e.g., cardiology or neurology) are individualized and discussed in the relevant sections later in this chapter.

Cardiovascular Disorders

Cardiac Physiology of ECT

Over the past several decades, numerous carefully conducted studies have investigated the hemodynamic, electrocardiographic, and echocardiographic findings during and shortly after ECT treatments. In brief, a sharp rise in pulse and blood pressure occurs during the seizures but returns to baseline usually within a few minutes postictally (Rasmussen et al. 1999).

After the electrical stimulus, there is a vagally (i.e., parasympathetically) mediated short-lived bradycardia, occasionally with asystole of several seconds. If the electrical stimulus is strong enough to cause a seizure, this initial parasympathetic phase is rapidly replaced by a sympathetically mediated tachycardia and rise in blood pressure during the seizure. Myocardial workload and cardiac output increase significantly. These effects generally subside within a few minutes to an hour. In the immediate postictal phase, if no antimuscarinic premedication has been given, there is often transient bradycardia, followed again by a smaller increase in heart rate that typically reverts to prestimulus levels within a few minutes. A mild increase in heart rate may persist over the preanesthesia baseline depending on the half-life of the antimuscarinic premedication, if given.

Thus, from a hemodynamic standpoint, the factor that is most relevant to cardiac patients is the sympathetically mediated sharp increase in myocardial workload.

If the electrical stimulus is not of sufficient intensity to cause a seizure, then the initial parasympathetic effects will not be offset by the sympathetic phase. Thus, there have been rare reports of prolonged asystole requiring resuscitation, especially in patients who have not been given antimuscarinic premedication or who received beta-blockers. For this reason, the use of antimuscarinic premedication is encouraged in ECT. This is especially true at the first treatment session, when a stimulus dose titration is performed to determine seizure threshold and subconvulsive stimuli are likely. However, at subsequent treatment sessions, subconvulsive stimuli are much less likely. If a patient experienced uncomfortable urinary hesitancy with the first treatment when an antimuscarinic agent was administered, then it should be withheld at subsequent sessions.

As would be expected given this stress on the heart, it is not uncommon to see a variety of transient electrocardiogram (ECG) abnormal findings during this time, including ST segment depression and T wave changes (Rasmussen et al. 2004) as well as temporary echocardiographic abnormalities, mainly abnormal wall motion (McCully et al. 2003). The parameters that are monitored routinely include blood pressure and ECG, and any untoward measurements can be treated promptly by the anesthesiologist (e.g., with blood pressure medication or antiarrhythmics) to prevent serious complications. It is easy to appreciate that these physiological changes might predispose cardiac patients to higher-than-usual risks during ECT, but the literature does not permit confident precise conclusions about such risks. Pre-ECT consultation with a cardiologist or an anesthesiologist familiar with the cardiac physiology of ECT should be undertaken. No universally agreed-upon standards of pre-ECT cardiac testing have been developed, but such testing should be individualized according to the particular patient's cardiac status.

Congestive Heart Failure

Patients with congestive heart failure (CHF) are particularly sensitive to increased myocardial demand such as occurs in ECT. The key for maximum safety with such patients is to stabilize ventricular pump function optimally before proceeding with treatments. What is known about risks comes from a few small case series. Zielinski et al. (1993) reported on 40 ECT patients with a variety of cardiac diagnoses, 12 of whom had CHF. There were no deaths in this series. Of the patients with CHF, 2 had (unspecified) ischemic changes on electrocardiography, and 1 had dysrhythmias. Seven of the CHF patients had minor cardiac complications, consisting usually of transient dysrhyth-

mias (atrial or ventricular). Finally, 2 of the CHF patients underwent ECT without cardiac complications. The authors found that in patients who did not receive initial pretreatment with antimuscarinic medication, bradycardia and brief periods of asystole were common and preventable with subsequent atropine.

Stern et al. (1997) described three patients with CHF who received ECT without any cardiac complications. The authors used nitroglycerin patch, sublingual nifedipine, and intravenous labetalol pre-ECT to lower the risk of decompensation of heart failure during the procedure. Goldberg and Badger (1993) treated two patients with CHF and implantable cardioverter defibrillators (ICDs). The first tolerated eight ECT treatments without consequence. The second, a 65-year-old man with dilated cardiomyopathy and pre-ECT ejection fraction of 20%, underwent four treatments. After recovery from the first and third treatments, he had respiratory difficulties and bouts of hypotension that responded to ephedrine. After the fourth treatment, he developed a wide complex tachycardia without palpable pulse and was resuscitated. No further ECT was administered, but he had a hypotensive episode 5 days later that ultimately led to his death from progressive heart failure several days thereafter.

Gerring and Shields (1982) provided detailed outcome data on four patients with CHF who were treated with ECT for depressive illness. A 60-year-old woman with mitral stenosis received ECT without complication. A 58-year-old woman, also with mitral stenosis in addition to CHF, experienced atrial fibrillation leading to severe decompensation of the CHF after the second treatment; on stabilization, she went on to receive another course of ECT without complication. A 71-year-old woman with a history of myocardial infarction (MI) in addition to CHF had a cardiopulmonary arrest 45 minutes after her fifth treatment and died. Finally, a 69-year-old woman showed transient ventricular and atrial dysrhythmias after several of her ECT treatments, which she otherwise tolerated well.

Petrides and Fink (1996), in a series of ECT patients with atrial fibrillation, reported that one 89-year-old woman with CHF converted to sinus rhythm after receiving a course of ECT. Also, a 76-year-old woman with CHF and atrial fibrillation received a course of seven ECT treatments, during which she fluctuated between atrial fibrillation and sinus rhythm. The CHF did not seem to worsen. In summary, most CHF patients have received ECT without worsening of ECT or other complications except transient arrhythmias in some, but there have been rare deaths.

CHF should optimally be treated and stabilized prior to ECT treatments. Once the patient is scheduled for ECT, cardiac medications should be administered in the morning before the treatment with a small amount of water, with

enough time to ensure absorption. Practice guidelines caution against administration of diuretic agents the morning of ECT to avoid bladder rupture or incontinence during the seizure (American Psychiatric Association 2001). However, the author generally recommends administering patients' usual stable medications, including diuretics, to avoid any abrupt changes in their medical regimen. The full bladder problem can be managed simply by having the patient void just before the treatment or, if necessary, by making transient use of a urinary catheter.

Whether to use an antimuscarinic agent in the patient with CHF must be decided on a case-by-case basis. The potential for such medication to increase myocardial workload through added tachycardia and hypertension is established (Rasmussen et al. 1999). However, if a patient receives a subconvulsive electrical stimulus, especially if he or she is also receiving beta-blocking medication, the risk of unopposed parasympathetic stimulation and resultant prolonged asystole is real (Tang and Ungvari 2001).

The attending anesthesiologist may elect to use other cardioprotective agents when ECT is being administered to the patient with CHF. For example, a beta-blocker such as esmolol or labetalol may dampen the seizure-induced sympathetic stimulation. Other strategies include preload reduction (e.g., nitrates), peripheral vasodilators (e.g., hydralazine), and calcium channel blockade (e.g., verapamil or diltiazem).

Finally, intertreatment assessment in patients with CHF is especially important, as shown by the case report of a patient who died of congestive decompensation that began several days after the last ECT treatment (Goldberg and Badger 1993). Daily rounds should include not only assessment of mood and cognitive status but also inquiries about symptoms of CHF (e.g., shortness of breath, orthopnea) and physical examination for signs of CHF (e.g., gallops, jugular venous distension, peripheral edema, pulmonary crackles). Any new or worsening findings should prompt careful evaluation and, if necessary, halting of ECT (even if temporarily) to stabilize the patient. Patients with known CHF should be evaluated by an internist or a cardiologist prior to initiating treatment.

Coronary Artery Disease/ Post-Myocardial Infarction

Easing the rise in myocardial oxygen demand is the goal in care of patients with coronary artery disease (CAD) during ECT. In several case series (Gerring and Shields 1982; Magid et al. 2005; Petrides and Fink 1996; Rice et al. 1994; Zielinski et al. 1993), numerous patients with CAD—some with remote history of MI—underwent ECT without major complications. Unfortunately, patients with precisely defined severity of CAD were prospectively followed up for

any effects of ECT in only a few reports. In an echocardiographic/sestamibi study by Ruwisch et al. (1994) in patients with known CAD, ECT did not cause any clinical complications (e.g., angina, MI, clinically significant ventricular dysfunction).

After the prospective ECT patient with CAD has had the appropriate pretreatment evaluation and stabilization, some measures may further reduce cardiac risk. Many studies have shown that pretreatment with a variety of antihypertensive agents (e.g., beta-blockers, calcium channel blockers, other vasodilators, nitrates) lowers the seizure-induced rise in heart rate or blood pressure (Abrams 2002, pp. 77–81). Whether this reliably translates into actual protection against cardiac complications is unknown. In fact, Castelli et al. (1995), O'Connor et al. (1996), and Zvara et al. (1997) found no evidence that use of beta-blockers during ECT reduced evidence of myocardial ischemia despite beneficial effects on blood pressure rises during the treatments. Thus, it remains uncertain whether beta-blocker pretreatment reduces morbidity associated with ECT. Given the well-documented salutary effects of such drugs in patients with ischemic heart disease, it seems reasonable to use them in selected cases before, during, or shortly after the treatment depending on the patient's hemodynamic status, after carefully weighing the risks and potential benefits of such treatment.

Dysrhythmias, Pacemakers, and Implantable Defibrillators

The most common dysrhythmia in ECT patients is atrial fibrillation. There are several reports of patients in atrial fibrillation who safely received ECT (Petrides and Fink 1996). Occasionally, such patients will convert to sinus rhythm during ECT or convert back to atrial fibrillation if already converted before ECT to sinus rhythm. Atrial fibrillation newly identified before ECT should be assessed by a cardiologist for optimal management, including the decision whether to choose rate control or cardioversion. Therapeutic anticoagulation should be maintained throughout the course of ECT if the patient is already anticoagulated. Close and meticulous monitoring of the patient's hemodynamic status, oxygenation, and electrocardiographic changes in response to treatment is critically important during ECT. Electrocardiographic rhythm should be inspected before each treatment. The patient without history of atrial fibrillation who develops this rhythm during ECT obviously should have a cardiac evaluation before treatment is resumed. In patients taking warfarin, therapeutic anticoagulation should be continued throughout ECT (Mehta et al. 2004).

Because cardiac patients are predisposed to a variety of atrial or ventricular dysrhythmias, it is important to ensure

that electrolytes are normal. Electrolyte abnormalities and other metabolic perturbations (e.g., thyroid dysfunction) can be even more proarrhythmic, along with medications that may prolong the QT interval, including many psychotropics, which are often prescribed for ECT patients (Rasmussen et al. 2006a). Some intriguing recent data suggest that high QTc dispersion (i.e., inhomogeneity of the QTc interval on the 12-lead ECG) is common in ECT patients (Dodd et al. 2008) and may predispose to arrhythmias during ECT treatments (Rasmussen et al. 2007a).

A related issue concerns the prospective ECT patient with a cardiac pacemaker or an ICD. There have been numerous case reports of patients with pacemakers who have undergone successful and uncomplicated ECT (Dolenc et al. 2004), as well as a few reports of patients with ICDs (Dolenc et al. 2004; Lynch et al. 2008). Pre-ECT device assessment to ensure normal functioning is advisable. Some practitioners have used a magnet placed on the chest above the device to convert a demand mode pacemaker to fixed mode during ECT to avoid spurious discharge of the device, which theoretically could occur as the result of muscle electrical activity; however, no evidence supports this practice. ICDs should be turned off prior to each ECT treatment while the patient is on an electrocardiographic monitor, the latter being continued until the ICD is turned back on. All patients with ICDs or pacemakers that have been reprogrammed prior to ECT should have device assessment after the procedure.

Aneurysms

Several case reports cite safe use of ECT in patients with aortic aneurysms, some after surgical correction (Mueller et al. 2009; Porquez et al. 2003). Assuming that patients have no preexisting conditions or surgical complications, there is no specific reason to assume that patients who have had an aneurysm repair are at increased risk during ECT.

The chief concern in patients with aneurysms is the potential risk of rupture or leakage caused by the rapid rise in blood pressure during ECT. If a patient is known to have an aortic aneurysm, the size should be evaluated (e.g., by ultrasound) prior to ECT. Consultation with a vascular surgeon would be prudent to evaluate the stability of the aneurysm and strategies for risk reduction. Pretreatment with antihypertensives before ECT anesthesia can optimize control of blood pressure and reduce arterial wall stress. Labetalol is ideal for this purpose because it has both alpha and beta blockade and thus can reduce peripheral vascular resistance and attenuate the rise in blood pressure during and shortly after the seizure. Repetitive imaging may be necessary during the course of ECT treatments if there is any concern with respect to the stability of the aneurysm.

Hypertension

There are two overarching concerns regarding blood pressure and ECT. The first is how well controlled blood pressure should be before it is safe to proceed with ECT in hypertensive patients. Hypertension is the most common cardiovascular condition in patients receiving ECT. Presumably, with the rise in blood pressure during seizures, uncontrolled hypertension might predispose to complications such as MI or cerebral infarction. A recent review concluded by suggesting that patients with blood pressure measurements greater than 140/90 mm Hg should be treated until blood pressure is normal before proceeding with ECT (Tess and Smetana 2009), but such an arbitrary cutoff is problematic. Although it seems intuitively obvious that good control of blood pressure is ideal before ECT, undue delays while waiting for complete normalization seem unwarranted. Furthermore, gaining tight control of blood pressure is difficult in many hypertensive patients, especially those with severe psychopathology such as catatonia, psychosis, or melancholia. Insisting on “normal” blood pressure effectively eliminates ECT for some patients. The author has personally overseen ECT in many patients over the years who have had somewhat elevated blood pressure, none of whom have had a peri-ECT stroke or MI. If the anesthesiologist is concerned about a patient’s blood pressure at the time of a treatment, intravenous beta blockade can effectively dampen the rise in pressure during the seizure. Furthermore, Albin et al. (2007) found that no sustained rise in blood pressure occurs in hypertensive patients during a course of ECT treatment. With the availability of short-acting antihypertensive agents (e.g., esmolol or labetalol), high blood pressure generally can be managed rapidly and effectively during the treatments. Data also indicate that labetalol does not predispose to orthostatic hypotension in the hours after ECT (Rasmussen et al. 2008c). Thus, although attempting to achieve good blood pressure control in hypertensive patients is obviously an excellent idea, the author recommends against strict limits that might lead to withholding ECT. The practitioner must weigh the urgency of ECT, the severity of the elevated pressure, and any comorbid cardiac condition (e.g., presence of known CHF) while taking reassurance from the knowledge that cardiac complications during ECT are extremely rare.

The second blood pressure concern in ECT is the management of spikes that occur during ECT treatments. As described earlier, there is no evidence that control of blood pressure spikes during ECT reduces complications. Given that the complication rate during ECT is so low, the sample size of a prospective controlled trial of antihypertensive administration at ECT sessions that would provide adequate

statistical power to detect a meaningful difference would probably be prohibitively large. In the meantime, it seems reasonable to use an agent to dampen the rise in ECT-induced blood pressure in selected patients (e.g., those with very high baseline blood pressure or concomitant cardiac conditions). Some data indicate that beta-blockers may shorten seizure length in ECT (Howie et al. 1990; Van den Broek et al. 1999), whereas other studies have not found this effect (Dannon et al. 1998; Howie et al. 1992; McCall et al. 1991). In either case, no evidence indicates that beta-blockers reduce the efficacy of ECT, and no correlation is found between seizure length and ECT efficacy (Abrams 2002, p. 122). To underscore this point, the anesthetic agent propofol is known to reduce seizure length potently in ECT, but several controlled trials indicate that it does not reduce ECT efficacy (Abrams 2002, p. 156). Thus, not all experts would agree with the recent review advising caution in the use of beta-blockers in ECT (Tess and Smetana 2009). Concomitant use of an anticholinergic agent at the time of treatment, typically either glycopyrrolate or atropine, is recommended if beta-blockers are used to prevent prolonged asystole after the electrical stimulus.

Valvular Abnormalities

Patients with aortic stenosis are at risk for low cardiac output under conditions of increased myocardial workload. Numerous reports exist of safe use of ECT in patients with aortic stenosis without prior surgical correction (Mueller et al. 2007; Rasmussen 1997), although a case of hypotension in such a patient (Sutor et al. 2008) illustrates the fragile hemodynamic status of this population. Aortic stenosis is common, especially in elderly patients, and may require special attention by the anesthesiologist during ECT treatments to balance the risk of hyper- or hypotension, both of which may be problematic (Mueller et al. 2007). If a patient has had mechanical valve replacement and has received appropriate anticoagulation, the risk of ECT treatment should not be significantly increased (assuming that no other cardiac dysfunction, such as impaired ventricular function or dysrhythmia, is present). However, if a patient has a valvular abnormality that has not been optimally treated or is newly identified, then cardiac consultation should be obtained.

Heart Transplant

Heart transplant patients are rarely encountered in ECT practice. Three cases of uncomplicated ECT in heart transplant recipients have been published (Kellner et al. 1991; Lee et al. 2001; Pargger et al. 1995). Obviously, one should undertake ECT in a cardiac transplant patient only in close consultation with the patient's cardiologist.

Neurological Disorders

Neurophysiology of ECT

In contrast to cardiac physiology and testing, no known neurodiagnostic tests specifically predict neurological risk with ECT, and neuroprotective strategies are unavailable. Thus, brain imaging and electroencephalogram are not routinely indicated to assess ECT risk. If there is some other reason to perform a neurodiagnostic procedure, such as a newly found focal neurological sign, then that should be done prior to ECT as part of the diagnostic evaluation. ECT causes a brief rise in intracranial pressure, which theoretically implies risk of brain stem herniation in patients who already have increased intracranial pressure. However, such patients rarely are considered for ECT.

Dementia

Dementia, of course, is a term encompassing heterogeneous conditions causing progressive cognitive impairment. In ECT practice, the typical scenario is the elderly patient with known neurodegenerative dementia such as Alzheimer's or Lewy body disease or, less frequently, frontotemporal dementia. There is no reason to believe that these conditions per se would increase risk of medical complications during ECT. It would not be surprising that such patients may have greater-than-average acute cognitive impairment with ECT, but is the trajectory of their dementia worsened by a series of electrically induced seizures? The definitive study would be to randomly assign patients with well-characterized dementia syndromes who have psychopathology that normally would indicate ECT treatment to ECT or other interventions and follow up carefully with longitudinal assessments of cognition. Such a study has never been done and is not likely to be. We have only a set of relatively small case series of heterogeneous dementia patients with depression or agitation who seemed to benefit from ECT and who, in the opinion of the authors, did not seem to experience undue cognitive impairment (Rasmussen et al. 2003; Sutor and Rasmussen 2008).

Prudent advice for the ECT practitioner treating patients with dementia is to use unilateral electrode placement and twice-weekly scheduling. If improvement seems to lag from what is expected, then more aggressive treatment (i.e., bitemporal electrode placement or thrice-weekly treatments) can be given. Dementia patients with either depression or agitation who are referred for ECT may improve, but if maintenance treatments are not administered, rapid relapse tends to occur. Furthermore, the frequency of maintenance treatments often needs to be no less than every other week or even weekly to maintain the gains of the index course. This often leads to ongoing worsening of cog-

niton, a side effect that obviously needs to be weighed against improvements in mood and behavior.

Some authors have cautioned against prescribing cholinesterase inhibitors such as donepezil during ECT, which synergistically increase the effects of succinylcholine and similar neuromuscular blocking agents (Walker and Perks 2002). However, Rasmussen et al. (2003) found no problems in their case series of ECT patients who received donepezil. The ECT practitioner may wish to discontinue such medication before ECT, but the time required for several half-lives of the medication delays what may be urgently needed treatment. Whether initial evidence in patients without dementia of lesser cognitive effects with ECT while using donepezil (Prakash et al. 2006) extends to patients with dementia awaits controlled trials.

Parkinson's Disease

Several case reports and series indicate that ECT is effective for treating depression and even the motor manifestations in patients with Parkinson's disease (PD) (Rasmussen and Abrams 1991, 1992; Rasmussen et al. 2002). Common side effects of ECT in patients with PD include delirium and treatment-emergent dyskinesias (Douyon et al. 1989). The duration of ECT-related antiparkinsonian effects has been variable (Fall and Granerus 1999) and may be extended with maintenance ECT, although the benefits must be balanced against cognitive impairment (Pridmore and Pollard 1996). Acute confusional states and dyskinesias are common during ECT in PD and may be reduced with cautious lowering of dopamine agonist dosage. As for patients with dementia, the ECT clinician should consider twice-weekly treatment frequency and the use of right-unilateral electrode placement.

With the introduction of deep brain stimulation to the PD treatment landscape, one would expect to see an occasional such patient receive ECT. There are a few reports of uncomplicated use of ECT in patients with deep brain stimulators (Bailine et al. 2008; Chou et al. 2005; Moscarillo and Annunziata 2000). In all three of these patients, one of whom had essential tremor and the other two parkinsonism, the stimulator was turned off for the duration of the patients' courses of ECT. So far, damage to the pulse generator, overheating of the electrode tip, and dislocation of the electrode during the seizure have not been reported.

Cerebrovascular Disease

In several small case series, patients with poststroke depression improved with ECT without development of further neurological injury (Weintraub and Lippmann 2000). No randomized prospective comparisons of ECT and other antidepressant treatment modalities have been done, however. Prudent advice for the ECT practitioner is not to

use ECT in patients with recent stroke if possible. However, occasionally such a patient is profoundly depressed with marked decrease in psychomotor effort, has low or no food intake, or is at high acute suicidal risk. In such cases, if ECT is judged to be necessary, risk reduction strategies include continuing anticoagulation if it already is indicated (i.e., it should not be started just for ECT) and paying close attention to blood pressure to avoid high spikes and potentially dangerous declines.

There is concern that intracerebral aneurysms may rupture during ECT because of the rapid increase in blood pressure during seizures. Several cases of safe use of ECT in such patients have been reported (Okamura et al. 2006; Sharma et al. 2005). Two cases of ECT-associated intracerebral hemorrhages have been reported (Rikher et al. 1997; Weisberg et al. 1991), both in patients without known pre-ECT cerebrovascular disease. Most investigators reporting on ECT in patients with known aneurysms used antihypertensive drugs to dampen the ECT-related increase in blood pressure.

Epilepsy

ECT has anticonvulsant activity, as indicated by a progressive increase in seizure threshold and decrease in seizure length during the course of treatments (Rasimas et al. 2007; Sackeim et al. 1983). In the pre-anticonvulsant era and sporadically in the modern era, ECT has been used successfully to treat intractable epilepsy (Regenold et al. 1998) and even status epilepticus (Lisanby et al. 2001). These effects are short-lived, however, and the use of ECT to treat epilepsy is largely only of historical interest.

There are two reports of status epilepticus following ECT in epileptic patients: one patient had been administered multiple monitored ECT (Maletzky 1981), a technique no longer recommended for routine use (American Psychiatric Association 2001); the other had previously unrecognized seizures and was not receiving anticonvulsant medication during ECT (Moss-Herjanic 1967). At present, no evidence indicates that spontaneous seizure frequency increases with ECT in epileptic patients. Furthermore, it does not appear that the incidence of chronic epilepsy is increased in nonepileptic patients who receive ECT (Blackwood et al. 1980). However, because epilepsy is fairly common in the general population, recurrent seizures do occasionally develop in patients receiving extended courses of maintenance ECT (Rasmussen and Lunde 2007).

A common clinical challenge is how to treat the epileptic patient whose psychiatric illness requires ECT. Several case reports, small case series, and one fairly large series suggested that such patients can be given ECT effectively without worsening spontaneous seizure frequency (Lunde

et al. 2006; Sienaert and Puskens 2007). Before undertaking a course of ECT in a patient with epilepsy, consultation with the patient's neurologist is advised. Pretreatment brain imaging or electroencephalography is not needed unless such testing is indicated as part of the patient's neurological care.

The most common technical problem in ECT with epileptic patients is elicitation of therapeutic seizures in the face of concomitant treatment with anticonvulsant medications. Cautious lowering of the patient's anticonvulsant medication dosages might be needed but increases the risk of spontaneous seizures and should be undertaken with the aid of a neurologist (Lunde et al. 2006). At present, it is not known whether various anticonvulsant agents differentially affect seizure threshold and duration in ECT.

Intracranial Tumors

Some reports indicate safe use of ECT in patients with a variety of intracranial masses (Kohler and Burock 2001; Patkar et al. 2000; Perry et al. 2007; Rasmussen and Fleming 2006; Rasmussen et al. 2007c). Presence of any central nervous system tumor may lead to an increased risk for neurological complications caused by ECT. In the absence of focal neurological signs, brain edema, mass effect, or papilledema, the risks likely are relatively small. In the presence of such findings, ECT should be considered only when no other reasonable option exists and after consultation with a neurosurgeon or neurologist to discuss strategies to reduce the increase in intracranial pressure that accompanies seizures.

Other Neurological Disorders

ECT may be lifesaving in some cases of refractory neuroleptic-induced malignant catatonia, which includes neuroleptic malignant syndrome (American Psychiatric Association 2001). Additionally, there are reports of patients with protracted delirium after traumatic brain injury or other neurological illness who responded to ECT (Rasmussen et al. 2008b). A prudent summary statement on this issue would be that although ECT is not a primary treatment for delirium, it sometimes may be dramatically effective in cases in which, despite intense medical and neurological assessment and management, severe agitation, psychosis, or catatonic features persist.

Several cases have been reported of patients with multiple sclerosis receiving ECT for psychopathology (Rasmussen and Keegan 2007). Isolated case reports and small series also describe, with varying details on outcome, the safe use of ECT for psychopathology in patients with other diverse neurological conditions such as cerebral palsy (Rasmussen et al. 1993). Of course, these do not prove that ECT

has the same risk profile as for patients without these conditions. A prudent approach in such patients is to be alert for signs of neurological worsening and especially for excessive cognitive side effects.

Other Medical Disorders

The heart and brain bear most of the physiological effects of ECT. Fortunately, most of the other organ systems are not substantially affected, nor do their diseases generally cause much concern for greater risk of complications during ECT. Some additional considerations are discussed below.

Pulmonary Conditions

Large case series attest to the safe use of ECT in patients with asthma (Mueller et al. 2006) and chronic obstructive pulmonary disease (Schak et al. 2008). Patients who are using inhalers should do so in the morning shortly before treatment. Theophylline has been associated with a risk of prolonged seizures and status epilepticus in ECT (Abrams 2002, pp. 170–171), and discontinuation before ECT if medically safe has been recommended (American Psychiatric Association 2001), although Rasmussen and Zorumski (1993) described seven patients with therapeutic theophylline levels during ECT, none of whom developed status epilepticus. If discontinuing theophylline is medically contraindicated, then the lowest therapeutic blood level should be maintained, and caffeine augmentation should be avoided.

Two cases of successful and safe use of ECT after a pulmonary embolus have been reported (Suzuki et al. 2008). Attention should focus on continuation of therapeutic anticoagulation during ECT in such patients.

Pregnancy

The most common adverse events in pregnant women during ECT are aspiration and those related to premature labor, uterine contractions, and vaginal bleeding, although ECT can be delivered safely during pregnancy (Bozkurt et al. 2007; Kasar et al. 2007). Measures to prevent aspiration pneumonia include tracheal intubation and alkalinizing intragastric pH with a nonparticulate antacid. Pretreatment obstetrical assessment, preferably to include fetal ultrasound, can identify high-risk pregnancies. Noninvasive monitoring of fetal heart tones before and after the seizure can document that no fetal distress occurred. Finally, probably the most important aspect of safe ECT in pregnant women is ready availability of obstetrical intervention in case of untoward events (American Psychiatric Association 2001).

Diabetes Mellitus

Single ECT treatments cause a brief approximately 8%–10% rise in blood sugar immediately after treatment in both diabetic and nondiabetic patients (Rasmussen and Ryan 2005; Rasmussen et al. 2006b). However, very little change occurs in blood sugar control over a course of treatments (Netzel et al. 2002). Diabetic patients should have blood glucose levels monitored closely during the ECT course, including finger-stick checks before treatment. Typically, type 1 diabetic patients are administered half their morning insulin dose and are treated with ECT promptly. They are then fed breakfast and given the remaining half of their insulin dose. Alternatively, the whole dose can be withheld, ECT can be delivered promptly early in the morning, and then posttreatment breakfast and the insulin dose can be given.

Chronic Pain

Chronic pain syndromes are quite common in psychiatric patients. When the pain symptom is clearly secondary to a melancholic or psychotic depression, the ECT clinician can be optimistic about resolution of the pain symptoms along with other psychiatric symptoms. When a chronic pain patient seems to have developed secondary depression, results are more mixed with ECT (Rasmussen 2003; Rasmussen and Rummans 2002). Patients who are highly entrenched in a “pain lifestyle” are not likely to benefit from ECT. An intriguing finding is that phantom limb pain may abate with ECT even in the absence of apparent mood disturbance (Rasmussen and Rummans 2000).

Miscellaneous Considerations

Mild sodium abnormalities have not proven to be problematic for safe administration of ECT (Rasmussen et al. 2007b). Some anesthesiologists prefer to give an extra dose of steroid—so-called stress doses—prior to ECT in patients who are already taking such medication. However, in a large series (Rasmussen et al. 2008a), this was found to be unnecessary. Histamine-2 antagonists or antacids may decrease gastric acid secretion and the risk of aspiration pneumonitis in patients with gastroesophageal reflux disease, gastroparesis, or obesity (as well as pregnancy, as discussed earlier). Patients at severe risk for aspiration may require intubation. Urinary retention from antimuscarinic agents given during ECT is quite uncomfortable for patients and can predispose to urinary tract infections and even bladder rupture if not monitored. In those patients who do experience significant urinary retention after treatments, antimuscarinic agents can be avoided, recognizing that the vagal effect of the electrical stimulus is not blocked and prolonged asystole can occur. Patients with severe osteoporosis or recent fractures require careful titration of muscle relaxant dosing; the adequacy of paralysis

can be tested with a peripheral nerve stimulator. Extra care should be exercised when ventilating the patient with unstable cervical spine disease to avoid spinal cord injury. With the brief increase in intraocular pressure lasting a few minutes after the seizures (Good et al. 2004), glaucoma patients should receive their medications in the mornings before treatment, an exception being anticholinesterase drugs, which may prolong the action of succinylcholine.

Conclusion

ECT represents a remarkably safe and effective treatment option for depressed, manic, or psychotic patients with concomitant medical illnesses. With proper attention to pretreatment medical evaluation, rational use of cardio-protective medications during the treatments, and ongoing monitoring of medical status in between treatments, virtually all patients requiring ECT can be safely treated.

Palliative Care

William Breitbart, M.D.

Harvey Max Chochinov, M.D., Ph.D., F.R.C.P.C.

Yesne Alici, M.D.

ONE OF THE MOST CHALLENGING roles for the psychosomatic medicine psychiatrist is to help guide terminally ill patients physically, psychologically, and spiritually through the dying process. Patients with advanced cancer, AIDS, and other life-threatening medical illnesses are at increased risk for developing major psychiatric complications and have an enormous burden of both physical as well as psychological symptoms (Breitbart et al. 2004a). In fact, surveys suggest that psychological symptoms such as depression, anxiety, and hopelessness are as frequent, if not more so, than pain and other physical symptoms (Portenoy et al. 1994; Vogl et al. 1999). The psychiatrist, as a consultant to or member of a palliative care team, has a unique role and opportunity to offer competent and compassionate palliative care to those with life-threatening illness.

In 1999 the Academy of Psychosomatic Medicine published its position statement titled "Psychiatric Aspects of Excellent End-of-Life Care" (Shuster et al. 1999), which stressed the importance of psychiatric issues in palliative care and the need for competent psychiatric care to be an integral component of palliative care. Major textbooks provide comprehensive reviews of the interface of psychiatry and palliative medicine (Chochinov and Breitbart 2009; Lloyd-Williams 2008), and an international journal with that focus has been in existence since 2003 (Breitbart 2003).

The importance of the psychiatric, psychosocial, and spiritual aspects of palliative care has also been recognized in reports from the American Board of Internal Medicine (Subcommittee on Psychiatric Aspects of Life-Sustaining Technology 1996), the Institute of Medicine (Field and Cas-

sel 1997; Foley and Helband 2001), the National Comprehensive Cancer Network (Levy et al. 2009), the U.S. Health Resources and Services Administration (O'Neill et al. 2003), and the National Consensus Project for Quality Palliative Care (2009). Several major national and international palliative care organizations also exist, and more than 10 national and international palliative care scientific journals have been published (Stjernsward and Clark 2004).

This chapter guides the psychosomatic medicine practitioner through the most salient aspects of effective psychiatric care of patients with advanced, life-threatening medical illnesses. In this chapter, we review basic concepts and definitions of palliative care and the experience of dying in the United States; the role of the psychiatrist in palliative care, including assessment and management of common psychiatric disorders in the terminally ill, with special attention to suicide and desire for hastened death. We describe the psychotherapies developed for use in palliative care settings and then discuss spirituality, cultural sensitivity, communication, grief and bereavement, and psychiatric contributions to the control of common physical symptoms.

Related topics are discussed elsewhere in this book, including advance directives and end-of-life decisions (see Chapter 3, "Ethical Issues," and Chapter 4, "Psychological Responses to Illness"), physician-assisted suicide (see Chapter 9, "Suicidality"), terminal sedation (see Chapter 19, "Lung Disease"), dialysis discontinuation (see Chapter 21, "Renal Disease"), and pain management (see Chapter 36, "Pain").

Palliative Care

Historical Perspectives

The term *palliation* is derived from the Latin root word *palliare*, which means “to cloak” or “to conceal.” *Pallium* also refers to the cloth that covers or cloaks burial caskets. These root words suggest that the dying patient, although not amenable to cure, can be “cloaked” or “embraced” in the comforting arms of the caregiver. What cannot be cured can always be comforted. The terms *palliative care* and *palliative medicine* are often used interchangeably. Palliative medicine refers to the medical discipline of palliative care, an approach to improve the quality of life of patients and their families facing life-threatening illness. The nature and focus of palliative care have evolved over the past century, expanding beyond just comfort for the dying to include palliative care and symptom control that begins with the onset of a life-threatening illness and proceeds past death to include bereavement interventions for family and others (Sepulveda et al. 2002).

Modern palliative care is an outgrowth of the hospice movement that began in the 1840s with Calvaires in Lyon, France, and progressed through 1900 and the establishment of the St. Joseph’s Hospice in London, finally culminating with the progenitor of all modern hospices, St. Christopher’s Hospice, established in 1967 by Cicely Saunders. By 1975, a large number of independent hospices had been developed in the United Kingdom, Canada, and Australia. The first hospice in the United States was established in 1974 in Connecticut. Soon after, the U.S. government established limited Medicare coverage for hospice benefits. This period also saw the establishment of the first “palliative care” program at Royal Victoria Hospital in Montreal, founded by Balfour Mount and his colleagues. This period of evolution from the traditional stand-alone, home-based hospice also saw the development of hospital-based pain and palliative care consultation services such as the pain service established in 1978 by Kathleen Foley at the Memorial Sloan-Kettering Cancer Center. Modern palliative care thus evolved from the hospice movement into a mixture of academic and nonacademic clinical care delivery systems that had components of home care and hospital-based services (Berger et al. 2006; Stjernsward and Clark 2004).

Definition of Palliative Care

The Palliative Care Foundation (1981) defined *palliative care* as “active compassionate care of the terminally ill at a time that their disease is no longer responsive to traditional treatment aimed at cure or prolongation of life, and when the control of symptoms is paramount” (p. 10). According to this definition, palliative care applies primarily

at the end of life. In 1990, the World Health Organization defined *palliative care* as

the active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with anti-cancer treatment. (p. 2)

This definition was the first to suggest applicability even at stages of disease that precede the end of life (World Health Organization 1990).

In 1995, the Canadian Palliative Care Association published its definition of *palliative care*:

Palliative care, as a philosophy of care, is the combination of active and compassionate therapies, intended to comfort and support individuals and families who are living with a life-threatening illness. During periods of illness and bereavement, palliative care strives to meet physical, psychological, social and spiritual expectations and needs, while remaining sensitive to personal, cultural and religious values, beliefs and practices. Palliative care may be combined with therapies aimed at reducing or curing illness or it may be the total focus of care. (p. 3)

This definition was perhaps the first to suggest that palliative care is not only applicable at all stages of life-threatening disease (intensifying once cure is no longer possible) but also that psychological, social, spiritual, and cultural issues are elements of palliative care as important as the control of pain and other physical symptoms.

The World Health Organization definition of palliative care has been revised and expanded through the years (Sepulveda et al. 2002; World Health Organization 2002). The most recent and comprehensive definition of palliative care as outlined by the World Health Organization (2002, 2009) provides a framework for palliative care in all settings. According to this definition, palliative care

- ♦ provides relief from pain and other distressing symptoms.
- ♦ affirms life and regards dying as a normal process.
- ♦ intends neither to hasten nor to postpone death.
- ♦ integrates psychological and spiritual aspects of patients care.
- ♦ offers a support system to help patients live as actively as possible until death.
- ♦ offers a support system to help families cope during the patient’s illness and in their own bereavement.
- ♦ is interdisciplinary and uses a team approach including physicians, nurses, mental health professionals,

clergy, and volunteers to address the needs of patients and their families.

- will enhance quality of life and may also positively influence the course of illness.
- is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, and includes those investigations needed to better understand and manage distressing complications.

Palliative Care Programs/Models of Care Delivery

Palliative care is not restricted to those who are dying or those who are enrolled in hospice programs, but rather can be applied cost-effectively to the control of symptoms and provision of support to those living with chronic life-threatening illnesses (Taylor et al. 2007). Palliative care has been successfully instituted for patients with AIDS and cancer as national policy in countries that are neither wealthy nor industrialized (Bruera et al. 2000).

Fully developed, model palliative care programs ideally include all of the following components: 1) a home care program (e.g., hospice program); 2) a hospital-based palliative care consultation service; 3) a day care program or ambulatory care clinic; 4) a palliative care inpatient unit (or dedicated palliative care beds in hospital); 5) a bereavement program; 6) training and research programs; and 7) Internet-based services. An updated U.S. national expert consensus process produced the Clinical Practice Guidelines for Quality Palliative Care, which notes the need for adaptation to specific care settings and training for all providers (National Consensus Project for Quality Palliative Care 2009).

It is estimated that there are currently more than 4,500 hospices and over 1,000 hospital-based pain and palliative care services in the United States, serving around 1.4 million patients (National Hospice and Palliative Care Organization 2008). The subspecialty of Hospice and Palliative Medicine has recently achieved recognition within the American Board of Medical Subspecialties (ABMS) and the Accreditation Council for Graduate Medical Education (ACGME), with the American Board of Psychiatry and Neurology one of the co-sponsoring boards. There are a total of 48 accredited hospice and palliative medicine fellowship programs in the United States (American Academy of Hospice and Palliative Medicine Web site 2009).

Death in America

To understand and treat psychiatric issues in the dying patient today, one must have an appreciation of why, when, where, and how Americans now die.

Where and How Do Americans Die?

Population surveys continue to show that the majority of people would prefer to be cared for and die at home (Higginson and Sen-Gupta 2000; Stajduhar et al. 2008). Despite these findings, most Americans die in institutions, surrounded by medical caregivers.

The SUPPORT clinical trial (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) (SUPPORT Principal Investigators 1995) and other studies have suggested that a technological imperative characterizes Western medical practice, including care of the dying. SUPPORT found substantial shortcomings in the care of seriously ill hospitalized patients—including poor communication between physicians and dying patients and implementation of overly aggressive treatment, often against patients' wishes. The findings of this study emphasized the need for greater skills and education in end-of-life issues as well as increased communication with and support of dying patients. Perhaps the most perturbing conclusion from this study was that in general, Americans were dying not good deaths but bad deaths, characterized by needless suffering and disregard for patients' or families' wishes or values.

The concept of death trajectories (Figure 41-1) has been used to describe the unique as well as relatively predictable patterns of approaching death (Field and Cassel 1997). Some people die suddenly and unexpectedly, as shown in Figure 41-1A (e.g., cardiac arrest). Among those with forewarning of death, many have a steady and relatively predictable decline, as shown in Figure 41-1B (e.g., advanced cancer). There is a third pattern (Figure 41-1C) of long periods of chronic illness punctuated by crises, any of which may result in death (e.g., AIDS, congestive heart failure, or chronic obstructive pulmonary disease). Each type of death trajectory brings with it a unique set of problems and illustrates the challenges of determining prognoses for patients with life-threatening illnesses.

What Is a "Good" Death?

A meaningful dying process is one throughout which the patient is physically, psychologically, spiritually, and emotionally supported by his or her family, friends, and caregivers. Weisman (1972) described four criteria for what he called an "appropriate death": 1) internal conflicts, such as fears about loss of control, should be reduced as much as possible; 2) the individual's personal sense of identity should be sustained; 3) critical relationships should be enhanced or at least maintained, and conflicts should be resolved, if possible; and 4) the person should be encouraged to set and attempt to reach meaningful goals, even though limited, such as attending a graduation, a wedding, or the

FIGURE 41-1. Prototypical death trajectories.

(A) Sudden death from an unexpected cause. (B) Steady decline from a progressive disease with a “terminal” phase. (C) Advanced illness marked by slow decline with periodic crises and “sudden” death.

birth of a child, as a way to provide a sense of continuity into the future. The World Health Organization (2002, 2009) outlined guidelines characterizing a “good” death as one that is 1) free from avoidable distress and suffering for patient, family, and caregivers; 2) in general accord with the patient’s and family’s wishes; and 3) reasonably consistent with clinical, cultural, and ethical standards. These guidelines and the aforementioned considerations for achieving a good death can serve as general principles for the psychosomatic medicine psychiatrist in caring for the dying.

What Is the Role of the Psychiatrist?

The traditional role of the psychiatrist is broadened in several ways in the care of the dying patient. The psychiatrist’s primary role in the palliative care setting is the diagnosis and treatment of comorbid psychiatric disorders. Psychosomatic medicine psychiatrists can provide expert care and teaching about the management of depression, suicide, anxiety, delirium, fatigue, and pain in terminally ill patients (Breitbart and Holland 1993; Chochinov and Breit-

bart 2009). The role of the psychiatrist, in the care of the dying, extends beyond the management of psychiatric symptoms and syndromes into existential issues, family and caregiver support, bereavement, doctor–patient communication, and education and training. Psychiatrists can play an important role in the management of social, psychological, ethical, legal, and spiritual issues that complicate the care of dying patients. The psychiatrist can provide assistance in dealing with the existential crisis posed by a terminal diagnosis. Through discussions with the primary care physician, the patient and family may have begun to confront the reality that the disease is no longer curable or controllable. The psychiatrist can help the patient deal with the prognosis and explore treatment options, including palliative care.

The psychiatrist helps resolve conflicts among patient, family, and staff by opening lines of communication and helping families to deal with the strong emotions that surround the imminent death of a loved one. Conflicts with the physician and staff are common because the clinicians

are also stressed; resolution of these conflicts is a critical intervention for the patient's physical and psychological well-being.

Psychotherapeutic interventions for patients and families who are experiencing anticipatory grief are also important. During the bereavement period, the family may turn to the psychiatrist who participated in the patient's care and who shares memories of the patient for continuing support.

The psychiatrist also has an ethical role in encouraging discussion of end-of-life decisions regarding treatment, withholding resuscitation, and life support. The capacity of the patient to make rational judgments and the proxy's ability to make an appropriate decision for the patient may require psychiatric evaluation. The decision to withdraw life support is highly emotional and may require psychiatric consultation (Subcommittee on Psychiatric Aspects of Life-Sustaining Technology 1996). The psychiatrist's role can include teaching the medical staff about the psychological issues involved in care of dying patients, including how to deliver bad news and discuss do-not-resuscitate (DNR) orders and other treatment preferences ideally with the patient or with family when the patient is unable to make such decisions (Levin et al. 2008; Misbin et al. 1993; Weissman 2004).

Psychiatric Disorders in the Palliative Care Setting

Patients with advanced disease, such as advanced cancer, are particularly vulnerable to psychiatric disorders and complications (Breitbart et al. 1995, 2004a; Miovic and Block 2007). Unfortunately, medical specialists frequently fail to recognize emotional distress and common psychiatric disorders in terminally ill patients (Breitbart and Alici 2008; Miovic and Block 2007). In this section we review psychiatric disorders frequently encountered in palliative care settings including anxiety disorders, depression, and delirium. The incidence, assessment, and treatment of specific psychiatric disorders in advanced diseases are discussed in earlier chapters in this volume—for example, cancer (Chapter 23, "Oncology"), heart failure (Chapter 18, "Heart Disease"), chronic obstructive pulmonary disease (Chapter 19, "Lung Disease"), end-stage renal disease (Chapter 21, "Renal Disease"), and AIDS (Chapter 28, "HIV/AIDS").

Anxiety Disorders

The terminally ill patient presents with a complex mixture of physical and psychological symptoms in the context of a frightening reality, making the identification of anxious symptoms requiring treatment challenging (see also Chapter 11, "Anxiety Disorders"). Patients with anxiety complain

of tension or restlessness, or they exhibit jitteriness, autonomic hyperactivity, vigilance, insomnia, distractibility, shortness of breath, numbness, apprehension, worry, or rumination. Often the physical or somatic manifestations of anxiety overshadow the psychological or cognitive ones and are the symptoms that the patient most often presents (Holland 1989). The consultant must use these symptoms as a cue to inquire about the patient's psychological state, which is commonly one of fear, worry, or apprehension.

The assumption that a high level of anxiety is inevitably encountered during the terminal phase of illness is neither helpful nor accurate. In deciding whether to treat anxiety during the terminal phase of illness, the clinician should consider the patient's subjective level of distress as the primary impetus for the initiation of treatment. Other considerations include problematic patient behavior such as noncompliance due to anxiety, family and staff reactions to the patient's distress, and the balancing of the risks and benefits of treatment (Roth and Massie 2009).

Prevalence

Prevalence of anxiety disorders among terminally ill cancer and AIDS patients ranges from 15% to 28% (Kerrihard et al. 1999). Prevalence studies of anxiety, primarily in cancer populations, report a higher prevalence of mixed anxiety and depressive symptoms rather than anxiety alone (Roth and Massie 2009). Prevalence of anxiety increases with advancing disease and decline in the patient's physical status (Rabkin et al. 1997). Brandberg et al. (1995) reported that 28% of advanced melanoma patients were anxious compared with 15% of control subjects. In the Canadian National Palliative Care Survey, 24.4% of the patients receiving palliative care for cancer were found to have at least one DSM-IV (American Psychiatric Association 1994) anxiety or depressive disorder. The prevalence of anxiety disorders in that survey was 13.9%. Younger patients and those with a lower performance status, smaller social networks, and less participation in organized religious services were more likely to have a psychiatric disorder (Wilson et al. 2007a). It was also notable that palliative care patients with a DSM-IV anxiety and/or depressive disorder reported more severe distress from several physical symptoms, social concerns, and existential issues (Wilson et al. 2007a).

Assessment

As outlined in Table 41-1, anxiety can occur in terminally ill patients as an adjustment disorder, a disease- or treatment-related condition, or an exacerbation of a preexisting anxiety disorder (Kerrihard et al. 1999; Massie 1989). Adjustment disorder with anxiety is related to adjusting to the existential crisis and the uncertainty of the prognosis and the future (Holland 1989). When faced with terminal

TABLE 41-1. Anxiety in terminally ill patients

Types of anxiety	Causes
Adjustment disorder with anxiety	Awareness of terminal condition Fears and uncertainty about death Conflicts with family or staff Do-not-resuscitate order discussion
Disease- and treatment-related anxiety	Poor pain control Delirium (can be misdiagnosed as an anxiety disorder in medical settings) Related metabolic disturbances Hypoxia Hypoglycemia Electrolyte imbalance Sepsis Bleeding Pulmonary embolus
Substance-induced anxiety	Anxiety-producing drugs Corticosteroids Antipsychotics (akathisia) Antiemetics (akathisia) Methoclopramide Prochlorperazine, promethazine Bronchodilators Withdrawal Opioids Benzodiazepines Alcohol
Preexisting anxiety disorders	Exacerbation of symptoms related to fears and distressing medical symptoms
General anxiety disorder	
Panic	
Phobias	
Posttraumatic stress disorder	

illness, patients with preexisting anxiety disorders are at risk for reactivation of symptoms. Generalized anxiety disorder or panic disorder are apt to recur, especially in the presence of dyspnea or pain. Persons with phobias will have an especially difficult time if the disease or treatment confronts them with their fears (e.g., claustrophobia, fear of needles, fear of isolation). Posttraumatic stress disorder (PTSD) may be activated in dying patients as they relate their situation to some prior frightening experience, such as the Holocaust, a combat experience, or a cardiac arrest. Patients with PTSD may present with high levels of anxiety, insomnia, frequent panic attacks, comorbid depressive symptoms, and avoidance of medical settings that trigger traumatic memories (Miovic and Block 2007).

As noted in Table 41-1, symptoms of anxiety in the terminally ill patient may arise from a medical complication

of the illness or treatment (Breitbart et al. 1995; Roth and Massie 2009). Hypoxia, sepsis, poorly controlled pain, medication side effects such as akathisia, and withdrawal states often present as anxiety (Miovic and Block 2007). In the dying patient, anxiety can represent impending cardiac or respiratory arrest, pulmonary embolism, sepsis, electrolyte imbalance, or dehydration (Strain et al. 1981). Delirium can present with anxiety and restlessness in palliative care settings. Disturbance in level of consciousness, impaired concentration, cognitive impairment, altered perception, and fluctuation of symptoms are important diagnostic indicators of delirium as opposed to a diagnosis of anxiety disorder (Roth and Massie 2009). During the terminal phase of illness, when patients become less alert, there is a tendency to minimize the use of sedating medications. It is important to consider the need to slowly taper

benzodiazepines and opioids, which may have been sustained at high doses for extended relief of anxiety or pain, in order to prevent acute withdrawal states. Withdrawal states in terminally ill patients often manifest first as agitation or anxiety and become clinically evident days later than might be expected in younger, healthier patients due to impaired metabolism.

As disease progresses, patients' anxiety may include fears about the disease process, the clinical course, possible treatment outcomes, and death. In addition, anxiety may result from fear of increasing social stigma as the medical illness becomes more evident as well as from fear of the increasing financial consequences of treatment.

Despite the fact that anxiety in terminal illness commonly results from medical complications, it is important to consider psychological factors that may play a role, particularly in patients who are alert and not confused (Holland 1989; Roth and Massie 2009). Patients frequently fear the isolation and separation of death. Claustrophobic patients may fear the idea of being confined and buried in a coffin. These issues can be disconcerting to consultants, who may find themselves at a loss for words that are consoling to the patient.

Treatment

The most effective management of anxiety is multimodal and usually involves a combination of psychotherapy and pharmacological management. The treatment of anxiety in terminal illness has been extensively reviewed (Breitbart et al. 1995; Levin and Alici 2010; Roth and Massie 2009) and is similar in most respects to its treatment in the medically ill in general (see Chapter 11, "Anxiety Disorders," and Chapter 38, "Psychopharmacology"). In this subsection, we note selected aspects specific to the terminally ill.

Pharmacological treatment. For patients who feel persistently anxious, the first-line antianxiety drugs are the benzodiazepines. For patients with severely compromised hepatic function, the use of shorter-acting benzodiazepines such as lorazepam, oxazepam, or temazepam is preferred, since these drugs are metabolized by conjugation with glucuronic acid and have no active metabolites (Roth and Massie 2009). Dying patients can be administered diazepam rectally when no other route is available, with dosages equivalent to those used in oral regimens. Rectal diazepam (Twycross and Lack 1984) has been used widely in palliative care to control anxiety, restlessness, and agitation associated with the final days of life. Clonazepam is available in an orally disintegrating formulation for patients with swallowing difficulties. The American College of Clinical Care Medicine and the Society of Critical Care Medicine guidelines for the management of anxiety in crit-

ically ill adult patients recommend use of lorazepam for prolonged (i.e., more than 24 hours) treatment of anxiety in critically ill patients (Shapiro et al. 1995). See also "Alternative Routes of Administration" section in Chapter 38, "Psychopharmacology." These guidelines may prove useful in palliative care settings as well (Levin and Alici 2010). On the other hand, a Cochrane review of pharmacotherapy for anxiety in palliative care concluded that there was lack of high level evidence on the role of antianxiety medications in terminally ill patients (Jackson and Lipman 2004). The excessive use of benzodiazepines may result in mental status changes. In anxious patients with severely compromised pulmonary function, the use of benzodiazepines that suppress central respiratory mechanisms may be unsafe. Low doses of a neuroleptic or an antihistamine can be useful, but the anticholinergic effects of antihistamines make them problematic in the debilitated patient prone to develop delirium. Anxiety symptoms in patients with delirium are better treated with antipsychotics than with benzodiazepines (Breitbart et al. 1996); however, none of the antipsychotics have been systematically studied in the treatment of anxiety among patients receiving palliative care (Jackson and Lipman 2004; Levin and Alici 2010).

Sedating antidepressants such as trazodone or mirtazapine may help patients with persistent anxiety, insomnia, and anorexia. Selective serotonin reuptake inhibitors (SSRIs) are also effective in the management of anxiety disorders (Roth and Massie 2009). The utility of antidepressants and buspirone for anxiety disorders is often limited in the dying patient because they require weeks to achieve therapeutic effect.

Opioid drugs such as the narcotic analgesics are primarily indicated for the control of pain but are also effective in the relief of dyspnea and associated anxiety (Elia and Thomas 2008). Continuous intravenous infusions of morphine or other narcotic analgesics allow for careful titration and control of respiratory distress, anxiety, pain, and agitation (Portenoy et al. 1989). Occasionally one must maintain the patient in a state of unresponsiveness in order to maximize comfort. When respiratory distress is not a major problem, it is preferable to use the opioid drugs solely for analgesia and to add more specific anxiolytics to control concomitant anxiety.

Nonpharmacological treatment. Nonpharmacological interventions for anxiety and distress include supportive psychotherapy, behavioral interventions, and cognitive-behavioral therapy that are used alone or in combination (see discussion later in this chapter and in Chapter 11, "Anxiety Disorders," and Chapter 39, "Psychotherapy"). Brief supportive psychotherapy is often useful in dealing with both crises and existential issues confronted by the terminally ill

(Roth and Massie 2009). Supportive-expressive group therapy has been shown to reduce distress and subsyndromal symptoms of PTSD in women with advanced breast cancer (Classen et al. 2001). Inclusion of the family in psychotherapeutic interventions should be considered, particularly as the patient with advanced illness becomes increasingly debilitated and less able to interact.

Relaxation, guided imagery, and hypnosis may help reduce anxiety and thereby increase the patient's sense of control. Many patients with advanced illness are still appropriate candidates for the use of behavioral techniques despite physical debilitation. A feasibility study of a brief cognitive-behavioral intervention has been shown to reduce anxiety and depression symptoms in a small population of hospice patients (T. Anderson et al. 2008). However the utility of such interventions for a terminally ill patient is limited by the degree of mental clarity of the patient (Breitbart et al. 1995). In some cases, techniques can be modified so as to include even mildly cognitively impaired patients. This involves the therapist taking a more active role by orienting the patient, creating a safe and secure environment, and evoking a conditioned response to his or her voice or presence. A typical behavioral intervention for anxiety in a terminally ill patient would include a relaxation exercise combined with some distraction or imagery technique. The patient is first taught to relax using passive breathing accompanied by either passive or active muscle relaxation. When in a relaxed state, the patient is taught a pleasant, distracting imagery exercise. In a randomized study comparing a relaxation technique with alprazolam in the treatment of anxiety and distress in non-terminally ill cancer patients, both treatments were demonstrated to be quite effective for mild to moderate degrees of anxiety or distress. Alprazolam was more effective for greater levels of distress or anxiety and had more rapid onset of beneficial effect (Holland et al. 1987). Of course, relaxation techniques can be prescribed concurrently with anxiolytic medications in highly anxious terminal patients.

Depression

See also Chapter 8, "Depression," for additional information.

Epidemiology

Most studies on the prevalence of major depression in patients with advanced cancer in palliative care settings suggest that the prevalence of depression in patients with advanced disease ranges from 9% to 20% (Breitbart et al. 2000; Wilson et al. 2000, 2007a). The Canadian National Palliative Care Survey has shown a prevalence rate of 20.7% for any depressive disorder among patients ($n = 381$) receiving palliative care (Wilson et al. 2007a). Family history of

depression and history of previous depressive episodes further increase the patient's risk of developing a depressive episode (Miovic and Block 2007). Loss of meaning and low scores on measures of spiritual well-being have been associated with higher levels of depressive symptoms, suggesting that the relationship between existential distress and depression in terminal illness warrants further investigation (Nelson et al. 2002). Depression is associated with poor treatment compliance, reduced quality of life, poor survival, and desire for hastened death among terminally ill patients (Breitbart et al. 2000; Chochinov et al. 1995; Lloyd-Williams et al. 2009; Potash and Breitbart 2002; van der Lee et al. 2005). Many studies have also found a correlation between depression, pain, and functional status (Breitbart 1989b; Potash and Breitbart 2002; Wilson et al. 2007a). Younger age and poor social support have also been identified as risk factors for depression in the terminally ill (Potash and Breitbart 2002). Corticosteroids (Stiefel et al. 1989), chemotherapeutic agents (e.g., vincristine, vinblastine, asparaginase, intrathecal methotrexate, interferon, interleukin) (Adams et al. 1984; Denicoff et al. 1987; Holland et al. 1974; Young 1982), amphotericin (Weddington 1982), whole brain radiation (DeAngelis et al. 1989), central nervous system (CNS) metabolic-endocrine complications (Breitbart 1989a), and paraneoplastic syndromes (Patchell and Posner 1989; Posner 1988) can all cause depressive symptoms (Potash and Breitbart 2002). The phenomenological similarities between depression and "sickness behavior syndrome" have led researchers to consider the role of proinflammatory cytokines in the development of depressive syndromes among patients with advanced disease (Jacobson et al. 2008).

Assessment

Depressed mood and sadness can be appropriate responses as the terminally ill patient faces death. These emotions can be manifestations of anticipatory grief over the impending loss of one's life, health, loved ones, and autonomy (Block 2000). Despite this, major depression is common in the palliative care setting, where it has been underdiagnosed and undertreated. Minimization of depressive symptoms as "normal reactions" by clinicians and the difficulties of accurately diagnosing depression in the terminally ill both contribute to the underdiagnosis of depression, and undertreatment is due in part to the concern that severely medically ill patients will not be able to tolerate the side effects of antidepressants (Block 2000). However, recent evidence from the increasing prevalence of antidepressant utilization among cancer patients suggests that clinicians have become more vigilant in recognition and treatment of depression in the medically ill (Wilson et al. 2009). Strategies for accurately diagnosing depression in seriously medically

ill patients are reviewed in Chapter 8, "Depression." A detailed description of their application in palliative care settings can be found in Wilson et al. 2009.

The diagnosis of a major depressive syndrome in a terminally ill patient, as in medically ill patients in general, often relies more on the psychological or cognitive symptoms of major depression than the neurovegetative symptoms. The strategy of relying on the psychological symptoms of depression for diagnostic specificity is itself not without problems. How is the clinician to interpret feelings of hopelessness in the dying patient when there is no hope for cure or recovery? Feelings of hopelessness, worthlessness, or suicidal ideation must be explored in detail. Although many dying patients lose hope for a cure, they are able to maintain hope for better symptom control. For many patients hope is contingent on the ability to find continued meaning in their day-to-day existence. Hopelessness that is pervasive and accompanied by a sense of despair or despondency is more likely to represent a symptom of a depressive disorder. Such patients often state that they feel they are burdening their families unfairly, causing them great pain and inconvenience. Those beliefs are less likely to represent a symptom of depression than if the patient feels that his or her life has never had any worth or that the illness is punishment for evil things he or she has done. Even mild and passive forms of suicidal ideation are very often indicative of significant degrees of depression in terminally ill patients (Breitbart 1987, 1990).

Several screening instruments have been studied for detection of depression in palliative care settings, a detailed description of these instruments can be found elsewhere (Wilson et al. 2009). Chochinov et al. (1997) studied brief screening instruments to measure depression in the terminally ill, including a single-item interview assessing depressed mood ("Have you been depressed most of the time for the past 2 weeks?"), a two-item interview assessing depressed mood and loss of interest in activities, a visual analogue scale for depressed mood, and the Beck Depression Inventory. Semistructured diagnostic interviews served as the standard against which the screening performance of the four brief screening methods was assessed. Most noteworthy, the single-item question correctly identified the diagnosis of every patient, substantially outperforming the questionnaire and visual analogue measures. The single-item depression question has been incorporated into routine clinical assessments in a variety of clinical settings to identify depression among medically ill patients (Wilson et al. 2009).

Treatment

Treatment of depression in the medically ill is reviewed in detail in Chapter 8, "Depression," Chapter 38, "Psycho-

pharmacology," and Chapter 39 "Psychotherapy," and in this discussion we note specific aspects relevant to palliative care. A combination of pharmacotherapy, supportive psychotherapy, cognitive-behavioral therapy, and psychoeducation is the mainstay of treatment for depression in palliative care settings (Miovic and Block 2007; Wilson et al. 2000). It is important to treat the distressing physical symptoms (such as pain, dyspnea, nausea) concurrently while managing depression in patients with advanced disease (Potash and Breitbart 2002).

Pharmacological treatment. Antidepressant medications are the mainstay of pharmacological management for gravely ill patients meeting diagnostic criteria for major depression (Block 2000; Wilson et al. 2000) and have established efficacy (Wilson et al. 2000, 2009). Factors such as prognosis and the time frame for treatment may play an important role in determining the type of pharmacotherapy for depression in the terminally ill. A depressed patient with several months of life expectancy can afford to wait the 2–4 weeks it may take to respond to a standard antidepressant. For the terminally ill, antidepressants are usually initiated at approximately half the usual starting dose because of patients' sensitivity to adverse effects. A Cochrane review supported the use of antidepressants in this patient population but emphasized the methodological weaknesses in reviewed studies (Gill and Hatcher 2000). The depressed dying patient with less than 3 weeks to live may do best with a rapid-acting psychostimulant (Block 2000; Homsy et al. 2001; Tremblay and Breitbart 2001). Patients who are within hours to days of death and in distress are likely to benefit most from the use of sedatives or narcotic analgesic infusions.

Psychostimulants are particularly helpful in the treatment of depression in the terminally ill because they have a rapid onset of action and energizing effects and typically do not cause anorexia, weight loss, or insomnia at therapeutic doses (Candy et al. 2008; Pessin et al. 2008; Potash and Breitbart 2002). In fact, at low doses, stimulants may actually increase appetite (see also Chapter 8, "Depression," and Chapter 38, "Psychopharmacology"). Abuse is almost always an irrelevant concern in the terminally ill, and stimulants should not be withheld on the basis of a patient's previous history of substance abuse. Occasionally, treatment with an SSRI and a psychostimulant may be initiated concurrently so that depressed patients may receive the immediate benefits of the psychostimulant drug while waiting the necessary weeks for the SSRI to work. At that point the psychostimulant may be withdrawn. Methylphenidate and dextroamphetamine are usually initiated at low doses (2.5–5.0 mg in the morning and at noon). The benefits can be assessed during the first 1–2 days of treatment and the dose

gradually titrated (usually to no greater than 30 mg/day total). An additional benefit of stimulants is that they have been shown to reduce sedation secondary to opioid analgesics and provide adjuvant analgesic effects (Bruera et al. 1987). A recent review of 19 controlled trials of methylphenidate in medically ill older adults and patients in palliative care has concluded that the use of low-dose methylphenidate is appropriate in the treatment of depression, fatigue, or apathy in this patient population with monitoring for response and adverse effects (Hardy 2009).

Nonpharmacological treatment. Depression in cancer patients with advanced disease is optimally managed with a combination of supportive psychotherapy, cognitive-behavioral techniques, psychoeducation, and antidepressant medications as discussed above (Miovic and Block 2007; Wilson et al. 2000). Psychotherapeutic interventions, in the form of either individual or group counseling, have been shown to effectively reduce psychological distress and depressive symptoms in advanced-stage cancer patients (Savard et al. 2006; Spiegel and Bloom 1983; Spiegel et al. 1981; Wilson et al. 2009). Cognitive-behavioral interventions such as relaxation and distraction with pleasant imagery also have been shown to decrease depressive symptoms in patients with mild to moderate levels of depression (Holland et al. 1987).

Supportive psychotherapy for the dying patient consists of active listening with supportive verbal interventions and the occasional interpretation (Peck et al. 1983). Despite the seriousness of the patient's plight, it is not necessary for the psychiatrist or psychologist to appear overly solemn or emotionally restrained. Often the psychotherapist is the only person among all of the patient's caregivers who is comfortable enough to converse lightheartedly and to allow the patient to talk about his or her life and experiences rather than focus solely on impending death. The dying patient who wishes to talk or ask questions about death should be encouraged to do so freely, with the therapist maintaining an interested, interactive stance.

Psychotherapies other than supportive psychotherapy have been described as potentially useful in the treatment of depressive symptoms and distress in palliative care patients. Chochinov and Breitbart (2009) extensively reviewed interpersonal, existential, life narrative, and group psychotherapies in palliative care. Several novel psychotherapies have been developed and are being tested in the treatment of depression, hopelessness, loss of meaning, and demoralization; these new modalities include meaning-centered psychotherapy (Breitbart 2002) and dignity-conserving care (Chochinov 2002), both of which are described later in this chapter.

Suicide and Desire for Hastened Death

Suicide, suicidal ideation, and desire for hastened death are all important and serious consequences of unrecognized and inadequately treated clinical depression (see also Chapter 9, "Suicidality"). Although clinical depression has been demonstrated to be a critically important factor in desire for hastened death (through suicide or other means), understanding more fully why some patients with a terminal illness wish or seek to hasten their death remains an important element in the practice of palliative care. Despite the continued legal prohibitions against assisted suicide in most of the United States, a substantial number of patients think about and discuss those alternatives with their physicians, family, and friends (Olden et al. 2009; Rosenfeld 2000).

Suicide

Factors associated with increased risk of suicide in patients with serious medical illnesses are reviewed in Chapter 9, "Suicidality," and elsewhere (Breitbart 1987; Olden et al. 2009).

Cancer patients commit suicide most frequently in the advanced stages of disease. With advancing disease the incidence of significant pain increases, and uncontrolled pain is a dramatically important risk factor for suicide.

Hopelessness is a key variable linking depression and suicide in the terminally ill. Chochinov et al. (1998) demonstrated that hopelessness was correlated more highly with suicidal ideation in terminally ill cancer patients than was level of depression. In Scandinavia, the highest incidence of suicide was found in cancer patients who were offered no further treatment and no further contact with the health care system (Bolund 1985; Louhivuori and Hakama 1979). Being left to face illness alone creates a sense of isolation and abandonment that is critical to the development of hopelessness.

The prevalence of delirium reaches as high as 85% during the terminal stages of illness (Massie et al. 1983). Although early work suggested that delirium was a protective factor in regard to suicide among cancer patients (Farberow et al. 1963), clinical experience has found confusional states to be a major contributing factor in impulsive suicide attempts, especially in the hospital setting (see Chapter 9, "Suicidality"). Delirium or any cognitive impairment often impairs one's ability to reason and increases risk of impulsive behavior (Olden et al. 2009). Pessin et al. (2003) reported that advanced AIDS patients with cognitive impairment were more likely to express a desire for hastened death than patients without cognitive impairment.

Loss of control and a sense of helplessness in the face of terminal illness are important factors in suicide vulnerability. *Control* refers to the helplessness induced by symptoms, deficits due to the illness or its treatments, and the excessive need on the part of some patients to be in control of all aspects of living or dying. Farberow et al. (1971) noted that patients who were accepting and adaptable were much less likely to commit suicide than those who exhibited a need to be in control of even the most minute details of their care. However, it is not uncommon for terminal illness to induce a great sense of helplessness even in those who are not typically controlling individuals, for example through loss of mobility, paraplegia, loss of bowel and bladder function, amputation, aphonia, sensory loss, and inability to eat or swallow. Most distressing to patients is the sense that they are losing control of their minds, especially when they are confused or sedated by medications. The risk of suicide is increased with such impairments, especially when accompanied by psychological distress and disturbed interpersonal relationships (Farberow et al. 1971).

Fatigue in the form of emotional, spiritual, financial, familial, communal, and other resource exhaustion increases risk of suicide in patients with terminal illness (Breitbart 1987). Increased survival in cancer, AIDS, chronic obstructive pulmonary disease, congestive heart failure, and other diseases is accompanied by increased numbers of hospitalizations, complications, and expenses. Symptom control thus becomes a prolonged process with frequent advances and setbacks. The dying process also can become extremely long and arduous for all concerned. It is not uncommon for both family members and health care providers to withdraw prematurely from the patient under these circumstances. A suicidal patient can thus feel even more isolated and abandoned. The presence of a strong support system for the patient that may act as an external control of suicidal behavior reduces risk of suicide significantly.

Suicidal Ideation

It is widely held that most terminally ill patients experience occasional thoughts of suicide as a means of escaping the threat of being overwhelmed by their illness ("If it gets too bad, I always have a way out") and will reveal this to a sensitive interviewer. However, some studies suggest that suicidal ideation is relatively infrequent and is limited to those who are significantly depressed (Achte and Vanhokouen 1971; Brown et al. 1986; Silberfarb et al. 1980). Among a cohort of cancer patients with pain, suicidal ideation was found in just 17% (Breitbart 1987). The actual prevalence of suicidal ideation may be higher, because patients may be less likely to disclose these thoughts to a research interviewer than in a well-established doctor-patient relationship.

Assessment and Management of the Suicidal Terminally Ill Patient

Assessment and management of suicidal ideation in the medically ill are discussed in Chapter 9, "Suicidality." Some physicians, nurses, and other caregivers fail to intervene for suicidal ideation in the terminally ill, either because they think it is rational ("I would feel that way too") or because they think that intervention is futile ("He's going to die anyway"). This is a serious error for several reasons. Suicide can be very traumatic to family and health caregivers, even in the terminally ill. Patients often reconsider and reject the idea of suicide after they have an opportunity to express underlying issues to an attentive physician, particularly fears of loss of control over aspects of their death. Suicidal ideation is often driven by unbearable symptoms that may not have been recognized and should become the focus of palliative care.

Psychiatric hospitalization can sometimes be helpful but is usually not desirable in the terminally ill patient. Thus, the medical hospital or home is the setting in which management most often takes place. Although it is appropriate to intervene when medical or psychiatric factors are clearly the driving force in a cancer patient's suicide, there are circumstances when usurping control from the patient and family with overly aggressive intervention may be contraindicated. This is most evident in those with advanced illness for whom comfort and symptom control are the primary concerns.

Ultimately, palliative care clinicians are not able to prevent all suicides in terminally ill patients for whom they provide care. Intervention should emphasize an aggressive attempt to prevent suicide that is driven by the desperation of physical and psychological symptoms, such as uncontrolled pain and unrecognized or untreated delirium or depression. Prolonged suffering caused by poorly controlled symptoms can lead to such desperation, and it is the appropriate role of the palliative care team to provide effective management of physical and psychological symptoms as an alternative to desire for death, suicide, or request for assisted suicide by patients. (Requests for assisted suicide are covered in Chapter 9, "Suicidality.")

Desire for Hastened Death

Desire for hastened death may be thought of as a unifying construct underlying requests for assisted suicide or euthanasia, as well as suicidal thoughts in general. Several studies have demonstrated that depression plays a significant role in the terminally ill patient's desire for hastened death (Olden et al. 2009; Rodin et al. 2007, 2009). Chochinov et al. (1995) found that 45% of terminally ill patients in a palliative care facility acknowledged at least a fleeting desire to

die, but these episodes were mostly brief and did not reflect a sustained or committed desire to die. However, 9% reported an unequivocal desire for death to come soon and indicated that they held this desire consistently over time. Among this group, 59% received a diagnosis of depression, compared with a prevalence of 8% in patients who did not endorse a genuine, consistent desire for death. Patients with depression were approximately six to seven times more likely to have a desire for hastened death than patients without depression. Patients with a desire for death were also found to have significantly more pain and less social support than those patients without a desire for death.

Breitbart et al. (2000) studied the relationships among depression, hopelessness, and desire for death in terminally ill cancer patients. Seventeen percent of the patients were classified as having a high desire for death (Rosenfeld et al. 1999, 2000), and 16% met criteria for a current major depressive episode. Of the patients who met criteria for major depressive episode, 47% were classified as having a high desire for hastened death; only 12% of those without a desire for death met criteria for depression. Thus, patients with major depression were four times more likely to have a high desire for hastened death. In addition, Breitbart et al. (2000) found that both depression and hopelessness, characterized as a pessimistic cognitive style rather than an assessment of one's poor prognosis, appear to be synergistic determinants of desire for hastened death. No significant association with the presence or the intensity of pain was found. Conversely, Mystakidou et al. (2005) have found that the severity of pain and the interference with daily activities due to pain significantly predicted desire for hastened death.

Researchers have also explored the desire for hastened death among patients with a better prognosis to determine whether similar contributing factors played a role (Rodin et al. 2007; Rosenfeld et al. 2006). In a sample of metastatic cancer patients with an expected prognosis of 6 months or longer, 5% of patients had a high desire for hastened death, a relatively lower rate compared to the 17% rate among patients with less than 1 month of survival expectancy. The desire for hastened death significantly correlated with high levels of depression and hopelessness in all of the individuals in that sample (Rodin et al. 2007).

Desire for hastened death also appears to be a function of psychological distress and social factors such as social support, spiritual well-being, quality of life, and perception of oneself as a burden to others (Chochinov et al. 2005a; Hudson et al. 2006; Olden et al. 2009). Among dying patients, the "will to live," as measured with a visual analogue scale, was found to fluctuate rapidly over time and correlated with anxiety, depression, and shortness of breath as death approached (Chochinov et al. 1999).

In a Canadian study of terminally ill cancer patients, detailed interviews of the patients with desire for hastened death revealed the following seven themes underlying their wishes for death including the futility of existence due to functional limitations and the imminence of death, physical and emotional suffering, sense of being a burden to others, readiness for death, the wish for a compassionate death that minimized suffering, preserving their autonomy of choice in the timing of death, and the influence of witnessing the death of others (Wilson et al. 2007b).

Interventions for Despair at the End of Life

The response of a clinician to despair at the end of life as manifest by a patient's expression of desire for death or request for assisted suicide has important and obvious implications for all aspects of care and affects patients, family, and staff (Breitbart et al. 2004a). These issues must be addressed both rapidly and thoughtfully, offering the patient a nonjudgmental willingness to discuss the factors contributing to the kind of suffering and despondency that leads to such a desire for death. Such despair has been variably described as "spiritual" suffering, "demoralization," loss of "dignity," and "loss of meaning" (Breitbart 2002; Cherny 2004; Chochinov et al. 2002b, 2005a; Greenstein and Breitbart 2000; Kissane et al. 2001; Rousseau 2000).

Although most palliative care clinicians believe that aggressive management of physical and psychological distress (such as depression) will prevent desire for hastened death or requests for assisted suicide, few studies have been conducted to validate this (Olden et al. 2009). A recent study demonstrated that desire for hastened death can often be ameliorated through treatment of depression with antidepressants (Breitbart et al. 2010a). If the treatment of depression reduces the wish for hastened death, it may also result in increased desire for life-sustaining medical therapies (Ganzini et al. 1994). When it is practical to do so, in severely depressed patients—particularly those who are hopeless—decisions about withdrawal of treatment should be discouraged until after treatment of their depression.

Several psychosocial interventions—some using cognitive techniques to restructure beliefs underlying hopelessness or demoralization, and others focusing on enhancing patients' sense of meaning and dignity—have been proposed and studied in terminally ill patients with a desire for hastened death (Breitbart et al. 2010b; Chochinov 2002; Chochinov et al. 2005b; Griffith et al. 2005). Specific therapeutic approaches for despair at the end of life are described in detail in the section on "Psychotherapy Interventions in Palliative Care" later in the chapter.

Delirium

Delirium is discussed in detail in Chapter 5, "Delirium"; in this discussion we focus on aspects most relevant to palliative care. In the palliative care literature, delirium occurring in the last days of life is often referred to as "terminal delirium," "terminal restlessness," or "terminal agitation." Despite being the most common neuropsychiatric complication of advanced illness, delirium is often underdiagnosed and untreated in palliative care settings. Delirium is a harbinger of impending death among terminally ill patients, and also a significant source of distress for patients, families, and staff. Delirium can interfere dramatically with the recognition and control of other physical and psychological symptoms such as pain in later stages of illness. Palliative care clinicians should thus be familiar with the assessment and management of delirium, as well as the controversies regarding the goals of management in the terminally ill (Breitbart and Alici 2008; Breitbart et al. 2002a; Coyle et al. 1994).

Prevalence

Delirium is the most common and serious neuropsychiatric complication in patients with advanced illnesses such as cancer and AIDS, particularly in the last weeks of life, with prevalence rates ranging from 25% to 85% (Breitbart 2001; Breitbart et al. 1996; Bruera et al. 1992; Fainsinger et al. 1991; Levine et al. 1978; Massie et al. 1983; Murray 1987). Pereira et al. (1997) found the prevalence of cognitive impairment in cancer inpatients to be 44%, and just prior to death, the prevalence rose to 62%. Lawlor et al. (2000a) reported that whereas 42% of advanced cancer patients had delirium upon admission to their palliative care unit, terminal delirium occurred in 88% of patients before their deaths.

The Experience of Delirium for Patients, Families, and Staff

Delirium causes significant distress in patients, families, and staff (Breitbart et al. 2002a; Buss et al. 2007; Morita et al. 2004). In a study of terminally ill cancer patients, Breitbart et al. (2002a) found that 54% of patients recalled their delirium experience after recovery from delirium. Factors predicting delirium recall included the degree of short-term memory impairment, delirium severity, and the presence of perceptual disturbances (the more severe, the less likely recall). Patients, spouses or other caregivers, and nurses each rated distress related to the episode of delirium. The most significant factor predicting distress for patients was the presence of delusions. Patients with hypoactive delirium were just as distressed as patients with hyperactive delirium. Spouse distress was predicted by the patients' Karnofsky Performance Status (the lower the Karnofsky score, the

worse the spouse distress), and nurse distress was predicted by delirium severity and perceptual disturbances.

Assessment and Reversibility of Delirium in the Terminally Ill

Delirium, in contrast with dementia, is classically conceptualized as a reversible process. Reversibility of delirium is often possible even in the patient with advanced illness, but it may not be reversible in the last 24–48 hours of life, with the outcome probably attributable to irreversible processes such as multiple organ failure occurring in the final hours of life.

Instruments available for diagnosing and monitoring severity of delirium are described in Chapter 5, "Delirium." Of those, the Memorial Delirium Assessment Scale (MDAS) and the Confusion Assessment Method have been validated in palliative care settings (Breitbart et al. 1997; Lawlor et al. 2000b; Ryan et al. 2009). The MDAS, validated in hospitalized patients with advanced cancer and AIDS, is a 10-item tool useful both for diagnostic screening and for assessing delirium severity among patients with advanced disease (Breitbart et al. 1997). Lawlor et al. (2000b) found that a cut-off score of 7 out of 30 yielded the highest sensitivity (98%) and specificity (76%) for a delirium diagnosis in advanced cancer patients in a palliative care unit. The Confusion Assessment Method (CAM), validated in palliative care settings with a sensitivity of 88% and a specificity of 100% when administered by well-trained clinicians, is a nine-item delirium diagnostic scale based on the DSM-III-R (American Psychiatric Association 1987) criteria for delirium (Inouye et al. 1990; Ryan et al. 2009).

The standard approach to managing delirium outlined in Chapter 5, "Delirium," remains relevant in the terminally ill, including a search for underlying causes, correction of those factors, and management of the symptoms of delirium (Breitbart 2001; Breitbart and Alici 2008; Breitbart et al. 2000). The ideal and often achievable outcome is a patient who is awake, alert, calm, cognitively intact, not psychotic, and communicating coherently with family and staff. In the terminally ill patient who develops delirium in the last days of life (terminal delirium), the management differs, presenting a number of dilemmas, and the desired clinical outcome may be significantly altered by the dying process.

Delirium can have multiple potential etiologies (Table 41-2). In patients with advanced cancer, for instance, delirium can be due to the direct effects of cancer on the CNS, indirect CNS effects of the disease or treatments (e.g., medications, electrolyte imbalance, failure of a vital organ, infection, vascular complications), and/or preexisting CNS disease (e.g., dementia) (Bruera et al. 1992; Lawlor et al. 2000a). Given the large numbers of drugs terminally ill pa-

suit of an etiology for delirium may be limited by either practical constraints such as the setting (home, hospice) or the focus on patient comfort, so that unpleasant or painful diagnostics may be avoided. Most often, however, the etiology of terminal delirium is multifactorial or may not be determined. Bruera et al. (1992) reported that an etiology is discovered in less than 50% of terminally ill patients with delirium. When a distinct cause is found for delirium in the terminally ill, it may be irreversible or difficult to treat. Studies in patients with earlier stages of advanced cancer have demonstrated the potential utility of a thorough diagnostic assessment (Bruera et al. 1992; Coyle et al. 1994). When such diagnostic information is available, specific therapy may be able to reverse delirium. A prospective study of delirium in patients on a palliative care unit found that 68% of delirious cancer patients could be improved, despite a 30-day mortality of 31% (Lawlor et al. 2000a). The etiology of delirium was multifactorial in the great majority of cases in that study. Although delirium occurred in 88% of dying patients in the last week of life, delirium was reversible in approximately 50% of episodes. Causes of delirium that were most associated with reversibility included dehydration and psychoactive or opioid medications. Hypoxic and metabolic encephalopathies were less likely to be reversible in terminal delirium (Lawlor et al. 2000a). Another study found a cause in 43% of the patients evaluated, and of these, one-third of the episodes of cognitive failure improved (Bruera et al. 1992). Leonard et al. (2008) have reported a delirium reversibility rate of 27% among patients in a palliative care unit. A study of patients with advanced cancer admitted to hospice found an overall delirium reversibility rate of 20% with a 30-day mortality rate of 83%. Reversibility of delirium was highly dependent on the etiology. Delirium due to hypercalcemia or medications was likely to be reversible, whereas delirium due to infections, hepatic failure, hypoxia, disseminated intravascular coagulation, or dehydration was likely to be irreversible (Morita et al. 2001).

Even in terminal delirium, a diagnostic workup should include basic assessment of potentially reversible causes of delirium while minimizing any investigation that would be burdensome for the patient. A full physical examination should be conducted to assess for evidence of sepsis, fecal impaction, dehydration, or major organ failure. Medications that could contribute to delirium should be reviewed. Oximetry can rule out hypoxia; one set of blood draws can screen for metabolic disturbances (e.g., hypercalcemia) and hematological abnormalities (e.g., anemia, leukocytosis). Imaging studies of the brain and assessment of the cerebrospinal fluid may be appropriate in some instances if they have the potential to identify lesions amenable to palliative treatment (e.g., radiosensitive CNS metastases).

tients require and the fragile state of their physiological functioning, even routinely ordered hypnotic agents may be enough to tip patients over into delirium. Narcotic analgesics, especially meperidine, are common causes of confusional states, particularly in the elderly and terminally ill.

In confronting delirium in the terminally ill or dying patient, a differential diagnosis should always be formulated as to the likely etiology. However, there is an ongoing debate as to the appropriate extent of diagnostic evaluation that should be pursued in a dying patient with a terminal delirium (Breitbart 2001). Most palliative care clinicians would undertake diagnostic studies only when a clinically suspected etiology can be identified easily, with minimal use of invasive procedures, and treated effectively with simple interventions that carry minimal burden or risk of causing further distress. Diagnostic workup in pur-

Interventions

Pharmacological

Pharmacotherapy of delirium is reviewed in detail in Chapter 5, "Delirium." A detailed review of the use of antipsychotic medications in the treatment of delirium is available elsewhere (Boettger and Breitbart 2005). While no medications have been approved by the U.S. Food and Drug Administration (FDA) for treatment of delirium, treatment with antipsychotics or sedatives is often required to control the symptoms of delirium in palliative care settings. Low doses of neuroleptic medication are usually sufficient in treating delirium in the terminally ill, but high doses have sometimes been required (Breitbart and Alici 2008). Haloperidol remains the drug of first choice and may be given orally or parenterally (Breitbart and Alici 2008; Breitbart et al. 1996). Delivery of haloperidol by the subcutaneous route is utilized by many palliative care practitioners (Bruera et al. 1992; Twycross and Lack 1983).

Many palliative care clinicians use low dose atypical antipsychotics in the management of delirium in terminally ill patients (Boettger and Breitbart 2005; Breitbart 2001; Breitbart and Alici 2008; Breitbart et al. 2002b). A Cochrane review comparing the efficacy and the adverse effects of haloperidol and atypical antipsychotics concluded that haloperidol, risperidone, and olanzapine were all effective in managing delirium, and that extrapyramidal adverse effects did not differ significantly between atypical antipsychotics and haloperidol (Lonergan et al. 2007).

Psychostimulants have been suggested in the treatment of hypoactive subtype of delirium, alone or in combination of antipsychotics (Keen and Brown 2004; Lawlor et al. 2000c). A prospective study (n=14) of methylphenidate use in advanced cancer patients with hypoactive delirium have shown improvement in cognitive functioning and psychomotor activities (Gagnon et al. 2005).

Although neuroleptic drugs are generally very beneficial in reducing agitation, anxiety, and confusion in delirium, this is not always possible in terminal delirium. A significant group (at least 10%–20%) of terminally ill patients experience delirium that can only be controlled by sedation to the point of a significantly decreased level of consciousness (Fainsinger et al. 2000; Lo and Rubenfeld 2005; Rietjens et al. 2008). The goal of treatment in those cases is quiet sedation only. Midazolam, given by subcutaneous or intravenous infusion in doses ranging from 30 to 100 mg per 24 hours, can be used to control agitated terminal delirium (Bottomley and Hanks 1990; de Sousa and Jepson 1988). Propofol, a short-acting anesthetic agent, is also used for this purpose, given in, for example, an intravenous loading dose of 20 mg followed by a continuous infusion with initial doses of 10–70 mg/hour titrated up to as high

as 400 mg/hour in severely agitated patients (Mercadante et al. 1995; Moyle 1995). Propofol's level of sedation may be more easily controlled, with more rapid recovery upon decreasing the rate of infusion than with midazolam (Mercadante et al. 1995).

Nonpharmacological

In addition to seeking out and potentially correcting underlying causes for delirium, environmental and supportive interventions are important, as described in Chapter 5, "Delirium." In fact, in the dying patient, these may be the only steps taken. The presence of family, frequent reorientation, correction of hearing and visual impairment, reversal of dehydration, and a quiet well-lit room with familiar objects all are helpful in reducing the severity and impact of delirium in seriously ill patients. However, these interventions are less applicable in the last days of life, and there is little likelihood that they would prevent terminal delirium.

Controversies in the Management of Terminal Delirium

Several aspects of the use of neuroleptics and other pharmacological agents in the management of delirium in the dying patient remain controversial in some circles. Some view delirium as a natural part of the dying process that should not be altered and argue that pharmacological interventions are inappropriate in the dying patient. In particular, some who care for the dying view hallucinations and delusions in which dead relatives communicate with dying patients or welcome them to heaven as important elements in the transition from life to death. There are some patients who experience hallucinations during delirium that are pleasant and even comforting, and many clinicians question the appropriateness of intervening pharmacologically in such instances.

Another concern often raised is that these patients are so close to death that aggressive treatment is unnecessary. Parenteral neuroleptics or sedatives may be mistakenly avoided because of exaggerated fears that they might hasten death through hypotension or respiratory depression. There is the possibility that sedation may worsen confusion in delirium. Many clinicians are unnecessarily pessimistic about the possible results of neuroleptic treatment for delirium. They argue that since the underlying pathophysiological process (such as hepatic or renal failure) often continues unabated, no improvement can be expected in the patient's mental status.

Clinical experience in managing delirium in dying patients suggests that the use of neuroleptics in the management of agitation, paranoia, hallucinations, and altered sensorium is safe, effective, and often quite appropriate

(Breitbart 2001; Breitbart and Alici 2008). Management of delirium on a case-by-case basis seems wisest. The agitated, delirious dying patient should usually receive a trial of neuroleptics to help restore calm. A “wait and see” approach prior to using neuroleptics may be appropriate with some patients who have a lethargic, somnolent presentation of delirium or those who are having frankly pleasant or comforting hallucinations. Such an approach must be tempered by the knowledge that a lethargic delirium may very quickly and unexpectedly become an agitated delirium that can threaten the serenity and safety of the patient, family, and staff. An additional rationale for intervening pharmacologically with patients who have “hypoactive” delirium is evidence that neuroleptics are effective in controlling the symptoms of delirium in both the hyperactive and hypoactive subtypes of delirium (Breitbart et al. 1996).

Finally, a very challenging clinical problem is management of terminal delirium that is unresponsive to standard neuroleptics and for which symptoms can only be controlled by sedation to the point of significantly decreased consciousness. Before undertaking interventions such as midazolam or propofol infusions, in which the aim is a calm, comfortable, but sedated and unresponsive patient, the clinician should discuss with the family (and the patient if he or she has lucid moments) the concerns and wishes for the type of care that can best honor the patient’s and family’s values. Family members should be informed that the goal of sedation is to provide comfort and symptom control and not to hasten death. Terminal sedation intended to maximize the patient’s comfort is not euthanasia. After the patient receives this degree of sedation, the family may experience a premature sense of loss, and they may feel their loved one is in some sort of limbo state, not yet dead but yet no longer alive in the vital sense. The distress and confusion that family members can experience during such a period can be ameliorated by including them in the decision making and emphasizing the shared goals of care. Sedation in such patients is not always complete or irreversible; some patients have periods of wakefulness despite sedation, and many clinicians will periodically lighten sedation to reassess the patient’s condition.

Psychotherapy Interventions in Palliative Care

The potential benefits of psychotherapy for seriously medically ill patients are frequently underestimated by clinicians (Rodin 2009). This bias against psychotherapeutic interventions tends to be even more pronounced in patients who are months away from death. However, psychotherapeutic interventions have been demonstrated to be

useful and effective for patients struggling with advanced life-threatening medical illness (Kissane et al. 2009). This section briefly describes different psychotherapeutic interventions and their relative applicability and efficacy for patients near the end of life. Psychotherapy in the medically ill is reviewed in detail in Chapter 39, “Psychotherapy.”

Individual Psychotherapy

Traditional insight-oriented psychotherapy has had limited application among dying patients. Insight-oriented psychotherapy is based on the development of a trusting relationship between the psychotherapist and the patient and an exploration of various unconscious conflicts and issues. Resolution of conflicts, through a process involving interpretation, catharsis, and enhanced insight, requires time, energy, and commitment. This approach may be too demanding for most patients nearing death, but elements of psychodynamic therapy have an important role in all palliative psychotherapies. Cognitive-behavioral and interpersonal therapies have been widely studied in the medically ill (Kissane et al. 2009; Rodin 2009). In full extended form they too may not be practical in imminently dying patients, but there are important cognitive and interpersonal elements in the specific psychotherapies as described in the following sections.

Existential Therapies

Existential therapies explore ways in which suffering can be experienced from a more positive and meaningful perspective. *Logotherapy* is one approach with the primary tenet that one always has control over one’s attitude or outlook, no matter the enormity of the adversity. The goal is to decrease patients’ suffering and encourage them to live life to its fullest by engaging in activities that bring the greatest amount of meaning and purpose to their lives (Frankl 1959/1992). The focus is on goals to achieve, tasks to fulfill, and responsibilities toward others. Rather than covering up patients’ distress, logotherapy acknowledges and fully explores patients’ suffering (Spira 2000). Although logotherapy was not designed for patients who were imminently dying, Zuehlke and Watkins (1975) explored the use of logotherapy with six dying patients and reported them to have a greater sense of freedom to change their attitudes and to see themselves and their lives as meaningful and worthwhile.

Another form of existential therapy useful with dying patients is the *life narrative*. This treatment explores the meaning of the physical illness in the context of the patient’s life trajectory. It is designed to create a new perspective of dealing with the illness, emphasize past strengths, increase self-esteem, and support effective past coping

strategies. The therapist emphatically summarizes the patient's life history and response to the illness to convey a sense that the therapist understands the patient over time (Viederman 2000; Viederman and Perry 1980). Life narrative can bolster patients' psychological and physical well-being. One study by Pennebaker and Seagal (1999) demonstrated that when patients wrote about important personal experiences in an emotional way for 15 minutes over 3 days, improvements in mental and physical health occurred. Life narrative has traditionally been used for treating depressed patients whose depression is a response to physical illness. However, the written form of this approach can be too demanding for patients at the end stage of their illness.

A similar method of intervention is the *life review*, which provides patients with the opportunity to identify and reexamine past experiences and achievements to find meaning, resolve old conflicts and make amends, or resolve unfinished business (Byock 1996; Heiney 1995; Lichter et al. 1993). The process of life review can be achieved through written or taped autobiographies, by reminiscing, through storytelling about past experiences or discussion of the patient's career or life work, and by creating family trees (Lewis and Butler 1974). Examples of other life review activities include going on pilgrimages, artistic expression (e.g., creating a collage or drawings, writing poetry), and journal writing (Pickrel 1989). Life review has traditionally been used in the elderly as a means of conflict resolution and to facilitate a dignified acceptance of death (Butler 1963). For dying patients, their stories have a special meaning. In negotiating one's way through serious illness and its treatment, the telling of one's own story takes on a renewed urgency. This approach has not, however, been widely utilized in palliative care settings.

Group Psychotherapy

Group interventions may offer benefits less available in individual therapies, such as a sense of universality, sharing a common experience and identity, a feeling of helping oneself by helping others, hopefulness fostered by seeing how others have coped successfully, and a sense of belonging to a larger group (self-transcendence, meaning, common purpose). However, patients in advanced stages of terminal illness are often too sick to participate in group therapy.

Emerging Psychotherapeutic Interventions in the Terminally Ill

Spiritual Suffering

Palliative care practitioners have recognized the importance of spiritual suffering in their patients and have begun to design interventions to address it (Puchalski and Romer 2000; Rousseau 2000). Rousseau (2000) has devel-

oped an approach for the treatment of spiritual suffering that centers on facilitating religious expression while also controlling physical symptoms; providing a supportive presence; encouraging life review to assist in recognizing purpose, value, and meaning; exploring guilt, remorse, forgiveness, and reconciliation; reframing goals; and encouraging meditative practices. Although this approach blends basic principles common to many psychotherapies, it should be noted that Rousseau's intervention includes a heavy emphasis on facilitating religious expression and confession and thus, although very useful to many patients, is not applicable to all and is not an intervention that all clinicians feel comfortable providing.

Meaning-Centered Psychotherapy

Breitbart and colleagues (Breitbart 2002; Breitbart and Heller 2003; Greenstein and Breitbart 2000) have applied Viktor Frankl's (1955/1986, 1959/1992, 1963, 1969/1988, 1975/1997) concepts of meaning-based psychotherapy (logotherapy) to address spiritual suffering in dying patients. This "Meaning-Centered Group Psychotherapy" (Greenstein and Breitbart 2000) utilizes a mixture of didactics, discussion, and experiential exercises that focus on particular themes related to meaning and advanced cancer. It is designed to help patients with advanced cancer sustain or enhance a sense of meaning, peace, and purpose in their lives even as they approach the end of life. In a recent randomized controlled trial comparing meaning-centered group psychotherapy (MCGP) and supportive group psychotherapy among advanced cancer patients, Breitbart et al. (2010b) showed that the MCGP resulted in significant improvements in spiritual well-being and sense of meaning, with reductions in anxiety and desire for hastened death.

Demoralization

Kissane et al. (2001) described a syndrome of "demoralization" in the terminally ill that is distinct from depression and consists of a triad of hopelessness, loss of meaning, and existential distress expressed as a desire for death. It is associated with life-threatening medical illness, disability, bodily disfigurement, fear, loss of dignity, social isolation, and feelings of being a burden (Kissane et al. 2009). Because of the sense of impotence and hopelessness, those with the syndrome predictably progress to a desire to die or commit suicide. The authors (Kissane et al. 2001) formulated a treatment approach for demoralization syndrome that emphasizes a multidisciplinary, multimodal approach consisting of 1) ensuring continuity of care and active symptom management; 2) ensuring dignity in the dying process; 3) using various types of psychotherapy to help sustain a sense of meaning, limit cognitive distortions, and maintain family relationships (i.e., meaning-

based, cognitive-behavioral, interpersonal, and family psychotherapy interventions); 4) using life review and narrative and attention to spiritual issues; and 5) administering pharmacotherapy for comorbid anxiety, depression, and delirium.

Dignity-Conserving Care

Ensuring dignity in the dying process is a critical goal of palliative care. Despite use of the term *dignity* in arguments for and against a patient's self-governance in matters pertaining to death, there is little empirical research on how this term has been used by patients who are nearing death. Chochinov et al. (2002a, 2002b) examined how dying patients understand and define *dignity* in order to develop a model of dignity in the terminally ill (Figure 41-2). A semi-structured interview was designed to explore how patients cope with their illness and their perceptions of dignity. Three major categories emerged, which included illness-related concerns (concerns related to the illness itself that threaten or impinge on the patient's sense of dignity), dignity-conserving repertoire (internally held qualities or personal approaches that patients use to maintain their sense of dignity), and social dignity inventory (social concerns or relationship dynamics that enhance or detract from a patient's sense of dignity). These broad categories and their carefully defined themes and subthemes form the foundation for an emerging model of dignity among the dying (Chochinov et al. 2006). The concept of dignity and the notion of dignity-conserving care offer a way of understanding how patients face advancing terminal illness and present an approach that clinicians can use to explicitly target the maintenance of dignity as a therapeutic objective.

Accordingly, Chochinov (2002) has developed a short-term dignity-conserving care intervention for palliative care patients coined "dignity therapy," which incorporates various facets from this model most likely to bolster the dying patient's will to live, lessen their desire for death or overall level of distress, and improve their quality of life. The dignity model establishes the importance of generativity as a significant dignity theme. As such, the sessions are taped, transcribed, and edited, and the transcription is returned to the patient within 1-2 days. The creation of a tangible product that will live beyond the patient acknowledges the importance of generativity as a salient dignity issue. The immediacy of the returned transcript is intended to bolster the patient's sense of purpose, meaning, and worth while giving them the tangible experience that their thoughts and words continue to be valued. In most instances, these transcripts will be left for family or loved ones and form part of a personal legacy that the patient will have actively participated in creating and shaping.

Spirituality in Palliative Care

Addressing spirituality as an essential element of quality palliative care has been identified as a priority by medical professionals as well as by patients (Chochinov and Cann 2005; Dufault and Pulchalski 2006). Spirituality encompasses concepts of faith and/or meaning. Viewing spirituality as a construct composed of faith and meaning is reflected in the FACIT Spiritual Well-Being Scale (Brady et al. 1999; Peterman et al. 1996). This scale generates a total score as well as two subscale scores; one corresponding to "Faith" and a second corresponding to "Meaning/Peace." Other measures that are commonly used to gauge aspects of spirituality include the Daily Spiritual Experiences Scale (Underwood and Teresi 2002) and the Spiritual Beliefs Inventory (Baider et al. 2001).

Spirituality and Life-Threatening Medical Illness

There has been great interest in spirituality, faith, and religious beliefs and their impact on health outcomes and their role in palliative care. Sloan et al. (1999) concluded in their review of the literature that evidence of an association between religion and health was weak and inconsistent and that it was premature to promote faith and religion as adjunctive treatments. Researchers theorize that religious beliefs may help patients construct meaning from the suffering inherent in illness, which may in turn facilitate acceptance (Koenig et al. 1998). A number of studies have found that religion and spirituality generally play a positive role in patients' coping with illnesses such as cancer or HIV (Baider et al. 1999; Nelson et al. 2002; Peterman et al. 1996).

Several studies (Breitbart et al. 2000; McClain et al. 2003; Nelson et al. 2002; Whitford et al. 2008) have demonstrated a central role for spiritual well-being and meaning as a buffering agent against depression, hopelessness, and desire for hastened death among advanced cancer patients. Although spiritual well-being (per the FACIT Spiritual Well-Being Scale) has a generally positive influence on the incidence of depression, hopelessness, and desire for death, it is the score on the Meaning/Peace subscale that has the most significant effect.

Communication About Spiritual Issues

Several factors may inhibit effective communication with patients about spirituality in a palliative care setting (C.L. Clayton 2000; Ellis et al. 1999; Post et al. 2000; Sloan et al. 1999). Promoting religion, faith, or specific religious beliefs or rituals (e.g., prayer, belief in an afterlife) in an effort to deal with patients' spiritual concerns or suffering at the end of life has limited acceptance among health care pro-

FIGURE 41-2. Model of dignity for the terminally ill.

viders and is not universally applicable to all patients. Maugans and Wadland (1991) suggested that there is often a great discrepancy between physicians and patients on such issues as belief in God, belief in an afterlife, regular prayer, and feeling close to God, with physicians endorsing such beliefs or practices less than half as often as patients (none greater than 40%).

Additional barriers include lack of time on the part of the provider, lack of training, fear of projecting one's own beliefs onto the patient, and concerns about patient autonomy (Ellis et al. 1999). Finally, providers may feel that these discussions are inappropriate because they are outside of their area of expertise or intrusive to the patient's privacy (Ellis et al. 1999; Post et al. 2000; Sloan et al. 1999). However, the majority of studies have demonstrated that patients welcome these discussions (J.M. Anderson et al. 1993; King and Bushwick 1994; Maugans 1996).

Communicating effectively with patients about spirituality requires comfort in several domains. These include 1) a basic knowledge of common spiritual concerns and sources of spiritual pain for patients; 2) the principles and beliefs of the major religions common to the patient populations one treats; 3) basic clinical communication skills, such as active and empathic listening, with an ability to identify and highlight spiritually relevant issues; and 4) the

ability to remain present while patients struggle with spiritual issues in light of their mortality (Storey and Knight 2001). This final domain is often the most trying, especially for clinicians early in their career.

The American Academy of Hospice and Palliative Medicine offers the following guidelines for clinicians when communicating about spiritual issues (Doyle 1992; Hay 1996; Storey and Knight 2001). First, it is important to recognize that every patient is an individual and has a unique belief system that should be honored and respected. A patient's spiritual views may or may not incorporate religious beliefs, as *spirituality* is considered the more inclusive category. Therefore, initial discussions should focus on broad spiritual issues and then, when appropriate, on more specific religious beliefs. Caregivers should maintain appropriate boundaries and avoid discussions of their own religious beliefs because they are usually not relevant. Finally, fostering hope and integrating meaning into a patient's life is a more important aspect of providing spiritual healing than adherence to a particular belief system or religious affiliation. Methods for taking a spiritual history are reviewed elsewhere (Puchalski and Romer 2000). Formal assessment tools are also available (Kuhn 1988; Maugans 1996).

Psychosomatic medicine clinicians should be aware of the importance of spirituality and the value of pastoral

care services not only for the patient but also for the family coping with a terminal illness. Referrals to chaplains are as important as referrals to any other specialist and an essential part of comprehensive care (Thiel and Robinson 1997).

Cross-Cultural Issues in Care of the Dying

Ethnicity and culture strongly influence attitudes toward death and dying. A full discussion of cultural and ethnic differences in the face of life-threatening illness is beyond the scope of this chapter and is described elsewhere, but some illustrative points should be noted (National Consensus Project for Quality Palliative Care 2009; Schim et al. 2006). Although fears of cancer and other debilitating diseases are universal (Butow et al. 1997), it appears that individuals from mainstream Western cultures generally use different coping strategies than those used in non-Western cultures (Barg and Gullatte 2001). Wide differences also exist within countries.

Blackhall et al. (1995) studied ethnic attitudes in the United States toward patient autonomy regarding disclosure of the diagnosis and prognosis of a terminal illness and toward end-of-life decision making. They found that different cultures have distinct opinions about how much information physicians should provide concerning diagnoses and prognoses. The investigators determined that African Americans (88%) and European Americans (87%) are significantly more likely than Mexican Americans (65%) or Korean Americans (47%) to believe that a patient should always be informed of a diagnosis of metastatic cancer. They also found that African Americans (63%) and European Americans (69%) are more likely than Korean Americans (35%) and Mexican Americans (48%) to believe a patient should be informed of a terminal prognosis and be actively involved in decisions concerning use of life-sustaining technology. They concluded that physicians should ask their patients whether they wish to be informed of their diagnoses and prognoses and to be involved in treatment decisions or prefer to let family members or caregivers handle such matters.

A similar study of Navajo Indian beliefs concerning autonomy in patient diagnosis and prognosis found that in the Navajo culture, physicians and patients must speak in only a positive way, avoiding any negative thought or speech (Carrese and Rhodes 1995). Because Navajos believe that language can “shape reality and control events,” informing patients of a negative diagnosis or prognosis is considered disrespectful and physically and emotionally

dangerous (Carrese and Rhodes 1995). As these two studies show, physicians must be careful to respect their patients’ cultural beliefs in disclosing the diagnosis and prognosis of a terminal illness. Important differences between cultures include those that exist in the roles of religion (Musick et al. 1998a, 1998b), family, alternative healing traditions and folk healers (Canive and Castillo 1997; Chan et al. 2001), attitudes toward pain and suffering (Gordon 2002), beliefs about afterlife, and customs regarding the deceased’s body and burial preparations (Parkes et al. 1997). At the same time, one should beware of cultural stereotypes and not assume that every member of a particular ethnic or cultural group holds identical shared values.

Doctor–Patient Communication

Doctor–patient communication is an essential component in caring for a dying patient (Baile and Beale 2001; Buckman 1993, 1998; Fallowfield 2004; Parker et al. 2001; Smith 2000). A study of cancer patients’ predictions regarding outcome and the treatments they chose revealed that inadequate communication between cancer patients and their physicians resulted in overestimation of survival by patients and a resulting tendency to choose more aggressive treatment (Weeks et al. 1996).

In a study of oncologists’ communication skills (Fallowfield et al. 1998), less than 35% reported having received any previous communication training, but most desired to learn better communication techniques. Psychosomatic medicine specialists can help improve communication skills in physicians and other health care professionals caring for dying patients. Intensive training programs in doctor–patient communication that use a variety of teaching methods, including role-playing, videotaped feedback, experiential exercises, and didactics, have been demonstrated to have both short-term as well as long-term efficacy in improving communication skills among physicians (Fallowfield 2004; Maguire 1999). Bylund et al. (2010) reported on the successful implementation of a curriculum for oncologists at Memorial Sloan-Kettering Cancer Center with improved communication skills following training.

One critical aspect of doctor–patient communication is how to break bad news. A useful six-step protocol for breaking bad news includes 1) getting the physical context right, 2) finding out how much the patient knows, 3) finding out how much the patient wants to know, 4) sharing information (aligning and educating), 5) responding to the patient’s feelings, and 6) planning and following through (Baile and Beale 2001; Buckman 1998).

Bereavement

Bereavement care is an integral dimension of palliative care, particularly for the 20% of bereaved individuals who develop complicated grief, for which effective therapies are available (Kissane 2004). Normal grief is an inevitable dimension of humanity, an adaptive adjustment process, and one that, with support, can be approached with courage.

Although words such as *grief*, *mourning*, and *bereavement* are commonly used interchangeably, the following definitions may be helpful:

- ♦ *Bereavement* is the state of loss resulting from death (Parkes 1998).
- ♦ *Grief* is the emotional response associated with loss (Stroebe et al. 1993).
- ♦ *Mourning* is the process of adaptation, including the cultural and social rituals prescribed as accompaniments (Raphael 1983).
- ♦ *Anticipatory grief* precedes the death and results from the expectation of that event (Raphael 1983).
- ♦ *Complicated grief* represents a pathological outcome involving psychological, social, or physical morbidity (Rando 1983).
- ♦ *Disenfranchised grief* represents the hidden sorrow of the marginalized patient, for whom there is less social permission to express many dimensions of loss (Doka 2000).

Nature of Normal Grief

The expression of normal grief is evident through its emotional, cognitive, physical, and behavioral features (Parkes 1998). In Lindemann's (1944) classic study of people who lost a relative in Boston's Coconut Grove Nightclub fire, he identified key features of grief including somatic distress with numbness, preoccupation with sad memories of the deceased, guilt, anger, loss of regular patterns of conduct, and identification with the deceased.

Emotional distress occurs in waves with unavoidable crying and a range of associated affects including sadness, anger, despair, anxiety, and guilt. Cognitive processes become dominated by memories, reflected in storytelling, reminiscences, and conversations about the deceased. Physical responses include numbness, restlessness, tension, tremors, sleep disturbance, anorexia, weight loss, fatigue, and painful symptoms. Finally, behavioral aspects are variously reflected in social withdrawal, wandering, searching, and seeking company and consolation.

A number of physiological changes have been identified in grief in neuroendocrine functioning (Jacobs et al. 1997), immune indices (Esterling et al. 1996), and sleep efficiency (Hall et al. 1998).

Clinical Presentations of Grief

As the patient and family journey through palliative care, the clinical phases of grief progress from anticipatory grief through to the immediate news of the death, to the stages of acute grief, and potentially for some, to the complications of bereavement.

Anticipatory Grief

Anticipatory grief generally draws the supportive family closer. In contrast, for some families difficulties emerge as they express their anticipatory grief. Impaired coping is exhibited through protective avoidance, denial of the seriousness of the threat, anger, or withdrawal from involvement. Sometimes family dysfunction is glaring. More commonly, however, subthreshold or mild depressive or anxiety disorders develop gradually as individuals struggle to adapt to unwelcome changes. Although anticipatory grief was historically suggested to reduce postmortem grief (Parkes 1975), intense distress is now well recognized as a marker of risk for complicated grief. During this phase of anticipatory grief, families that are capable of effective communication should be encouraged to openly share their feelings as they go about the care of their dying family member or friend. Saying goodbye needs to be recognized as a process that evolves over time, with opportunities for reminiscence, celebration of the life and contribution of the dying person, expressions of gratitude, and completion of any unfinished business (Meares 1981). These tasks have the potential to generate creative and positive emotional aspects of what is otherwise a sad time for all.

Sometimes staff will have concerns about the emotional response of the bereaved. If there is uncertainty about its cultural appropriateness, consultation with an informed cultural intermediary may prove helpful.

Caution is needed in those settings where grief could be marginalized, well exemplified by ageism (see Doka 2000). If a death is normalized because it appears in step with the life cycle, family members may receive less support and reduced permission to express many aspects of their loss.

Acute Grief and Time Course of Bereavement

The sequence or stages through which the bereaved move over time are not rigidly demarcated but merge gradually one into the other (Parkes 1998; Raphael 1983). Starting with initial numbness and a sense of unreality, waves of distress begin to occur as bereaved individuals experience intense pining and yearning for their lost one. Memories of the deceased trigger these acute pangs of grief. Then, as the pain of separation grows, a phase of disorganization emerges as loneliness resulting from the loss sets in. Hofer (1984) described this phase aptly as a constant background distur-

bance of restlessness, inattention, sadness, and despair, with social withdrawal that can last for several months. Eventually a phase of reorganization and recovery develops as nostalgia replaces sadness, morale improves, and an altered worldview is constructed.

The time course of mourning is proportional to the strength of attachment to the lost person and also varies with cultural expression, there being no sharply defined end point to grief. Just as a mother's grief following sudden infant death syndrome usually lasts longer than grief following a neonatal death, so too with adult loss—the mourning that follows many years of marriage is generally longer than that in brief relationships. Some, including older widows and widowers, may continue to display their grief for several years (Zisook and Shuchter 1985). This may represent a continuing relationship with the deceased that, for some, is their choice and leads to a prolonged period of bereavement that may be quite appropriate and within the normal range of grief experience. The clinical task is then to differentiate those that remain within the spectrum of normality from those that cross the threshold of complicated grief.

Complicated Grief

Normal and abnormal responses to bereavement span a spectrum in which intensity of reaction, presence of a range of related grief behaviors, and time course determine the differentiation. Complicated grief has been conceptualized as a stress response syndrome that results from failure to integrate the loss, making it difficult to function in a world without the deceased, with avoidance a central feature (Shear et al. 2007). In complicated grief, yearning for the lost one is even more common than depressed mood (Maciejewski et al. 2007). Diagnostic criteria have been proposed for “complicated grief disorder” by Zhang et al. (2006) to be included in DSM-V. The proposed criteria capture the essential features of complicated grief including daily yearning for the deceased to a distressing or disruptive degree accompanied by any four of the following symptoms: difficulty accepting death, inability to trust others, anger about the death, feeling uneasy about moving on with one's life, feeling numb, feeling life is empty, feeling the future holds no meaning, and feeling agitated or on edge since the death.

Inhibited or Delayed Grief

Although avoidance may serve some as a temporary coping mechanism, its persistence is usually associated with relationship or other difficulties. Cultural and individual variation significantly influences grief expression; a placid external emotional response cannot be equated with internal avoidance. Empirical studies have generally identified

avoidant forms of complicated grief in up to 5% of the bereaved—the grief may not always present clinically but may reappear in later years as an unresolved issue.

Chronic Grief

A common form of complicated grief, chronic grief is particularly associated with overly dependent relationships in which a sense of abandonment is avoided by perpetuation of the relationship through memorialization of the deceased and maintenance of continuing bonds. Social withdrawal and depression are common. A fantasy of reunion with the deceased can cause suicide to be an increasingly attractive option. Active treatment using antidepressants and cognitive-behavioral therapy to reality test the loss and promote socialization (via activity scheduling) is often appropriate for chronic grief (keeping in mind that not all persistent grief is pathological).

Traumatic Grief

When death has been unexpected or its nature in some way shocking—traumatic, violent, stigmatized, or perceived as undignified—its integration and acceptance may be interfered with by the arousal and increased distress that memories can trigger. Intensive recollections including flashbacks, nightmares, and recurrent intrusive memories cause hyperarousal, disbelief, insomnia, irritability, and disturbed concentration that distort normal grieving (Prigerson and Jacobs 2001). The shock of the death can precipitate mistrust, anger, detachment, and an unwillingness to accept its reality. These reactions at a subthreshold level are on a continuum with the full features of acute and posttraumatic stress disorders, but subthreshold states have been observed to persist for years and contribute substantial morbidity. Palliative care deaths involving profound breakdown of bodily surfaces, gross disfigurement due to head and neck cancers, or other changes eliciting fear, disgust, or mortification may generate traumatic memories in the bereaved. Schut et al. (1997) found that PTSD was often correlated with the perceived inadequacy of the goodbye and suggested that rituals to complete this be incorporated into related grief therapies. The researchers who initially proposed the term “traumatic grief” have suggested returning to the original term “complicated grief” in order to avoid confusion between traumatic grief and posttraumatic stress disorder (Zhang et al. 2006).

Psychiatric Disorders in Bereavement

Psychiatric disorders commonly complicating grief include clinical depression, anxiety disorders, alcohol abuse or other substance abuse, and psychotic disorders. When frank psychiatric disorders complicate bereavement, they are more likely to be recognized and treated than sub-

threshold states. Studies of the bereaved identify clusters of intense grief symptoms distinct from uncomplicated grief (Parkes and Weiss 1983; Prigerson et al. 1995a, 1995b). Their recognition calls for an experienced clinical judgment that does not normalize the distress as understandable.

Rates of major depression in the bereaved have varied between 16% and 50%, peaking during the first 2 months (P. Clayton 1990; Zisook and Shuchter 1991) and gradually decreasing to 15% across the next 2 years (Harlow et al. 1991; Zisook et al. 1994). The features of any major depressive episode following bereavement resemble major depression at other points of the life cycle (Kendler et al. 2008). There is a tendency toward chronicity, considerable social morbidity, and risk of inadequate treatment.

Anxiety disorders take the form of adjustment disorders, generalized anxiety disorder, acute and posttraumatic stress disorders, and phobias and occur in up to 30% of the bereaved (Jacobs 1993).

Individuals predisposed to alcohol or other substance use disorders are at higher risk for relapse during grief (Jacobs 1993), as are those with psychotic disorders. The latter should not be confused with the “normal” hallucinations that can occur in grief, typically limited to the voice, sight, and/or sense of presence of the deceased.

Risk factors that, when present, can aid recognition of those at greater risk of complicated grief are summarized in Table 41–3.

Grief Therapies

The most basic model is a supportive–expressive intervention in which the person is invited to share his or her feelings about the loss to a health professional who will listen and seek to understand the other’s distress in a comforting manner. The key therapeutic aspects of this encounter are the sharing of distress and, through the relational understanding that is acknowledged, some shift in cognitive appraisal of the reality that has been forever altered. There are multiple possible formal interventions for bereaved people, but the first question is whether an intervention is actually warranted. For most, although bereavement is painful, personal resilience will ensure normal adaptation. There can therefore be no justification for routine intervention, because grief is not a disease. Early intervention should be considered for those at risk of maladaptive outcomes, and those who later develop complicated bereavement need active treatments.

The spectrum of interventions spans individual-, group-, and family-oriented therapies and encompasses all schools of psychotherapy as well as appropriately indicated pharmacotherapy. A typical intervention entails six to eight sessions over several months. In this sense, grief therapy is focused and time limited, but multimodal ther-

TABLE 41–3. Risk factors for complicated grief

Category	Range of circumstances
Nature of the death	Untimely within the life cycle (e.g., death of a child) Sudden and unexpected Traumatic/shocking Stigmatized
Strengths and vulnerabilities of the caregiver/bereaved	Past history of psychiatric disorder Personality and coping style Cumulative experience of losses
Nature of the relationship with the deceased	Overly dependent Ambivalent
Family and support network	Dysfunctional family Isolated Alienated

apies are common (Kissane 2004). Table 41–4 lists commonly used forms of grief therapy (Kissane 2004).

Pharmacotherapy is widely used to support the bereaved, but prescribing should be judicious. Benzodiazepines allay anxiety and assist sleep, but excessive use may interfere with adaptive mourning. Antidepressants are indicated when bereavement is complicated by major depression or panic disorder (Pasternak et al. 1991; Zisook et al. 2001).

Palliation of Selected Physical Symptoms

Although the diagnosis and treatment of psychiatric disorders in the patient with advanced illness is important, pain and other distressing physical symptoms must also be aggressively treated to enhance the patient’s quality of life. Some key points are noted in this discussion, but a comprehensive review of pharmacological and nonpharmacological interventions for common physical symptoms encountered in the terminally ill can be found in a curriculum published by the American Society of Clinical Oncology (2001) and in major palliative care texts (Chochinov and Breitbart 2009; Doyle et al. 2003; Portenoy et al. 2009).

Pain

The Agency for Health Care Policy and Research (Jacox et al. 1994) published a practice guideline for management of cancer pain in the early 1990s, with more recent guidelines from the National Comprehensive Cancer Network (NCCN Adult Cancer Pain Panel Members 2008). Breitbart et al. (2004b) provided an up-to-date detailed discussion of the

TABLE 41-4. Models of grief therapy

Model	Potential focus for application	Clinical issues when indicated
Supportive-expressive therapy (guided grief work, crisis intervention)	Individual and/or group	Avoidance of emotional expression Inhibited or delayed grief Isolated and needing support Established psychiatric disorders including depression
Interpersonal or psychodynamic therapy	Individual and/or group	Relational issues dominate Role transition difficulties
Cognitive-behavioral therapy	Individual and/or group	Chronic grief with "stuck" behaviors Traumatic grief Posttraumatic stress disorder
Family-focused grief therapy	Family	Family either at risk or clearly dysfunctional in its relating Adolescents or children at risk
Combined pharmacotherapies with any of the psychotherapeutic models	Individual	Depressive disorders Anxiety disorders Sleep disorders

use of behavioral, psychotherapeutic, and psychopharmacological interventions for pain control in palliative care (see also Chapter 36, "Pain"). After adequate medical treatment, mild to moderate levels of residual pain can be effectively managed with behavioral techniques that are quite similar to those used for anxiety, phobias, and anticipatory nausea and vomiting. Relaxation techniques, imagery, hypnosis, biofeedback, and multicomponent cognitive-behavioral interventions have been used to provide comfort and minimize pain in adults, children, and adolescents.

Anorexia and Weight Loss

While physiological changes associated with terminal illness account for most of the anorexia and cachexia in the terminally ill, with additional contributions from adverse effects of treatments, psychological and psychiatric factors, including anxiety, depression, and conditioned food aversions, may also play a role (Lesko 1989). The treatment of anorexia and weight loss begins with the identification and correction of reversible causes (e.g., opioid-induced nausea, stomatitis from chemotherapy, or thrush) (NCCN Palliative Care Panel Members 2009). Progestational drugs (medroxyprogesterone or megestrol acetate) or corticosteroids are often tried for nonspecific cachexia (NCCN Palliative Care Panel Members 2009). Appetite-stimulating antidepressants (e.g., tricyclic antidepressants [TCAs], trazodone, mirtazapine) should be considered when the cause is major depression, but depression should never be diagnosed solely on the basis of unexplained anorexia and

weight loss. Treatment of conditioned nausea and vomiting is discussed later.

Asthenia/Fatigue

Asthenia and fatigue are extremely common in patients with advanced cancer, AIDS, and organ failure as a result of deconditioning, catabolism, malnutrition, infection, profound anemia, metabolic abnormalities, or adverse effects of treatment, but a reversible cause often cannot be identified. As with unexplained weight loss in advanced disease, there is a tendency to overdiagnose depression in the terminally ill patient with extreme fatigue.

The literature in support of the pharmacotherapy of fatigue in cancer patients is limited, but practice guidelines are available (Mock et al. 2000; NCCN Cancer-Related Fatigue Panel Members 2008). Antidepressants have been recommended to treat the underlying depression when present (NCCN Cancer-Related Fatigue Panel Members 2008). Identifiable causes should be specifically treated when possible, for example, erythropoietin for anemia. Some patients respond to corticosteroids, but the benefits tend to be fleeting and prolonged use can cause proximal myopathy. Psychostimulants have been used in the treatment of asthenia with good results, however further research is needed (Breitbart et al. 2001; NCCN Cancer-Related Fatigue Panel Members 2008; see also Chapter 28, "HIV/AIDS"). Low doses of stimulants do not appear to cause appetite suppression or weight loss and may actually improve energy and appetite in fatigued terminally ill patients.

Nausea and Vomiting

Common causes of nausea and vomiting in advanced cancer patients include radiation, medications, toxins, metabolic derangements, obstruction of the gastrointestinal tract, and chemotherapy (NCCN Antiemesis Panel Members 2009). Conditioned by the experience of profound nausea and vomiting secondary to highly emetic chemotherapy agents, some patients report being nauseated in anticipation of treatment. Anticipatory nausea and vomiting used to be very frequent but has become less so with current antiemetic therapy.

Antiemetic drugs are the mainstay of managing chemotherapy-induced nausea and vomiting in patients with advanced disease. Several antiemetics (e.g., metoclopramide, prochlorperazine, promethazine) have dopamine-blocking properties and so can cause the same extrapyramidal side effects as neuroleptics, with acute akathisia and dystonia common. Extrapyramidal side effects are not a problem with newer antiemetics like ondansetron. Rapid-onset, short-acting benzodiazepines are also helpful in controlling anticipatory nausea and vomiting once they have developed (Greenberg et al. 1987). Behavioral control of anticipatory nausea and vomiting was shown to be highly effective (Barnes 1988) but has largely been replaced by antiemetic drugs.

Conclusion

The psychosomatic medicine practitioner can play an important role in the care of patients with advanced, life-threatening medical illnesses. Palliative care for terminally ill patients must include not only control of pain and physical symptoms but also assessment and management of psychiatric and psychosocial complications. The psychosomatic medicine practitioner working in the palliative care setting must be knowledgeable in the assessment and management of major psychiatric complications, such as anxiety, depression, and delirium, and also must be adept in dealing with issues of existential despair and spiritual suffering. Cultural issues, communication issues, ethical issues, and issues of bereavement are all areas requiring attention and awareness. As part of an interdisciplinary team, the psychosomatic medicine practitioner can play an important role in the provision of comprehensive palliative care.

"Already a classic, the new edition of Levenson's *Textbook of Psychosomatic Medicine* offers significant updates in this increasingly important field of psychiatry. From general principles of clinical assessment, including legal and ethical issues, to specific concerns in understanding and managing patients with psychiatric problems associated with virtually every organ system afflicted by every type of pathogenic process across the life cycle, authoritative chapters in this book provide state-of-the-art information and clinical guidance. Practitioners, residents, and students who need to stay current with the rapidly expanding evidence base in all aspects of this field pertinent to the care of patients in both ambulatory and hospital settings can do no better than to have this volume close at hand."

—**Joel Yager, M.D.**, Chair, American Psychiatric Association Steering Committee on Practice Guidelines; Professor of Psychiatry, University of Colorado; Professor Emeritus, Department of Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine, University of California at Los Angeles; Professor Emeritus, Department of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico

"The second edition of *The American Psychiatric Publishing Textbook of Psychosomatic Medicine: Psychiatric Care of the Medically Ill*, edited by James L. Levenson, M.D., provides up-to-date, evidence-based information about the diagnosis and treatment of the common conditions seen in consultation-liaison psychiatry. Once again, Dr. Levenson has called upon a diverse group of national and international experts to write chapters on their particular areas of knowledge and skill. This will remain the classic reference book in this important subspecialty of psychiatry."

—**Daniel K. Winstead, M.D.**, Robert G. Heath Professor and Chair, Department of Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, Louisiana

Extensively updated in this second edition, *The American Psychiatric Publishing Textbook of Psychosomatic Medicine: Psychiatric Care of the Medically Ill* again brings together a multinational group of distinguished contributors to address every aspect of psychiatric care in the medically ill. This book captures the diversity of the field, whose practitioners—scholars, physicians, and clinicians of varied backgrounds—represent a multiplicity of perspectives.

A quarter of this comprehensive text's chapters are entirely new, and all have been extensively revised. Early chapters cover general principles in evaluation and management, legal and ethical issues, and psychological reactions to illness. The middle sections are devoted to a review of psychiatric syndromes in the medically ill, followed by review of psychiatric issues in each of 20 medical specialties. For each major psychiatric disorder and major medical disorder, chapters discuss epidemiology and risk factors; the effects of the psychiatric disorder on medical disorders and, conversely, the effects of medical diseases on the psyche; clinical features; diagnosis and assessment; differential diagnosis; management; and treatment. Chapters in the final section summarize psychiatric treatment in the medically ill, including psychopharmacology, psychotherapy, electroconvulsive therapy, and palliative care.

The American Psychiatric Publishing Textbook of Psychosomatic Medicine brings together the body of knowledge and skills that defines the subspecialty of psychosomatic medicine. It will be a frequently consulted source of guidance for all clinicians and health care providers who engage in psychiatric or mental health consultation, those who care for the psychological needs of patients facing medical and surgical concerns, and those who treat psychiatric patients contending with concurrent general medical and surgical problems.
