Psychiatric Care of the Medically Ill

SECOND EDITION

Edited by
James L. Levenson, M.D.

American
Psychiatric
Publishing, Inc.

Washington, DC
London, England

Note: The authors have worked to ensure that all information in this book is accurate at the time of publication and consistent with general psychiatric and medical standards, and that information concerning drug dosages, schedules, and routes of administration is accurate at the time of publication and consistent with standards set by the U.S. Food and Drug Administration and the general medical community. As medical research and practice continue to advance, however, therapeutic standards may change. Moreover, specific situations may require a specific therapeutic response not included in this book. For these reasons and because human and mechanical errors sometimes occur, we recommend that readers follow the advice of physicians directly involved in their care or the care of a member of their family.

Books published by American Psychiatric Publishing, Inc., represent the views and opinions of the individual authors and do not necessarily represent the policies and opinions of APPI or the American Psychiatric Association.

If you would like to buy between 25 and 99 copies of this or any other APPI title, you are eligible for a 20% discount; please contact APPI Customer Service at appi@psych.org or 800-368-5777. If you wish to buy 100 or more copies of the same title, please e-mail us at bulksales@psych.org for a price quote.

Contents

Contributors.	ix
Foreword <i>Thomas N. Wise, M.D.</i>	xv
Preface <i>James L. Levenson, M.D.</i>	xvii

PART I

General Principles in Evaluation and Management

1 Psychiatric Assessment and Consultation.	3
<i>Felicia A. Smith, M.D., James L. Levenson, M.D., and Theodore A. Stern, M.D.</i>	
2 Legal Issues.	19
<i>Rebecca W. Brendel, M.D., J.D., Ronald Schouten, M.D., J.D., and James L. Levenson, M.D.</i>	
3 Ethical Issues	33
<i>Donald L. Rosenstein, M.D., and Franklin G. Miller, Ph.D.</i>	
4 Psychological Responses to Illness	45
<i>Mark S. Groves, M.D., and Philip R. Muskin, M.D.</i>	

PART II

Symptoms and Disorders

5 Delirium	71
<i>Paula T. Trzepacz, M.D., David J. Meagher, M.D., M.R.C.Psych., M.Sc., and Maeve Leonard, M.B., M.R.C.Psych.</i>	
6 Dementia	115
<i>Antonio Lobo, M.D., Ph.D., Pedro Saz, M.D., Ph.D., and Miguel Ángel Quintanilla, M.D., Ph.D.</i>	
7 Aggression and Violence.	153
<i>Chiadi U. Onyike, M.D., M.H.S., and Constantine G. Lyketsos, M.D., M.H.S.</i>	

8	Depression	175
	<i>Madeline Li, M.D., Ph.D., F.R.C.P.C., and Gary Rodin, M.D., F.R.C.P.C.</i>	
9	Suicidality	199
	<i>John Michael Bostwick, M.D., and James L. Levenson, M.D.</i>	
10	Psychosis, Mania, and Catatonia	219
	<i>Oliver Freudenreich, M.D., Shamim H. Nejad, M.D., Andrew Francis, Ph.D., M.D., and Gregory L. Fricchione, M.D.</i>	
11	Anxiety Disorders	241
	<i>Steven A. Epstein, M.D., and Daniel Hicks, M.D.</i>	
12	Somatization and Somatoform Disorders	261
	<i>Susan E. Abbey, M.D., F.R.C.P.C., Lawson Wulsin, M.D., and James L. Levenson, M.D.</i>	
13	Deception Syndromes: Factitious Disorders and Malingering	291
	<i>Charles V. Ford, M.D.</i>	
14	Eating Disorders	305
	<i>Michael J. Devlin, M.D., Joel P. Jahraus, M.D., and Ilyse Dobrow DiMarco, Ph.D.</i>	
15	Sleep Disorders	335
	<i>Lois E. Krahn, M.D.</i>	
16	Sexual Dysfunction	361
	<i>Rosemary Basson, M.D., and Peter M. Rees, M.D., Ph.D.</i>	
17	Substance-Related Disorders	381
	<i>Michael Weaver, M.D., F.A.S.A.M.</i>	

PART III

Specialties and Subspecialties

18	Heart Disease	407
	<i>Peter A. Shapiro, M.D.</i>	
19	Lung Disease	441
	<i>Kathy L. Coffman, M.D., and James L. Levenson, M.D.</i>	
20	Gastrointestinal Disorders	463
	<i>Catherine C. Crone, M.D., and Christopher R. Dobbstein, M.D.</i>	
21	Renal Disease	491
	<i>Daniel Cukor, Ph.D., Deborah Rosenthal-Asher, M.A., Lewis M. Cohen, M.D., James L. Levenson, M.D., and Paul L. Kimmel, M.D.</i>	

22	Endocrine and Metabolic Disorders	503
	<i>Ann Goebel-Fabbri, Ph.D., Gail Musen, Ph.D., and James L. Levenson, M.D.</i>	
23	Oncology	525
	<i>Mary Jane Massie, M.D., and Kimberley Miller, M.D., F.R.C.P.C.</i>	
24	Hematology	551
	<i>Madeleine Becker, M.D., M.A., David J. Axelrod, M.D., J.D., Olu Oyesanmi, M.D., M.P.H., Dimitri D. Markov, M.D., Elaine Martin, M.D., and Elisabeth J. Shakin Kunkel, M.D.</i>	
25	Rheumatology	571
	<i>James L. Levenson, M.D., Chris Dickens, M.B.B.S., Ph.D., and Michael R. Irwin, M.D.</i>	
26	Chronic Fatigue and Fibromyalgia Syndromes	593
	<i>Michael C. Sharpe, M.A., M.D., F.R.C.P., F.R.C.Psych., and Patrick G. O'Malley, M.D., M.P.H., F.A.C.P.</i>	
27	Infectious Diseases	615
	<i>James L. Levenson, M.D.</i>	
28	HIV/AIDS	637
	<i>Crystal C. Watkins, M.D., Ph.D., Niccolo D. Della Penna, M.D., Andrew A. Angelino, M.D., and Glenn J. Treisman, M.D., Ph.D.</i>	
29	Dermatology	667
	<i>Madhulika A. Gupta, M.D., F.R.C.P.C., and James L. Levenson, M.D.</i>	
30	Surgery	691
	<i>Pauline S. Powers, M.D., and Carlos A. Santana, M.D.</i>	
31	Organ Transplantation	725
	<i>Andrea F. DiMartini, M.D., Jorge Luis Sotelo, M.D., and Mary Amanda Dew, Ph.D.</i>	
32	Neurology and Neurosurgery	759
	<i>Alan J. Carson, M.B.Ch.B., M.Phil., M.D., F.R.C.Psych., Adam Zeman, M.A., D.M., F.R.C.P., Jon Stone, M.B.Ch.B., Ph.D., F.R.C.P., and Michael C. Sharpe, M.A., M.D., F.R.C.P., F.R.C.Psych.</i>	
33	Obstetrics and Gynecology	797
	<i>Donna E. Stewart, M.D., F.R.C.P.C., Simone N. Vigod, M.D., F.R.C.P.C., and Nada Logan Stotland, M.D., M.P.H.</i>	
34	Pediatrics	827
	<i>Brenda Bursch, Ph.D., and Margaret Stuber, M.D.</i>	
35	Physical Medicine and Rehabilitation	855
	<i>Jesse R. Fann, M.D., M.P.H., Richard Kennedy, M.D., and Charles H. Bombardier, Ph.D.</i>	
36	Pain	901
	<i>Michael R. Clark, M.D., M.P.H., M.B.A.</i>	

37	Medical Toxicology	929
	<i>J. J. Rasimas, M.D., Ph.D.</i>	

PART IV

Treatment

38	Psychopharmacology	957
	<i>James A. Owen, Ph.D.</i>	

39	Psychotherapy	1021
	<i>Elsbeth Guthrie, M.B., Ch.B., M.R.C.Psych., M.Sc., M.D.</i>	

40	Electroconvulsive Therapy	1043
	<i>Keith G. Rasmussen, M.D.</i>	

41	Palliative Care	1053
	<i>William Breitbart, M.D., Harvey Max Chochinov, M.D., Ph.D., F.R.C.P.C., and Yesne Alici, M.D.</i>	

	Index	1085

Contributors

Susan E. Abbey, M.D., F.R.C.P.C.

Director, Program in Medical Psychiatry, and Director, Psychosocial Team, Multi-Organ Transplant Program, University Health Network; Associate Professor, Department of Psychiatry, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada

Yesne Alici, M.D.

Attending Psychiatrist, Geriatric Services Unit, Central Regional Hospital, Butner, North Carolina

Andrew A. Angelino, M.D.

Associate Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland

David J. Axelrod, M.D., J.D.

Assistant Professor, Internal Medicine, Jefferson Medical College; Clinical Director, Thomas Jefferson University Hospital Sickle Cell Program, Philadelphia, Pennsylvania

Rosemary Basson, M.D.

Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada

Madeleine Becker, M.D., M.A.

Assistant Professor, Department of Psychiatry and Human Behavior, Thomas Jefferson University, Philadelphia, Pennsylvania

Charles H. Bombardier, Ph.D.

Professor and Head, Division of Clinical and Neuropsychology, Department of Rehabilitation Medicine, University of Washington, Seattle

John Michael Bostwick, M.D.

Professor of Psychiatry, Mayo Clinic College of Medicine, Rochester, Minnesota

William Breitbart, M.D.

Chief, Psychiatry Service, Department of Psychiatry and Behavioral Sciences, and Attending Psychiatrist, Pain and Palliative Care Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center; Professor of Clinical Psychiatry, Department of Psychiatry, Weill Medical College of Cornell University, New York, New York

Rebecca W. Brendel, M.D., J.D.

Assistant Psychiatrist, Massachusetts General Hospital; Assistant Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts

Brenda Bursch, Ph.D.

Professor, Clinical Psychiatry and Biobehavioral Sciences, and Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, California

Alan J. Carson, M.B.Ch.B., M.Phil., M.D., F.R.C.Psych.

Consultant Neuropsychiatrist and Part-Time Senior Lecturer, Department of Clinical Neurosciences, Western General Hospital, University of Edinburgh, Edinburgh, United Kingdom

Harvey Max Chochinov, M.D., Ph.D., F.R.S.C.

Director and Canada Research Chair in Palliative Medicine, Manitoba Palliative Care Research Unit, CancerCare Manitoba; Distinguished Professor of Psychiatry and Family Medicine, Departments of Psychiatry and Family Medicine, University of Manitoba, Winnipeg, Manitoba, Canada

Michael R. Clark, M.D., M.P.H., M.B.A.

Associate Professor and Director, Adolf Meyer Chronic Pain Treatment Services, Department of Psychiatry and Behavioral Sciences, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Kathy L. Coffman, M.D.

Staff Psychiatrist, Psychiatry and Surgery; and Program Director, Psychosomatic Medicine Fellowship, Cleveland Clinic, Cleveland, Ohio

Lewis M. Cohen, M.D.

Professor of Psychiatry, Tufts University School of Medicine, Boston, Massachusetts; Director of Renal Palliative Care Initiative, Baystate Medical Center, Springfield, Massachusetts

Catherine C. Crone, M.D.

Associate Professor of Psychiatry, George Washington University Medical Center, Washington, D.C.; Vice Chair, Department of Psychiatry, Inova Fairfax Hospital, Falls Church, Virginia; Clinical Professor of Psychiatry, Virginia Commonwealth University School of Medicine, Northern Virginia Branch, Fairfax, Virginia

Daniel Cukor, Ph.D.

Assistant Professor of Psychiatry, SUNY Downstate Medical Center, Brooklyn, New York

Niccolo D. Della Penna, M.D.

Instructor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland

Michael J. Devlin, M.D.

Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Clinical Co-Director, Eating Disorders Research Unit, New York State Psychiatric Institute, New York, New York

Mary Amanda Dew, Ph.D.

Professor of Psychiatry, Psychology, and Epidemiology; Director of Quality of Life Research, Artificial Heart Program, Western Psychiatric Institute and Clinics, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chris Dickens, M.B.B.S., Ph.D.

Senior Lecturer in Psychological Medicine, Department of Psychiatry, Manchester Royal Infirmary, Manchester, United Kingdom

Andrea F. DiMartini, M.D.

Associate Professor of Psychiatry and of Surgery, Western Psychiatric Institute; Consultation Liaison to the Liver Transplant Program, Starzl Transplant Institute, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Christopher R. Dobbelsstein, M.D.

Clinical Assistant Professor of Psychiatry, Western Psychiatric Institute and Clinic, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Ilyse Dobrow DiMarco, Ph.D.

Director of Eating Disorders and Weight Management Program, The American Institute for Cognitive Therapy, New York, New York

Steven A. Epstein, M.D.

Professor and Chair, Department of Psychiatry, Georgetown University Hospital and School of Medicine, Washington, D.C.

Jesse R. Fann, M.D., M.P.H.

Associate Professor, Department of Psychiatry and Behavioral Sciences, and Adjunct Associate Professor, Departments of Rehabilitation Medicine and Epidemiology, University of Washington, Seattle; Affiliate Investigator, Fred Hutchinson Cancer Research Center; and Director, Psychiatry and Psychology Service, Seattle Cancer Care Alliance, Seattle, Washington

Charles V. Ford, M.D.

Professor, Department of Psychiatry and Behavioral Neurobiology, University of Alabama at Birmingham, Birmingham, Alabama

Andrew Francis, Ph.D., M.D.

Professor of Psychiatry, Department of Psychiatry and Behavioral Sciences, Stony Brook University Medical Center, Health Sciences Center, Stony Brook, New York

Oliver Freudenreich, M.D.

Assistant Professor of Psychiatry, Division of Psychiatry and Medicine, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Gregory L. Fricchione, M.D.

Professor of Psychiatry, Division of Psychiatry and Medicine, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Ann Goebel-Fabbri, Ph.D.

Psychologist, Behavioral and Mental Health Unit, Joslin Diabetes Center; and Instructor in Psychiatry, Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Mark S. Groves, M.D.

Assistant Clinical Professor of Psychiatry and Neurology, Albert Einstein College of Medicine; Attending Psychiatrist, Departments of Psychiatry and Neurology, Beth Israel Medical Center, New York, New York

Madhulika A. Gupta, M.D., F.R.C.P.C.

Professor, Department of Psychiatry, Schulich School of Medicine and Dentistry, University of Western Ontario, London, Ontario, Canada

Elsbeth Guthrie, M.B., Ch.B., M.R.C.Psych., M.Sc., M.D.

Honorary Professor of Psychological Medicine and Medical Psychotherapy, University of Manchester; Consultant in Psychological Medicine, Manchester Royal Infirmary, Manchester, United Kingdom

Daniel Hicks, M.D.

Associate Professor and Director of Psychosomatic Medicine, Department of Psychiatry, Georgetown University Hospital and School of Medicine, Washington, D.C.

Michael R. Irwin, M.D.

Distinguished Professor of Psychiatry and Biobehavioral Sciences, UCLA David Geffen School of Medicine; Norman Cousins Chair for Psychoneuroimmunology, UCLA Semel Institute for Neuroscience and Human Behavior; and Director, Cousins Center for Psychoneuroimmunology, Los Angeles, California

Joel P. Jahraus, M.D.

Executive Director, Park Nicollet Melrose Institute, Minneapolis, Minnesota; Adjunct Clinical Professor, University of Minnesota Medical School, Minneapolis, Minnesota

Richard Kennedy, M.D., Ph.D.

Postdoctoral Fellow, Section on Statistical Genetics, Department of Biostatistics, University of Alabama-Birmingham, Birmingham, Alabama

Paul L. Kimmel, M.D.

Senior Advisor, Division of Kidney, Urologic, and Hematologic Diseases, National Institute of Diabetes, Digestive, and Kidney Diseases, National Institutes of Health, Bethesda, Maryland

Lois E. Krahn, M.D.

Professor of Psychiatry, Mayo Clinic College of Medicine; Chair, Department of Psychiatry and Psychology, Mayo Clinic, Scottsdale, Arizona

Elisabeth J. Shakin Kunkel, M.D.

Professor, Department of Psychiatry and Human Behavior, Thomas Jefferson University, Philadelphia, Pennsylvania

Maeve Leonard, M.B., M.R.C.Psych.

Clinical and Research Tutor in Psychiatry, Graduate Entry Medical School, University of Limerick, Limerick, Ireland

James L. Levenson, M.D.

Professor of Psychiatry, Medicine, and Surgery, Virginia Commonwealth University School of Medicine, Richmond, Virginia

Madeline Li, M.D., Ph.D., F.R.C.P.C.

Assistant Professor, Department of Psychiatry, University of Toronto; Psychiatrist, Department of Psychosocial Oncology and Palliative Care, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada

Antonio Lobo, M.D., Ph.D.

Professor and Chairman, Department of Medicine and Psychiatry, Universidad de Zaragoza; and Chief, Psychosomatics and Consultation-Liaison Psychiatry Service, Hospital Clínico Universitario, Zaragoza, Spain

The Elizabeth Plank Althouse Professor and Chairman, Department of Psychiatry, Johns Hopkins Bayview Medical Center; Vice Chairman, Department of Psychiatry and Behavioral Sciences, The Johns Hopkins Hospital; Co-Director, Division of Geriatric Psychiatry and Neuropsychiatry, and Director, Memory and Alzheimer's Treatment Center, The Johns Hopkins University and Hospital, Baltimore, Maryland

Dimitri D. Markov, M.D.

Assistant Professor, Departments of Psychiatry and Human Behavior and of Medicine, Thomas Jefferson University, Philadelphia, Pennsylvania

Elaine Martin, M.D.

Fellow in Psychosomatic Medicine, Department of Psychiatry and Human Behavior, Thomas Jefferson University, Philadelphia, Pennsylvania

Mary Jane Massie, M.D.

Professor of Clinical Psychiatry, Weill Medical College of Cornell University; Attending Psychiatrist, Memorial Sloan-Kettering Cancer Center, New York, New York

David J. Meagher, M.D., M.R.C.Psych., M.Sc.

Professor of Psychiatry, University of Limerick Medical School, Castletroy, Limerick, Ireland

Franklin G. Miller, Ph.D.

Bioethicist, Department of Bioethics, Clinical Center, Bethesda, Maryland

Kimberley Miller, M.D., F.R.C.P.C.

Lecturer, University of Toronto; Attending Psychiatrist, Princess Margaret Hospital, Toronto, Ontario, Canada

Gail Musen, Ph.D.

Assistant Investigator, Behavioral and Mental Health Unit, Joslin Diabetes Center; and Instructor in Psychiatry, Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Philip R. Muskin, M.D.

Chief, Consultation-Liaison Psychiatry, Columbia University Medical Center; Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Faculty, Columbia University Psychoanalytic Center for Training and Research, New York, New York

Shamim H. Nejad, M.D.

Instructor in Psychiatry, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts

Patrick G. O'Malley, M.D., M.P.H., F.A.C.P.

Professor of Medicine, Uniformed Services University, Bethesda, Maryland

Chiadi U. Onyike, M.D., M.H.S.

Assistant Professor of Psychiatry and Behavioral Sciences and Co-Director, FTD & Young-Onset Dementias Clinic, Division of Geriatric Psychiatry and Neuropsychiatry, The Johns Hopkins University and Hospital, Baltimore, Maryland

James A. Owen, Ph.D.

Associate Professor of Psychiatry and of Pharmacology and Toxicology, Queen's University; Director, Psychopharmacology Lab, Providence Care Mental Health Services, Kingston, Ontario, Canada

Olu Oyesanmi, M.D., M.P.H.

Research Analyst, ECRI Institute, Plymouth Meeting, Pennsylvania

Pauline S. Powers, M.D.

Professor of Psychiatry and Behavioral Medicine, Clinical and Translational Science Institute, College of Medicine, University of South Florida, Tampa, Florida

Miguel Ángel Quintanilla, M.D., Ph.D.

Attending Psychiatrist, Hospital Clínico Universitario; and Instructor, Department of Medicine and Psychiatry, Universidad de Zaragoza, Zaragoza, Spain

J. J. Rasimas, M.D., Ph.D.

Associate Professor of Psychiatry, Penn State College of Medicine/Milton S. Hershey Medical Center, Hershey, Pennsylvania; Medical Toxicology Fellow, Penn State College of Medicine, PinnacleHealth Toxicology Center, Harrisburg, Pennsylvania

Keith G. Rasmussen, M.D.

Associate Professor of Psychiatry, Mayo Clinic Department of Psychiatry and Psychology, Rochester, Minnesota

Peter M. Rees, M.D., Ph.D.

Department of Medicine, Burnaby Hospital, Burnaby, British Columbia, Canada

Gary Rodin, M.D., F.R.C.P.C.

Professor, Department of Psychiatry, University of Toronto; Head, Department of Psychosocial Oncology and Palliative Care, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada

Donald L. Rosenstein, M.D.

Professor and Director, Comprehensive Cancer Support Program, Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Deborah Rosenthal-Asher, M.A.

Doctoral Candidate, Ferkauf Graduate School of Psychology, Albert Einstein College of Medicine, Yeshiva University, Brooklyn, New York

Carlos A. Santana, M.D.

Associate Professor of Psychiatry and Behavioral Medicine, Director of Outpatient Services, Director of Psychiatry Research Division, College of Medicine, University of South Florida, Tampa, Florida

Pedro Saz, M.D., Ph.D.

Professor, Department of Medicine and Psychiatry, Universidad de Zaragoza, Zaragoza, Spain

Ronald Schouten, M.D., J.D.

Psychiatrist, Massachusetts General Hospital; Associate Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts

Peter A. Shapiro, M.D.

Professor of Clinical Psychiatry, Columbia University; Director, Fellowship Training Program in Psychosomatic Medicine; and Associate Director, Consultation-Liaison Psychiatry Service, New York Presbyterian Hospital-Columbia University Medical Center, New York, New York

Michael C. Sharpe, M.A., M.D., F.R.C.P., F.R.C.Psych.

Professor of Psychological Medicine, Psychological Medicine Research, University of Edinburgh, Royal Edinburgh Hospital, Edinburgh United Kingdom

Felicia A. Smith, M.D.

Director, Acute Psychiatry Service, Massachusetts General Hospital, Boston, Massachusetts

Jorge Luis Sotelo, M.D.

Assistant Professor of Clinical Psychiatry, Division of Consultation Psychiatry/Psychosomatic Medicine; Co-Director, Psychiatry Clerkship for Medical Students, Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, Florida

Theodore A. Stern, M.D.

Chief, Psychiatric Consultation Service, Massachusetts General Hospital; Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts

Donna E. Stewart, M.D, F.R.C.P.C.

University Professor and Chair of Women's Health, University of Toronto, University Health Network Women's Health Program, Toronto, Ontario, Canada

Jon Stone, M.B.Ch.B., Ph.D., F.R.C.P.

Consultant Neuropsychiatrist and Part-Time Senior Lecturer, Department of Clinical Neurosciences, Western General Hospital, University of Edinburgh, Edinburgh, United Kingdom

Nada Logan Stotland, M.D., M.P.H.

Professor of Psychiatry and Obstetrics/Gynecology, Rush Medical College, Chicago, Illinois

Margaret Stuber, M.D.

Jane and Marc Nathanson Professor, Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine at UCLA, Los Angeles, California

Glenn J. Treisman, M.D., Ph.D.

Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland

Paula T. Trzepacz, M.D.

Senior Medical Fellow, Neurosciences, Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, Indiana; Clinical Professor of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana; Clinical Professor of Psychiatry, University of Mississippi Medical School, Jackson, Mississippi; Adjunct Professor of Psychiatry, Tufts University School of Medicine, Boston, Massachusetts

Simone N. Vigod, M.D., F.R.C.P.C.

Assistant Professor, Department of Psychiatry, University of Toronto, Women's College Hospital, Toronto, Ontario, Canada

Crystal C. Watkins, M.D., Ph.D.

Clinical Fellow, Mood Disorders and Neuroimaging, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland

Michael Weaver, M.D., F.A.S.A.M.

Associate Professor of Internal Medicine and Psychiatry and Medical Director, Substance Abuse Consult Service, Virginia Commonwealth University School of Medicine, Richmond, Virginia

Thomas N. Wise, M.D.

Chairman, Department of Psychiatry, Inova Health System, Falls Church, Virginia; Associate Chair and Professor, Department of Psychiatry, George Washington University School of Medicine, Washington, D.C.; Professor of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland; Professor of Psychiatry, Virginia Commonwealth University School of Medicine, Inova Campus, Falls Church, Virginia

Lawson Wulsin, M.D.

Professor of Psychiatry and Family Medicine, Department of Psychiatry, University of Cincinnati, Cincinnati, Ohio

Adam Zeman, M.A., D.M., F.R.C.P.

Consultant Neurologist and Part-Time Senior Lecturer, Department of Clinical Neurosciences, Western General Hospital, University of Edinburgh, Edinburgh, United Kingdom

Foreword

Thomas N. Wise, M.D.

THIS SECOND EDITION of *The American Psychiatric Publishing Textbook of Psychosomatic Medicine* demonstrates the evolution of the medical textbook as well as the field of Psychosomatic Medicine. Both have long and circuitous developmental pathways. Among the first recorded medical texts were classic Egyptian papyri that outlined empirical observations from ancient physicians on burn care, wound management, gastrointestinal ailments, and congestive heart failure (Trevisanato 2006). The Hippocratic and Galenic traditions also carefully described diseases as well as invoked religious etiological explanations but incorporated the role of emotions into the genesis of physical disorders (Schwab 1985). Heinroth is said to have coined the term *psychosomatic* in 1818 (Steinberg 2007), although he emphasized the quasi-religious mechanism of disorders of the “soul” (Steinberg 2004).

The initial “modern” textbooks of psychiatry tended to ignore psychiatric issues interfacing with medical disorders. This was most likely a result of Psychiatry’s isolation in the asylum setting. Griesinger’s 1867 textbook was one of the first to view Psychiatry as a legitimate field of medicine with a strong organic substrate. Griesinger discussed delirium and dementia but gave only passing reference to hysteria. He felt that hypochondriasis was often due to “moral causes” but noted that such sufferers “often read medical books.” Cheyne’s (1733/1991) *The English Malady* is a monograph upon what would now be considered severe health anxiety and the proposed diagnosis for DSM-V, complex somatic symptom disorder.

With the rise of sophisticated bacteriology and molecular biology, the role of psychiatric disorders was relegated to the “art” of medicine rather than the “science” of the profession (Brown 1989). In the introduction to the fourteenth edition of Osler’s venerable *Principles and Practice of Medicine*, the editor, Dr. Henry Christian, defined psychosomatic medicine as “that part of medicine, which is concerned with an appraisal of both the emotional and the

physical mechanisms involved in the disease processes of the individual patient with particular emphasis on the influence that these two factors exert on each other and on the individual as a whole” (Christian 1942, p. 1). This concept is similar to the first of the three basic definitions of psychosomatic medicine discussed by Lipowski (1984): 1) a research approach looking at biological, psychological, and cultural variables; 2) a “holistic” view of patients; and 3) a subspecialized type of psychiatry, commonly called consultation-liaison. Christian followed his own definition by sadly stating that “psychiatry... will need to be correlated with the demonstrable systemic changes and effects of disease before we can make much advance in psychosomatic medicine” (Christian 1942, p. 2). Contemporary medical and psychiatric science has reached such a stage in the development of our field.

Under the able direction of Dr. Levenson, a collection of outstanding authors have compiled the current knowledge of our field, which is now a formal subspecialty of Psychiatry. A thousand or more in the United States have qualified for this designation via the examination rigorously administered by the American Board of Psychiatry and Neurology. Pessimism about our field being marginalized was premature, as was the belief that the name *Psychosomatic Medicine* would not be accepted (Friedman 1988; Steinberg 2004). This volume demonstrates both the breadth and the knowledge base of our field. As a research approach, the database is increasing, both in the mechanisms of interaction between mind and body and in the clinical importance of recognizing the role of psychiatric issues in medical disorders and medical care. Such data complement the unique skills of psychosomatic specialists who seek to systematically understand how each patient’s life story affects his or her life trajectory in the face of illness (Engel 1990; Viederman and Perry 1980).

With advances in such information, textbooks are essential and require regular updating. Kraepelin’s textbook

had nine editions, while Osler's original text went through twenty-four (Hippius and Muller 2008). *Psychosomatic Medicine* is a term that is now clearly recognized within Psychiatry as a body of research and a clinical subspecialty (Fava and Sonino 2010). I am sure that this second iteration is the first of many more as Psychosomatic Medicine continues to accrue knowledge in its quest to alleviate the suffering of patients. As Osler (1921) noted, "Medicine arose out of the primal sympathy of man with man; out of the desire to help those in sorrow, need and sickness" (pp. 6-7). This Textbook clearly offers great help with that task.

Preface

James L. Levenson, M.D.

WHAT IS PSYCHOSOMATIC Medicine? In the past, Psychosomatic Medicine has had ambiguous connotations, alternatively “psychogenic” or “holistic,” but it is the latter meaning that has characterized its emergence as a contemporary scientific and clinical discipline (Lipowski 1984). In this book, Psychosomatic Medicine refers to a specialized area of psychiatry whose practitioners have particular expertise in the diagnosis and treatment of psychiatric disorders and difficulties in complex medically ill patients (Gitlin et al. 2004). We treat and study three general groups of patients: 1) those with comorbid psychiatric and general medical illnesses complicating each other’s management, 2) those with somatoform and functional disorders, and 3) those with psychiatric disorders that are the direct consequence of a primary medical condition or its treatment. Psychosomatic Medicine practitioners work as hospital-based consultation-liaison psychiatrists (Kornfeld 1996), on medical-psychiatric inpatient units (Kathol and Stoudemire 2002), and in settings in which mental health services are integrated into primary care (Unutzer et al. 2002). Thus, the field’s name reflects the fact that it exists at the interface of psychiatry and medicine.

Historical Background

Psychosomatic Medicine is the newest psychiatric subspecialty formally approved by the American Board of Medical Specialties (ABMS). There have been many other names for this specialized field, including consultation-liaison psychiatry, medical-surgical psychiatry, psychological medicine, and psychiatric care of the complex medically ill. In 2001, the Academy of Psychosomatic Medicine applied to the American Board of Psychiatry and Neurology (ABPN) for the recognition of Psychosomatic Medicine as a subspecialty field of psychiatry, choosing to return to the name for the field embedded in our history, our journals, and our national organizations. Subsequent formal approval was received from the American Psychiatric Association, the

ABPN, the Residency Review Committee (RRC) of the Accreditation Council for Graduate Medical Education (ACGME), and the ABMS. In the 4 years that have elapsed since the first certifying examination in 2005, 1,078 psychiatrists have been certified in Psychosomatic Medicine in the United States.

Psychosomatic Medicine has a rich history. The term *psychosomatic* was introduced by Johann Heinroth in 1818, and Felix Deutsch introduced the term *psychosomatic medicine* around 1922 (Lipsitt 2001). Psychoanalysts and psychophysiatrists pioneered the study of mind-body interactions from very different vantage points, each contributing to the growth of Psychosomatic Medicine as a clinical and scholarly field. The modern history of the field (see Table 1) perhaps starts with the Rockefeller Foundation’s funding of psychosomatic medicine units in several U.S. teaching hospitals in 1935. The National Institute of Mental Health made it a priority to foster the growth of consultation-liaison psychiatry through training grants (circa 1975) and a research development program (circa 1985).

Psychosomatic Medicine is a scholarly discipline with classic influential texts (Table 2), many devoted journals (Table 3), and both national (Table 4) and international (Table 5) professional/scientific societies. The Academy of Psychosomatic Medicine (APM) is the only U.S. national organization primarily dedicated to Psychosomatic Medicine as a psychiatric subspecialty. The American Psychosomatic Society (APS), an older cousin, is primarily devoted to psychosomatic research, and its members come from many disciplines (Wise 1995). While consultation-liaison psychiatry and psychosomatic medicine first flourished in the United States, exciting work now comes from around the world. APM’s counterpart in Europe is the European Association of Consultation-Liaison Psychiatry and Psychosomatics (EACLPP) (Wise and Lobo 2001), and similar to APS is the European Conference on Psychosomatic Research (ECPR). There are now associations or special interest groups for

psychosomatic medicine and consultation-liaison psychiatry in many countries, including Argentina, Brazil, Germany, Italy, the Netherlands, Portugal, Spain, and the United Kingdom. The international nature of the field is reflected in this textbook's Editorial Board and the contributors to this text, who include psychiatrists from Austria, Brazil, Canada, Germany, Hong Kong, Ireland, the Netherlands, Spain, the United Kingdom, and the United States. The first edition of this book has been translated into Chinese and Spanish.

Second Edition of the Textbook

There are 97 contributors to the second edition of this textbook, 38 of them new authors. Twenty-three of the contributors are from countries other than the United States, including Canada, Ireland, Spain, and the United Kingdom. Of this textbook's 41 chapters, 2 are new, bringing topics not covered in the first edition. An additional 9 chapters are newly authored. The remaining 30 chapters have all been extensively revised. In sum, about 40% of the content of this edition is new. All 41 chapters have been reviewed by at least one member of the Editorial Board, and most have been reviewed by an expert in the relevant medical specialty or allied health profession. The distinguished Editorial Board includes noted authorities in psychosomatic medicine and consultation-liaison psychiatry from 17 leading academic centers, representing Austria, Brazil, Canada, Germany, Hong Kong, the Netherlands, Spain, the United Kingdom, and the United States.

This book is organized into four sections. Chapters 1–4 cover general principles in evaluation and management, legal and ethical issues, and psychological reactions to illness. Chapters 5–17 are devoted to psychiatric symptoms and disorders in the medically ill. Chapters 18–37 address issues within each of the medical specialties and subspecialties. The final 4 chapters review psychiatric treatment

in the medically ill, including psychopharmacology, psychotherapy, electroconvulsive therapy, and palliative care.

This book has attempted to capture the diversity of our field, whose practitioners do not place equal emphasis on the syllables of “bio-psycho-social.” There is not unanimity among us on some questions, and diverse opinions will be found in this book. Psychosomatic Medicine has evolved, since its start, from a field based on clinical experience, conjecture, and theorizing into a discipline grounded in empirical research that is growing and spreading its findings into many areas of medical care.

Acknowledgments

I owe an enormous debt of gratitude to the many people who made this book possible. First, to the contributors, who were patient under repeated onslaughts of red track-changes from me. An assertive Editorial Board pushed us all toward the highest standards.

I am particularly grateful to Richard Shaw at Stanford University and my colleagues at Virginia Commonwealth University who generously gave their time to critique chapters in their respective disciplines, including Ericka Breden, Christian Barrett, Christopher Kogut, Susan Kornstein, Julia Nunley, Mary Ellen Olbrisch, and Brandon Wills.

Tina Coltri-Marshall provided invaluable service, going beyond the call of duty to keep everyone organized and on schedule. Editor-in-Chief Bob Hales as well as John McDuffie and Bob Pursell at American Psychiatric Publishing, Inc. (APPI) gave expert advice and encouragement from start to finish, and I am grateful to all of the APPI staff, including Ellie Abedi, Judy Castagna, Bessie Jones, Greg Kuny, Rebecca Richters, and Susan Westrate.

Finally, this book would not have been possible without enthusiastic support from my chair, Joel Silverman; the help of my assistant, Pam Copeland; and the patience and tolerance of my wife, Janet Distelman.

PART I

General Principles in Evaluation and Management

Psychiatric Assessment and Consultation

Felicia A. Smith, M.D.

James L. Levenson, M.D.

Theodore A. Stern, M.D.

PSYCHOSOMATIC MEDICINE IS rooted in the practice of consultation-liaison psychiatry, having expanded from its beginnings on a handful of general medical wards in the 1930s to specialized medical units throughout various parts of the health care delivery system. Practitioners in this psychiatric subspecialty assist with the care of a variety of patients, especially those with complex conditions such as cancer, organ failure, HIV infection, dementia, delirium, agitation, psychosis, substance abuse or withdrawal, somatoform disorders, personality disorders, and mood and anxiety disorders, as well as suicidal ideation, treatment nonadherence, and aggression and other behavioral problems (Gitlin et al. 2004; Hackett et al. 2004). In addition, ethical and legal considerations are often critical elements of the psychiatric consultation. In the medical setting, prompt recognition and evaluation of psychiatric problems are essential because psychiatric comorbidity commonly exacerbates the course of medical illness, causes significant distress in the patient, prolongs hospital length of stay, and increases costs of care.

In this introductory chapter, we present a detailed approach to psychiatric assessment and consultation in medical settings. Successful psychiatric consultants must be flexible when evaluating affective, behavioral, and cognitive disturbances in the medically ill. In the final section of the chapter, we briefly outline the benefits of psychiatric consultation for patients as well as for the greater hospital and medical communities.

Psychiatric Consultation in the General Hospital

Psychiatrists who work in medical settings are charged with providing expert consultation to medical and surgical patients. In many respects, the psychiatric care of such patients is no different from the treatment of patients in a psychiatric clinic or in a private office. However, the constraints of the modern hospital environment demand a high degree of adaptability. Comfort, quiet, and privacy are scarce commodities in medical and surgical units, and the consultant's bedside manner is important in compensating for this. Interruptions by medical or nursing staff, visitors, and roommates erode the privacy that the psychiatrist usually expects. Patients who are sick, preoccupied with their physical condition, and in pain are ill-disposed to engage in the exploratory interviews that often typify psychiatric evaluations conducted in other settings. Monitoring devices replace the plants, pictures, and other accoutrements of a typical office. Nightstands and tray tables are littered with medical paraphernalia commingled with personal effects.

The consultant must be adept at gathering the requisite diagnostic information related to a patient's condition and must be able to tolerate the sights, sounds, and smells of the sickroom. Additional visits for more history are often inevitable. In the end, the diagnosis will likely fall into

TABLE 1-1. Categories of psychiatric differential diagnoses in the general hospital

- ♦ Psychiatric presentations of medical conditions
- ♦ Psychiatric complications of medical conditions or treatments
- ♦ Psychological reactions to medical conditions or treatments
- ♦ Medical presentations of psychiatric conditions
- ♦ Medical complications of psychiatric conditions or treatments
- ♦ Comorbid medical and psychiatric conditions

Source. Adapted from Lipowski 1967.

one (or more) of the categories outlined in Lipowski's (1967) timeless classification (Table 1-1).

Although the consultant is summoned by the patient's physician, in most cases the visit is unannounced and is not requested by the patient, from whom cooperation is expected. Explicitly acknowledging this reality is often sufficient to gain the patient's cooperation. Cooperation is enhanced if the psychiatrist sits down and operates at eye level with the patient. By offering to help the patient get comfortable (e.g., by adjusting the head of the bed, bringing the patient a drink or a blanket, or adjusting the television) before and after the encounter, the consultant can increase the chances of being welcomed then and for follow-up evaluations.

When psychiatrists are consulted for unexplained physical symptoms or for pain management, it is useful to empathize with the distress that the patient is experiencing. This avoids conveying any judgment on the etiology of the pain except that their suffering is real. After introductions, if the patient is in pain, the consultant's first questions should address this issue. Failing to do so conveys a lack of appreciation for the patient's distress and may be taken by the patient as disbelief in his or her symptoms. Starting with empathic questions about the patient's suffering establishes rapport and also guides the psychiatrist in setting the proper pace of the interview. Finally, because a psychiatric consultation will cause many patients to fear that their physician thinks they are "crazy," the psychiatrist may first need to address this fear.

Process of the Consultation

Although it is rarely as straightforward as the following primer suggests, the process of psychiatric consultation should, in the end, include all the components explained below and summarized in Table 1-2.

TABLE 1-2. Procedural approach to psychiatric consultation

- ♦ Speak directly with the referring clinician.
- ♦ Review the current records and pertinent past records.
- ♦ Review the patient's medications.
- ♦ Gather collateral data.
- ♦ Interview and examine the patient.
- ♦ Formulate diagnostic and therapeutic strategies.
- ♦ Write a note.
- ♦ Speak directly with the referring clinician.
- ♦ Provide periodic follow-up.

Speak Directly With the Referring Clinician

Requests for psychiatric consultation are notorious for being vague and imprecise (e.g., "rule out depression" or "patient with schizophrenia"). They sometimes signify only that the team recognizes that a problem exists; such problems may range from an untreated psychiatric disorder to the experience of countertransference feelings. In speaking with a member of the team that has requested the consultation, the consultant employs some of the same techniques that will be used later in examining the patient; that is, he or she listens to the implicit as well as the explicit messages from the other physician (Murray 2004). Is the physician angry with the patient? Is the patient not doing what the team wants him or her to do? Is the fact that the patient is young and dying leading to the team's overidentification with him or her? Is the team frustrated by an elusive diagnosis? All of these situations generate emotions that are difficult to reduce to a few words conveyed in a consultation request; moreover, the feelings often remain out of the team's awareness. This brief interaction may give the consultant invaluable information about how the consultation may be useful to the team and to the patient.

Review the Current Records and Pertinent Past Records

When it is done with the unfailing curiosity of a detective hot on the trail of hidden clues, reading a chart can be an exciting and self-affirming part of the consultation process. Although it does not supplant the consultant's independent history taking or examination, the chart review provides a general orientation to the case. Moreover, the consultant is in a unique position to focus on details that may have been previously overlooked. For example, nurses often document salient neurobehavioral data (e.g., the level of awareness and the presence of confusion or agitation);

physical and occupational therapists estimate functional abilities crucial to the diagnosis of cognitive disorders and to the choice of an appropriate level of care (e.g., nursing home or assisted-living facility); and speech pathologists note alterations in articulation, swallowing, and language, all of which may indicate an organic brain disease. All of them may have written progress notes about adherence to treatment regimens, unusual behavior, interpersonal difficulties, or family issues encountered in their care of the patient. These notes may also provide unique clues to the presence of problems such as domestic violence, factitious illness, or personality disorders. In hospitals or clinics where nurses' notes are kept separate from the physician's progress notes, it is essential for the consultant to review those sections.

Review the Patient's Medications

Construction of a medication list at various times (e.g., when at home, on admission, on transfer within the hospital, and at present) is a good, if not essential, practice. Special attention should be paid to medications with psychoactive effects and to those associated with withdrawal syndromes (both obvious ones like benzodiazepines and opiates, and less obvious ones like antidepressants, anti-convulsants, and beta-blockers). Review of order sheets or computerized order entries is not always sufficient, because—for a variety of reasons—patients may not always receive prescribed medications; therefore, medication administration records should also be reviewed. Such records are particularly important for determining the frequency of administration of medicines ordered on an as-needed basis. For example, an order for lorazepam 1–2 mg every 4–6 hours as needed may result in a patient receiving anywhere from 0 mg to 12 mg in a day, which can be critical in cases of withdrawal or oversedation.

Gather Collateral Data

Histories from hospitalized medically ill patients may be especially spotty and unreliable, if not nonexistent (e.g., with a patient who is somnolent, delirious, or comatose). Data from collateral sources (e.g., family members; friends; current and outpatient health care providers; case managers; and, in some cases, police and probation officers) may be of critical importance. However, psychiatric consultants must guard against prizing any single party's version of historical events over another's; family members and others may lack objectivity, be in denial, be overinvolved, or have a personal agenda to advance. For example, family members tend to minimize early signs of dementia and to overreport depression in patients with dementia. Confidentiality

must be valued when obtaining collateral information. Ideally, one obtains the patient's consent first; however, this may not be possible if the patient lacks capacity or if a dire emergency is in progress (see Chapter 2, "Legal Issues," and Chapter 3, "Ethical Issues"). Moreover, in certain situations there may be contraindications to contacting some sources of information (e.g., an employer of a patient with substance abuse or the partner of a woman who is experiencing abuse). Like any astute physician, the psychiatrist collates and synthesizes all available data and weighs each bit of information according to the reliability of its source.

Interview and Examine the Patient

Armed with information gleaned and elicited from other sources, the psychiatric consultant now makes independent observations of the patient and collects information that may be the most reliable of all because it comes from direct observations. For non-English-speaking patients, a translator is often needed. Although using family members may be expedient, their presence often compromises the questions asked and the translations offered because of embarrassment or other factors. It is therefore important to utilize hospital translators or, for less common languages, services via telephone. This can be difficult, but it may be necessary in obtaining a full and accurate history.

The process and content of the psychiatric interview must be adapted to the consultation setting. To establish rapport and to have a therapeutic impact, the psychiatrist should assume an engaging, more spontaneous stance (typically, after explaining the purpose of the visit and inquiring about the patient's physical complaints) and deviate from the principles of anonymity, abstinence, and neutrality that help form the foundation for psychodynamic psychotherapy (see Perry and Viederman 1981). Long silences common in psychoanalytic psychotherapy are rarely appropriate with medical patients, who have not sought out psychiatric assessment and who lack the stamina for long interviews. Deeply exploring traumatic events shortly after they occur may not be ideal; it is often sufficient to acknowledge the patient's past hardships and provide a perspective of what treatment after discharge can offer. Neither a rigidly biological approach (which can impede rapport) nor an exclusively psychoanalytic inquiry should be adopted. It is especially important to elicit patients' beliefs about their illness (what is wrong, what caused it, what treatment can do) so that emotional responses and behaviors can be placed in perspective. Although the psychiatric consultant often works under pressure of time (e.g., conducting the evaluation between medical tests and procedures), an open-ended interview style should be used.

Mental Status Examination

A thorough mental status examination is central to the psychiatric evaluation of the medically ill patient. Because the examination is hierarchical, care must be taken to complete it in a systematic fashion (Hyman and Tesar 1994). The astute consultant will glean invaluable diagnostic clues from a combination of observation and questioning.

Level of consciousness. Level of consciousness depends on normal cerebral arousal by the reticular activating system. A patient whose level of consciousness is impaired will inevitably perform poorly on cognitive testing. The finding of disorientation implies cognitive failure in one or several domains. It is helpful to test orientation near the start of the mental status examination.

Attention. The form of attention most relevant to the clinical mental status examination is the sustained attention that allows one to concentrate on cognitive tasks. Disruption of attention—often by factors that diffusely disturb brain function, such as drugs, infection, or organ failure—is a hallmark of delirium. Sustained attention is best tested with moderately demanding, nonautomatic tasks such as reciting the months backward or, as in the Mini-Mental State Examination (MMSE; Folstein et al. 1975), spelling *world* backward or subtracting 7 serially from 100. Serial subtraction is intended to be a test of attention, not arithmetic ability, so the task should be adjusted to the patient's native ability and educational level (serial 3s from 50, serial 1s from 20). An inattentive patient's performance on other parts of the mental status examination may be affected on any task requiring sustained focus.

Memory. Working memory is tested by asking the patient to register some information (e.g., three words) and to recall that information after an interval of at least 3 minutes during which other testing prevents rehearsal. This task can also be considered a test of recent memory. Semantic memory is tapped by asking general knowledge questions (e.g., "Who is the president?") and by naming and visual recognition tasks. The patient's ability to remember aspects of his or her history serves as an elegant test of episodic memory (as well as of remote memory). Because semantic and episodic memories can be articulated, they constitute declarative memory. In contrast, procedural memory is implicit in learned action (e.g., riding a bicycle) and cannot be described in words. Deficits in procedural memory can be observed in a patient's behavior during the clinical evaluation.

Executive function. Executive function refers to the abilities that allow one to plan, initiate, organize, and monitor thought and behavior. These abilities, which localize

broadly to the frontal lobes, are essential for normal social and professional performance but are difficult to test. Frontal lobe disorders often make themselves apparent in social interaction with a patient and are suspected when one observes disinhibition, impulsivity, disorganization, abulia, or amotivation. Tasks that can be used to gain some insight into frontal lobe function include verbal fluency, such as listing as many animals as possible in 1 minute; motor sequencing, such as asking the patient to replicate a sequence of three hand positions; the go/no-go task, which requires the patient to tap the desk once if the examiner taps once, but not to tap if the examiner taps twice; and tests of abstraction, including questions like "What do a tree and a fly have in common?"

Language. Language disorders result from lesions of the dominant hemisphere. In assessing language, one should first note characteristics of the patient's speech (e.g., nonfluency or paraphasic errors) and then assess comprehension. Naming is impaired in both major varieties of aphasia, and anomia can be a clue to mild dysphasia. Reading and writing should also be assessed. Expressive (Broca's or motor) aphasia is characterized by effortful, nonfluent speech with use of phonemic paraphasias (incorrect words that approximate the correct ones in sound), reduced use of function words (e.g., prepositions and articles), and well-preserved comprehension. Receptive (Wernicke's or sensory) aphasia is characterized by fluent speech with both phonemic and semantic paraphasias (incorrect words that approximate the correct ones in meaning) and poor comprehension. The stream of incoherent speech and the lack of insight in patients with Wernicke's aphasia sometimes lead to misdiagnosis of a primary thought disorder and psychiatric referral; the clue to the diagnosis of a language disorder is the severity of the comprehension deficit. Global dysphasia combines features of Broca's and Wernicke's aphasias. Selective impairment of repetition characterizes conduction aphasia. The nondominant hemisphere plays a part in the appreciation and production of the emotional overtones of language.

Praxis. Apraxia refers to an inability to perform skilled actions (e.g., using a screwdriver, brushing one's teeth) despite intact basic motor and sensory abilities. These abilities can be tested by asking a patient to mime such actions or by asking the patient to copy unfamiliar hand positions. Constructional apraxia is usually tested with the Clock Drawing Test. Gait apraxia involves difficulty in initiating and maintaining gait despite intact basic motor function in the legs. Dressing apraxia is difficulty in dressing caused by an inability to coordinate the spatial arrangement of clothes with the body.

Mood and affect. Mood and affect both refer to the patient's emotional state, mood being the patient's perception and affect being the interviewer's perception. The interviewer must interpret both carefully, taking into account the patient's medical illness. Normal but intense expressions of emotion (e.g., grief, fear, or irritation) are common in patients with serious medical illness but may be misperceived by nonpsychiatric physicians as evidence of psychiatric disturbance. Disturbances in mood and affect may also be the result of brain dysfunction or injury. Irritability may be the first sign of many illnesses, ranging from alcohol withdrawal to rabies. Blunted affective expression may be a sign of Parkinson's disease. Intense affective lability (e.g., pathological crying or laughing) with relatively normal mood occurs with some diseases or injuries of the frontal lobes. In addition, depressed or euphoric affect may be a medication side effect.

Perception. Perception in the mental status examination is primarily concerned with hallucinations and illusions. However, before beginning any part of the clinical interview and the mental status examination, the interviewer should establish whether the patient has any impairment in vision or hearing that could interfere with communication. Unrecognized impairments have led to erroneous impressions that patients were demented, delirious, or psychotic. Although hallucinations in any modality may occur in primary psychotic disorders (e.g., schizophrenia or affective psychosis), prominent visual, olfactory, gustatory, or tactile hallucinations suggest a secondary medical etiology. Olfactory and gustatory hallucinations may be manifestations of seizures, and tactile hallucinations are often seen with substance abuse.

Judgment and insight. The traditional question for the assessment of judgment—"What would you do if you found a letter on the sidewalk?"—is much less informative than questions tailored to the problems faced by the patient being evaluated; for example, "If you couldn't stop a nosebleed, what would you do?" "If you run out of medicine and you can't reach your doctor, what would you do?" Similarly, questions to assess insight should focus on the patient's understanding of his or her illness, treatment, and life circumstances.

Further guidance on mental status examination. An outline of the essential elements of a comprehensive mental status examination is presented in Table 1-3. Particular cognitive mental status testing maneuvers are described in more detail in Table 1-4. More detailed consideration of the mental status examination can be found elsewhere (Strub and Black 2000; Trzepacz and Baker 1993).

TABLE 1-3. The mental status examination

Level of consciousness

- ♦ Alert, drowsy, somnolent, stuporous, comatose; fluctuations suggest delirium

Appearance and behavior

- ♦ Overall appearance, grooming, hygiene
- ♦ Cooperation, eye contact, psychomotor agitation or retardation
- ♦ Abnormal movements: tics, tremors, chorea, posturing

Attention

- ♦ Vigilance, concentration, ability to focus, sensory neglect

Orientation and memory

- ♦ Orientation to person, place, time, situation
- ♦ Recent, remote, and immediate recall

Language

- ♦ Speech: rate, volume, fluency, prosody
- ♦ Comprehension and naming ability
- ♦ Abnormalities including aphasia, dysarthria, agraphia, alexia, clanging, neologisms, echolalia

Constructional ability

- ♦ Clock drawing to assess neglect, executive function, and planning
- ♦ Drawing of a cube or intersecting pentagons to assess parietal function

Mood and affect

- ♦ Mood: subjective sustained emotion
- ♦ Affect: observed emotion—quality, range, appropriateness

Form and content of thought

- ♦ Form: linear, circumstantial, tangential, disorganized, blocked
- ♦ Content: delusions, paranoia, ideas of reference, suicidal or homicidal ideation

Perception

- ♦ Auditory, visual, gustatory, tactile, and olfactory hallucinations

Judgment and insight

- ♦ Understanding of illness and consequences of specific treatments offered

Reasoning

- ♦ Illogical versus logical; ability to make consistent decisions

Physical Examination

Although the interview and mental status examination as outlined above are generally thought to be the primary diagnostic tools of the psychiatrist, the importance of the

TABLE 1-4. Detailed assessment of cognitive domains

Cognitive domain	Assessment
Level of consciousness and arousal	Inspect the patient.
Orientation to place and time	Ask direct questions about both of these.
Registration (recent memory)	Have the patient repeat three words immediately.
Recall (working memory)	Have the patient recall the same three words after performing another task for at least 3 minutes.
Remote memory	Ask about the patient's age, date of birth, milestones, or significant life or historical events (e.g., names of presidents, dates of wars).
Attention and concentration	Subtract serial 7s (adapt to the patient's level of education; subtract serial 3s if less educated). Spell <i>world</i> backward (this may be difficult for non-English speakers). Test digit span forward and backward. Have the patient recite the months of the year (or the days of the week) in reverse order.
Language	(Adapt the degree of difficulty to the patient's educational level.)
♦ Comprehension	Inspect the patient while he or she answers questions. Ask the patient to point to different objects. Ask yes-or-no questions. Ask the patient to write a phrase (paragraph).
♦ Naming	Show a watch, pen, or less familiar objects, if needed.
♦ Fluency	Assess the patient's speech. Have the patient name as many animals as he or she can in 1 minute.
♦ Articulation	Listen to the patient's speech. Have the patient repeat a phrase.
♦ Reading	Have the patient read a sentence (or a longer paragraph if needed).
Executive function	Determine if the patient requires constant cueing and prompting.
♦ Commands	Have the patient follow a three-step command.
♦ Construction tasks	Have the patient draw interlocked pentagons. Have the patient draw a clock.
♦ Motor programming tasks	Have the patient perform serial hand sequences. Have the patient perform reciprocal programs of raising fingers.
Judgment and reasoning	Listen to the patient's account of his or her history and reason for hospitalization. Assess abstraction (similarities: dog/cat; red/green). Ask about the patient's judgment about simple events or problems: "A construction worker fell to the ground from the seventh floor of the building and broke his two legs; he then ran to the nearby hospital to ask for medical help. Do you have any comment on this?"

physical examination should not be forgotten, especially in the medical setting. Most psychiatrists do not perform physical examinations on their patients. The consultation psychiatrist, however, should be familiar with and comfortable performing neurological examinations and other selected features of the physical examination that may uncover the common comorbidities in psychiatric patients (Granacher 1981; Summers et al. 1981a, 1981b). At an absolute minimum, the consultant should review the physical examinations performed by other physicians. However,

the psychiatrist's examination of the patient, especially of central nervous system functions relevant to the differential diagnosis, is often essential. A more complete physical examination is appropriate on medical-psychiatric units or whenever the psychiatrist has assumed responsibility for the care of a patient's medical problems. Even with a sedated or comatose patient, simple observation and a few maneuvers that involve a laying on of hands may potentially yield a bounty of findings. Although it is beyond the scope of this chapter to discuss a comprehensive physical

TABLE 1–5. Selected elements of the physical examination and significance of findings

Elements	Examples of possible diagnoses
General	
General appearance healthier than expected	Somatoform disorder
Fever	Infection or NMS
Blood pressure or pulse abnormalities	Withdrawal, thyroid or cardiovascular disease
Body habitus	Eating disorders, polycystic ovaries, or Cushing's syndrome
Skin	
Diaphoresis	Fever, withdrawal, NMS
Piloerection (“gooseflesh”)	Opioid withdrawal
Dry, flushed	Anticholinergic toxicity, heatstroke
Pallor	Anemia
Changes in hair, nails, skin	Malnutrition, thyroid or adrenal disease, polycystic ovaries
Jaundice	Liver disease
Characteristic stigmata	Syphilis, cirrhosis, or self-mutilation
Bruises	Physical abuse, ataxia, traumatic brain injury
Eyes	
Mydriasis	Opiate withdrawal, anticholinergic toxicity
Miosis	Opiate intoxication, cholinergic toxicity
Kayser-Fleischer rings	Wilson's disease
Neurological	
Tremors	Delirium, withdrawal syndromes, parkinsonism, lithium toxicity
Primitive reflexes present (e.g., snout, glabellar, grasp)	Dementia, frontal lobe dysfunction
Hyperactive deep tendon reflexes	Withdrawal, hyperthyroidism
Ophthalmoplegia	Wernicke's encephalopathy, brain stem dysfunction, dystonic reaction
Papilledema	Increased intracranial pressure
Hypertonia, rigidity, catatonia, parkinsonism	EPS, NMS
Abnormal movements	Parkinson's disease, Huntington's disease, EPS
Abnormal gait	Normal-pressure hydrocephalus, Parkinson's disease, Wernicke's encephalopathy
Loss of position and vibratory sense	Vitamin B ₁₂ deficiency

Note. EPS = extrapyramidal symptoms; NMS = neuroleptic malignant syndrome.

examination, Table 1–5 provides a broad outline of selected findings of the physical examination and their relevance to the psychiatric consultation.

Formulate Diagnostic and Therapeutic Strategies

By the time the consultant arrives on the scene, routine chemical and hematological tests and urinalyses are almost always available and should be reviewed along with any other laboratory, imaging, and electrophysiological tests. The consultant then considers what additional tests are needed to arrive at a diagnosis. Attempts have been

made in the past to correlate biological tests, such as the dexamethasone suppression test, with psychiatric illness; despite extensive research, however, no definitive biological tests are available to identify psychiatric disorders. Before ordering a test, the consultant must consider the likelihood that the test will contribute to making a diagnosis.

While there is an extensive list of studies that could be relevant to psychiatric presentations, the most common screening tests in clinical practice are listed in Table 1–6. It was once common practice for the psychiatrist to order routine batteries of tests, especially in cognitively impaired patients, in a stereotypical diagnostic approach to the eval-

TABLE 1–6. Common tests in psychiatric consultation

Complete blood count
Serum chemistry panel
Thyroid-stimulating hormone (thyrotropin) concentration
Vitamin B ₁₂ (cyanocobalamin) concentration
Folic acid (folate) concentration
Human chorionic gonadotropin (pregnancy) test
Toxicology
Serum
Urine
Serological tests for syphilis
HIV tests
Urinalysis
Electrocardiogram

uation of dementia or delirium. In modern practice, tests should be ordered selectively, with consideration paid to sensitivity, specificity, and cost-effectiveness. Perhaps most importantly, careful thought should be given to whether the results of each test will affect the patient's management. Finally, further studies may be beneficial in certain clinical situations as described throughout this book.

Routine Tests

A complete blood cell count may reveal anemia that contributes to depression or infection that causes psychosis. Leukocytosis is seen with infection and other acute inflammatory conditions, lithium therapy, and neuroleptic malignant syndrome, whereas leukopenia and agranulocytosis may be caused by certain psychotropic medications. A serum chemistry panel may point to diagnoses as varied as liver disease, eating disorders, renal disease, malnutrition, and hypoglycemia—all of which may have psychiatric manifestations (Alpay and Park 2004). Serum and urine toxicological screens are helpful in cases of altered sensorium and obviously whenever substance abuse, intoxication, or overdose is suspected. Because blood tests for syphilis, thyroid disease, and deficiencies of vitamin B₁₂ and folic acid (conditions that are curable) are readily available, they warrant a low threshold for their use. In patients with a history of exposures, HIV infection should not be overlooked. Obtaining a pregnancy test is often wise in women of childbearing age to inform diagnostically as well as to guide treatment options. Urinalysis, chest radiography, and electrocardiography are particularly important screening tools in the geriatric population.

Although it is not a first-line test, cerebrospinal fluid analysis should be considered in cases of mental status changes associated with fever, leukocytosis, meningismus, or unknown etiology. Increased intracranial pressure should be ruled out before a lumbar puncture is performed, however. More detailed discussion of specific tests is provided in relevant chapters throughout this text.

Neuroimaging

The psychiatric consultant must also be familiar with neuroimaging studies. Neuroimaging may aid in fleshing out the differential diagnosis of neuropsychiatric conditions, although it rarely establishes the diagnosis by itself (Dougherty and Rauch 2004). In most situations, magnetic resonance imaging (MRI) is preferred over computed tomography (CT). MRI provides greater resolution of subcortical structures (e.g., basal ganglia, amygdala, and other limbic structures) of particular interest to psychiatrists. It is also superior for detection of abnormalities of the brain stem and posterior fossa. Furthermore, MRI is better able to distinguish between gray matter and white matter lesions. CT is most useful in cases of suspected acute intracranial hemorrhage (having occurred within the past 72 hours) and when MRI is contraindicated (in patients with metallic implants). Dougherty and Rauch (2004) suggest that the following conditions and situations merit consideration of neuroimaging: new-onset psychosis, new-onset dementia, delirium of unknown cause, prior to an initial course of electroconvulsive therapy, and an acute mental status change with an abnormal neurological examination in a patient with either a history of head trauma or an age of 50 years or older. Regardless of the modality, the consultant should read the radiologist's report, because other physicians tend to dismiss all but acute focal findings and, as a result, misleadingly record the results of the study as normal in the chart. Psychiatrists recognize, however, that even small abnormalities (e.g., periventricular white matter changes) or chronic changes (e.g., cortical atrophy) have diagnostic and therapeutic implications (see Chapter 6, "Dementia," Chapter 8, "Depression," and Chapter 32, "Neurology and Neurosurgery").

Electrophysiological Tests

The electroencephalogram (EEG) is the most widely available test that can assess brain activity. The EEG is most often indicated in patients with paroxysmal or other symptoms suggestive of a seizure disorder, especially complex partial seizures, or pseudoseizures (see Chapter 32, "Neurology and Neurosurgery"). An EEG may also be helpful in distinguishing between neurological and psychiatric etiologies for a mute, uncommunicative patient. An EEG may

be helpful in documenting the presence of generalized slowing in a delirious patient, but it rarely indicates a specific etiology of delirium and it is not indicated in every delirious patient. However, when the diagnosis of delirium is uncertain, electroencephalographic evidence of dysrhythmia may prove useful. For example, when the primary treatment team insists that a patient should be transferred to a psychiatric inpatient service because of a mistaken belief that the symptoms of delirium represent schizophrenia or depression, an EEG may provide concrete data to support the correct diagnosis. EEGs may also facilitate the evaluation of rapidly progressive dementia or profound coma; but because findings are neither sensitive nor specific, they are not often helpful in the evaluation of space-occupying lesions, cerebral infarctions, or head injury (Bostwick and Philbrick 2002). Continuous electroencephalographic recordings with video monitoring or ambulatory electroencephalographic monitoring may be necessary in order to document abnormal electrical activity in cases of complex partial seizures or when factitious seizures are suspected. As with neuroimaging reports, the psychiatric consultant must read the electroencephalographic report, because nonpsychiatrists often misinterpret the absence of dramatic focal abnormalities (e.g., spikes) as indicative of normality, even though psychiatrically significant brain dysfunction may be associated with focal or generalized slowing or with sharp waves. Other electrophysiological tests may be helpful in specific situations; for example, sensory evoked potentials to distinguish multiple sclerosis from conversion disorder, or electromyography with nerve conduction velocities to differentiate neuropathy from malingering.

Other Tests

Other diagnostic tools may also prove useful as adjuncts. Neuropsychological testing may be helpful in diagnosis, prognosis, and treatment planning in patients with neuropsychiatric disorders. Psychological testing can help the consultant better understand a patient's emotional functioning and personality style. For example, elevations on the Hypochondriasis and Hysteria scales of the Minnesota Multiphasic Personality Inventory and a normal or minimally elevated result on the Depression scale constitute the so-called conversion V or psychosomatic V pattern, classically regarded as indicative of a significant psychological contribution to the etiology of somatic symptoms but now recognized as confounded by medical illness.

The amobarbital interview has been used as a tool in the diagnosis and treatment of a variety of psychiatric conditions (e.g., conversion disorder, posttraumatic stress disorder, factitious disorder, psychogenic amnesia, neurosis, and catatonia) for the past 70 years (Kavarirajan 1999).

The psychiatric literature has been mixed, however, on the utility of the amobarbital interview, and intravenous lorazepam is now generally regarded as a safer alternative. However, the diagnostic validity of amobarbital and lorazepam interviews has not been systematically assessed.

Write a Note

The consultation note should be clear, concise, and free of jargon and should focus on specific diagnostic and therapeutic recommendations. Although an understanding of the patient's psychodynamics may be helpful, the consultant should usually avoid speculations in the chart regarding unconscious motivations. Consultees fundamentally want to know what is going on with the patient and what they should and can do about it; these themes should dominate the note. Mental health professionals are trained to construct full developmental and psychosocial formulations, but these do not belong in a consultation note (although they may inform key elements of the assessment and recommendations). Finger-pointing and criticism of the primary team or other providers should be avoided. The consultant should also avoid rigid insistence on a preferred mode of management if there is an equally suitable alternative (Kontos et al. 2003).

The consultation note should include a condensed version of all the elements of a general psychiatric note with a few additions (Querques et al. 2004). The consultant should begin the note with a summary of the patient's medical and psychiatric history, the reason for the current admission, and the reason for the consultation. Next should be a brief summary of the current medical illness with pertinent findings and hospital course; this summary is meant to demonstrate an appreciation for the current medical issues rather than to repeat what has already been documented in the chart. It is often helpful for the consultant to include a description of the patient's typical patterns of response to stress and illness, if known. Physical and neurological examinations, as well as germane laboratory results or imaging studies, should also be summarized. The consultant should then list the differential diagnosis in order of decreasing likelihood, making clear which is the working diagnosis or diagnoses. If the patient's symptoms are not likely to be due to a psychiatric disorder, this should be explicitly stated. Finally, the consultant should make recommendations or clearly describe plans in order of decreasing importance. Recommendations include ways to further elucidate the diagnosis as well as therapeutic suggestions. It is especially important to anticipate and address problems that may appear at a later time (e.g., offering a medication recommendation for treatment of agitation in a delirious patient who is currently calm). For medication recommendations, brief no-

tation of side effects and their management is useful. The inclusion of a statement indicating that the consultant will provide follow-up will reassure the consulting team, and the consultant should include contact information in the event that they have further questions.

Speak Directly With the Referring Clinician

The consultation ends in the same way that it began—with a conversation with the referring clinician. Personal contact is especially crucial if diagnostic or therapeutic suggestions are time-sensitive. Some information or recommendations may be especially sensitive, whether for reasons of confidentiality or risk management, and are better conveyed verbally than fully documented in the chart. The medical chart is read by a variety of individuals, including the patient at times, and, thus, discretion is warranted.

Provide Periodic Follow-Up

Many consultations cannot be completed in a single visit. Rather, several encounters may be required before the problems identified by both the consultee and the consultant are resolved. Moreover, new issues commonly arise during the course of the consultative process, and a single consultation request often necessitates frequent visits, disciplined follow-up, and easy accessibility. All follow-up visits should be documented in the chart. Finally, it may be appropriate to sign off of a case when the patient is stabilized or when the consultant's opinion and recommendations are being disregarded (Kontos et al. 2003).

Role of Other Providers

Although the emphasis of this chapter is on the psychiatrist as consultant, the value of members of other professions, working together as a team, should not be overlooked. Psychologists play an essential role in performing neuropsychological and psychological testing and providing psychotherapeutic and behavioral interventions. Psychiatric clinical nurse specialists provide services to the nursing staff that parallel those that the psychiatrist provides to the medical team. They are especially helpful in organizing interdisciplinary care conferences and nursing behavioral treatment plans that include behavioral contracts with patients. Case managers facilitate transfers and set up aftercare. Chaplains address the spiritual needs of patients in distress. Finally, communication with primary care physicians remains of utmost importance, since the primary care physician is well positioned to oversee and coordinate ongoing care after discharge.

Consultation and Collaborative Care in the Outpatient Setting

Whereas the majority of this chapter has focused on psychiatric consultation in the inpatient setting, it could be argued that the consultation psychiatrist provides an even greater impact by working collaboratively with primary care physicians in the outpatient domain (Stern et al. 2004). Many studies over the past 30 years have established both the high prevalence of mental disorders in outpatient medical settings and the fact that more people with mental health disorders present to general medical settings than to psychiatrists (Unützer et al. 2006). In their report for the President's New Freedom Commission on Mental Health, Unützer et al. (2006) described a number of common barriers to effective mental health care at the interface with medicine, including the following: incorrect identification of symptoms by patients or reluctance to seek psychiatric care due to stigma; lack of mental health training for primary care providers; lack of time to fully address mental health issues in brief clinical encounters in the primary care setting; and restrictions in insurance coverage for mental health services. The elderly, children and adolescents, ethnic minorities, and uninsured individuals are especially susceptible to having their needs unmet in this regard (Unützer et al. 2006). Given that general medical settings comprise such a significant portion of the mental health care system, what strategies may be used to improve quality and efficacy of care?

Initial studies that focused on the improvement of mental health care in general medical settings stressed diagnosis and screening techniques (Gilbody et al. 2001; Spitzer et al. 1999) (see a detailed description of screening tools for this population later in this chapter). Subsequent inquiries then combined screening with systematic feedback of diagnoses to the primary care providers. These studies revealed that whereas screening and giving feedback to providers often increase the rate of diagnosis of mental disorders, they are not sufficient to improve patient outcomes (Katon and Gonzales 1994; Klinkman and Okkes 1998). Similar results were obtained when researchers looked at the efficacy of employing treatment guidelines for the care of common psychiatric disorders in primary care settings in combination with developing comprehensive training for providers (Hodges et al. 2001; Simon 2002). A simple referral to a psychiatrist is often inadequate for a myriad of reasons, including lack of access to mental health practitioners (especially for underserved populations), lack of patient follow-through (e.g., the patient never makes it to the appointment), and inability to

pay for mental health services. Although adequate screening, use of practice guidelines, provider training, and referral to specialists are all important components of improving mental health care in general medical settings, research has shown that these alone are inadequate (Unützer et al. 2006). The development of collaborative care models represents a potential solution to this problem.

Collaborative care refers to the joining together of mental health care providers with primary care physicians and their teams to deliver specialized care within the outpatient primary care setting. Consultation psychiatrists are uniquely positioned for this role, given the focus of psychosomatic medicine at the interface of medicine and psychiatry. While specific models of collaborative care vary, effective programs generally share certain key components. The first is systematic care management (often by a trained nurse, social worker, or psychologist). The care manager helps identify patients in need, coordinates an initial treatment plan, educates patients, provides follow-up, monitors progress, and helps change the treatment course as needed. These tasks may be performed in person (e.g., in the primary care clinic) or by telephone (Worth and Stern 2003). The next essential piece is consultation and appropriate sharing of information between the primary care provider, the care manager, and the consulting psychiatrist (Unützer et al. 2006). This does not necessarily mean that the psychiatric specialist provides a consultation for every patient; in fact, research has shown that the most efficient and cost-effective measures often involve a stepwise approach in which progressively more intensive interventions are applied until a successful outcome is achieved (Katon et al. 2005, 2008; Richards et al. 2007; Unützer et al. 2001; Von Korff and Tiemens 2000). Thus, stepped care for a patient with depression might involve an initial intervention of prescription of an antidepressant by the primary care provider along with care management either by phone or in person, as detailed above. If the patient remains symptomatic, the next step would be referral for brief psychotherapy or other behavioral interventions and/or a switch to another medication. While much of this process takes place under the supervision of a consulting psychiatrist, referral to mental health specialists is generally reserved for treatment nonresponders. For example, in the IMPACT (Improving Mood—Promoting Access to Collaborative Treatment) randomized trial for depressed elderly patients in primary care, consulting psychiatrists saw only about 10% of patients but served as key members of the collaborative team by providing consultation and education to care managers and primary care providers (Hunkeler et al. 2006; Unützer et al. 2002). Collaborative care models have been shown to improve outcomes and enhance patient function and quality of life as well as to be cost-effective

(Schoenbaum et al. 2001, 2004; Simon et al. 2001). Finally, ethnic minorities seem to benefit in particular from collaborative care models (Miranda et al. 2003; Wells et al. 2004).

Screening

As mentioned in the previous section, the use of screening tools may be helpful in specific situations. For example, even though a comprehensive assessment of cognitive function is not required for every patient, even a slim suspicion of the possibility of a cognitive deficit should prompt performance of cognitive screening. Although individualized mental status examinations performed as part of a psychiatrist's clinical interview are much preferred to standardized tests, screening tests may be particularly useful in case finding (e.g., in primary care settings as part of a collaborative care approach) and in research domains. The same has been proposed for a variety of other psychiatric disorders, including depression, anxiety, and substance abuse. An important note in this regard, however, is that screening and case finding are unlikely to be helpful without a systematic approach to treatment (see the discussion of collaborative care above). This is evidenced by a recent meta-analysis, which showed that when used alone, screening questionnaires for depression did not have an impact on the actual detection and management of depression by clinicians in non-mental health settings (Gilbody et al. 2008). Such findings underscore the importance of collaboration between psychosomatic medicine specialists and general medical teams (in both the outpatient and inpatient settings), with screening tools as just one aspect of this collaboration. Selected instruments are described below; others are discussed in the relevant chapters in this book.

Tests such as the MMSE or the Mini-Cog (Borson et al. 2000) are helpful adjuncts in the hands of nonpsychiatrists to quickly identify potential cognitive disorders. The MMSE is a 19-question test that provides an overview of a patient's cognitive function at a moment in time; it includes assessment of orientation, attention, and memory. It is of limited use without modification, however, in patients who are deaf or blind, who are intubated, or who do not speak English. The MMSE is also particularly insensitive in measuring cognitive decline in very intelligent patients, who may appear less impaired than they really are. The Mini-Cog, on the other hand, combines a portion of the MMSE (3-minute recall) with the Clock Drawing Test, as described by Critchley in 1953 (Scanlan and Borson 2001). In screening for dementia, the MMSE and the Mini-Cog have been shown to have similar sensitivity (76%–79%) and specificity (88%–89%) (Borson et al. 2003). However, the Mini-Cog is significantly shorter and enables screening temporoparietal

and frontal cortical areas via the Clock Drawing Test, areas that are not fully assessed by the MMSE.

In addition, these tests may be supplemented with others—including Luria maneuvers and cognitive estimations (e.g., How many slices are there in an average loaf of white bread? How long is the human spinal cord?)—that further assess the functioning of frontal-subcortical networks. A formal neuropsychological battery may be useful if these bedside tests produce abnormal results. In a patient with an altered level of awareness or attention, formal cognitive tests should be deferred until the sensorium clears, because clouding of consciousness will produce uninterpretable results.

Other screening instruments may also help to identify patients in medical settings who could benefit from a comprehensive psychiatric interview. The Patient Health Questionnaire (PHQ), an abbreviated form of the Primary Care Evaluation of Mental Disorders (PRIME-MD), is a three-page questionnaire that can be entirely self-administered by the patient (Spitzer et al. 1999). In addition to the assessment of mood, anxiety, eating, alcohol use, and somatization disorders, the PHQ screens for posttraumatic stress disorder and common psychosocial stressors and also elicits a pregnancy history. The PHQ is valid and reliable and has improved the diagnosis of psychiatric conditions in primary care and other ambulatory medical settings (Spitzer et al. 1999); it may also have a role at the bedside. Subsets of the PHQ's items have been validated for specific screening purposes. For example, the nine-item PHQ-9, a self-administered depression-specific questionnaire that can be completed by the patient in roughly 2 minutes (Gilbody et al. 2007a; Kroenke et al. 2001), has been shown to perform as well (in a range of countries, populations, and clinical settings) as longer clinician-administered instruments that screen for depression in medical settings (Gilbody et al. 2007b); it can also be used to monitor the severity of depression. The PHQ-2 for depression, which includes just the items for mood and anhedonia, is sensitive and specific for both major depressive disorder and other depressive disorders, performing almost as well as the PHQ-9 (Löwe et al. 2005).

The PHQ-15 assesses 15 somatic symptoms and is useful as an index of somatization (Kroenke et al. 2009). The Generalized Anxiety Disorder 7-item (GAD-7) scale is a valid and efficient tool for screening for generalized anxiety disorder and assessing its severity (Spitzer et al. 2006).

The Clinical Outcomes in Routine Evaluation—Outcome Measure (CORE-OM; Barkham et al. 2001) is a 34-item instrument that measures a range of mental health problems as well as functional capacity and risk of harm to self or others that has been validated for assessment of depression in the primary care setting (Gilbody et al. 2007a).

The General Health Questionnaire (GHQ) is another instrument originally developed in the 1970s to screen for psychiatric disorders in medical outpatients (Goldberg and Blackwell 1970). The original 60-item version has been replaced with well-validated 28- and 12-item versions. The GHQ has been translated into numerous languages worldwide and is cross-culturally validated (Tait et al. 2003). Because of its emphasis on identifying new symptoms, the GHQ is most useful for assessing state rather than trait conditions (Tait et al. 2003).

The CAGE questionnaire is a well-known screening device developed by Ewing (1984) to identify alcohol abuse. Two or more positive responses on the four-question screen correlate with an 89% chance of alcohol abuse (Mayfield et al. 1974) (see Chapter 17, “Substance-Related Disorders”). Other screening tests are described in the chapters covering specific syndromes (e.g., depression, anxiety, delirium).

Practice Guidelines

Groups from several countries have developed psychosomatic medicine practice guidelines that detail professional standards for psychiatric consultation in nonpsychiatric settings, referencing the appropriate knowledge base as well as delineating integrated clinical approaches, effective methods, and ways to enhance adherence to recommendations made by the consulting psychiatrist (Bronheim et al. 1998; Leentjens et al. 2009; Royal Colleges of Physicians and Psychiatrists 1995). Although a complete review of these guidelines is beyond the scope of this chapter, they may serve as excellent additions to the information provided here. Especially helpful are practice guidelines informing evaluation of specific disorders (e.g., delirium [Leentjens and Diefenbacher 2006]) or specific tasks (e.g., psychosocial evaluation of living unrelated organ donors [Dew et al. 2007]).

Benefits of Psychiatric Services

The benefits of psychiatric services in health care delivery are significant. An extensive body of evidence has demonstrated a link between comorbid psychopathology and increased length of hospital stay and, consequently, increased inpatient costs. Levenson et al. (1990) described a longer median length of hospital stay (a 40% increase) and hospital costs that were 35% higher in medical inpatients with depression, anxiety, cognitive dysfunction, or high levels of pain (independent of severity of medical illness). Cognitively impaired geriatric patients in one sample were shown to have an increased length of stay compared with

those without cognitive impairment (Fulop et al. 1998), whereas depressed elderly patients in another sample had more hospitalizations and longer hospital stays (Koenig and Kuchibhatla 1998). Although some have suggested that psychiatric consultation might decrease lengths of stay and inpatient costs (Levitan and Kornfeld 1981; Strain et al. 1991), that is not where its primary value lies. Patients benefit from the reductions in mental suffering and improvements in psychological well-being that result from more accurate diagnosis and more appropriate treatment. The adverse effects of psychopathology on specific medical disorders, and the benefits of treating it, are reviewed in remaining chapters of this textbook. Providers of health care profit from the added diagnostic and therapeutic expertise of the psychiatric consultant as well as from a better understanding of health behaviors. This has been best demonstrated in ambulatory collaborative care models, as discussed earlier in this chapter. The hospital milieu also benefits from having readily available medically knowledgeable psychiatrists, whose assistance improves the care of the complex patients described in the rest of this textbook, contributing to better risk management and a safer and more pleasant work environment.

Conclusion

Psychiatric assessment and consultation can be crucial to seriously ill medical patients. The psychosomatic medicine psychiatrist is an expert in the diagnosis and care of psychopathology in the medically ill. Psychiatric consultation affords a unique ability to offer a panoramic view of the patient, the illness, and the relationship between the two. The psychiatric consultant will be called on to help diagnose, understand, and manage a wide array of conditions; when effective, the consultant addresses the needs of both the patient and the medical-surgical team. In this manner, psychiatric consultation is essential to the provision of comprehensive care in the medical setting.

Legal Issues

Rebecca W. Brendel, M.D., J.D.

Ronald Schouten, M.D., J.D.

James L. Levenson, M.D.

MEDICAL PRACTICE OCCURS in a legal and regulatory context. Concerns often emerge at the intersection of law and medicine, and the field of psychosomatic medicine is no exception. In fact, for a number of reasons, legal questions may arise frequently for the consultation-liaison psychiatrist, and even more often than in many other areas of medicine. One reason is the sensitive nature of communications made by patients to psychiatrists and the historical protections afforded to psychiatric and psychotherapy records that may raise concerns about laws related to confidentiality in the course of a psychiatric evaluation. A second is that medical and surgical practitioners may rely on the psychiatric colleagues' training and expertise in understanding disorders of behavior and cognition for assistance in determining patients' ability to make medical decisions, give informed consent for treatment, or refuse recommended treatment. Third, the complex balancing of individual interests against public policy considerations may lead to questions in the treatment of a particular patient in a number of contexts, including duties to third parties, mandated reporting, and malpractice liability.

For most practitioners, legal concerns are likely background considerations that remain largely unfocused and absent from conscious awareness in daily practice. However, when legal issues arise, they often occur in the context of particularly challenging clinical issues and, if not properly understood and considered, may lead to confusion, departure from sound clinical judgment, and even bad outcomes (Schouten and Brendel 2009). It is therefore critical for clinicians to be aware of relevant legal principles and regulations pertaining to the provision of medi-

cal care in jurisdictions relevant to their practice. However, it is also critical for clinicians to appreciate that the best way of minimizing legal complications and providing care to patients is through attention to thorough and sound clinical judgment and care (Brendel and Schouten 2007; Schouten and Brendel 2004, 2009).

This chapter covers a series of legal issues and principles frequently encountered in the practice of psychosomatic medicine, including privacy and confidentiality, capacity and competency, informed consent for treatment and treatment refusal, substitute decision making and guardianship, and malpractice. The information in this chapter should serve as a resource for the general hospital psychiatrist's practice and also as a guide to avoid unnecessary legal entanglements due to misconceptions, overreliance on the law rather than exercise of clinical judgment, and/or failure to be aware of or seek counsel of appropriate legal resources and advice in the course of consultative practice. In addition, this chapter describes principles that are broadly applicable to most United States jurisdictions. That being said, many of these principles reflect practices in other nation's jurisdictions, and variations also occur between U.S. states. Therefore, while this chapter provides an overview, it does not serve as a substitute for practitioners' awareness of legal requirements and resources in the jurisdictions in which they practice.

Confidentiality

The principle of doctor-patient confidentiality was codified in the Hippocratic oath as early as 430 B.C.: "Whatever I

see or hear, professionally or privately, which ought not to be divulged, I will keep secret and tell no one" (Lloyd 1983). Since that time, confidentiality has remained a central facet of the doctor–patient relationship on the rationale that it promotes the open and honest exchange of information in the interest of treatment and patient welfare (American Psychiatric Association 1978, 2001; Appelbaum 2002; Brendel and Brendel 2005). Doctor–patient confidentiality is a professional, legal, and ethical requirement. Signs in hospital hallways and elevators reminding staff to respect patient confidentiality serve as just one reminder and symbol of the responsibility of health care providers to their patients. However, the notion of total confidentiality in medicine is, in practice, arcane. Even before the recent expansion of health information systems and electronic medical records over the last decade in particular, medical information was not strictly confidential between doctor and patient in the setting of hospital treatment. For example, even more than 15 years ago, one observer detailed the large number of individuals with access to a patient's medical chart (Siegler 1982). Now, as medical charts have become increasingly electronic, questions about ownership, access, and commoditization are emerging at a rapid pace and will likely further challenge notions of confidentiality as time goes on (Hall and Schulman 2009). In addition, increasing attention has started to focus on the scope of confidentiality after a patient's death (Robinson and O'Neill 2007).

Over time, the principle of strict or absolute confidentiality between one physician and one patient has eroded beyond the sharing of medical information with hospital personnel as described by Siegler (1982). The considerations of a complex society have increasingly led to an erosion of confidentiality as it was understood in the era of Hippocrates and subsequent centuries. Courts and legislatures have created limitations to doctor–patient confidentiality in circumstances where confidentiality is determined to be at odds with public safety or to be more harmful than beneficial for the patient. More recently, federal law has recognized efficiency and effectiveness of the health care system as a principle to be balanced with traditional management and safeguarding of protected health information under the Health Insurance Portability and Accountability Act of 1996 (HIPAA 1996, P.L. 104-191) (Brendel and Bryan 2004).

Public Safety and Welfare Exceptions to Confidentiality

Physicians often express concern that reporting information to government authorities, social service agencies, or other third parties may expose them to potential liability. While protecting patient information and confidentiality is the default rule, there are several situations in which

physicians have an affirmative duty to disclose information to authorities. One such example is child and elder abuse and neglect reporting. Every jurisdiction in the United States mandates that physicians report suspected child and elder abuse and neglect (Brendel 2005; Kazim and Brendel 2004; Milosavljevic and Brendel 2008).

Thirty-five years ago, federal law set a minimum standard for what actions or inactions constitute child abuse or neglect, respectively (Child Abuse Prevention and Treatment Act 2003). However, individual states have interpreted the federal definition in different ways, leading to variations in the definition of child abuse among U.S. jurisdictions. As a general rule of thumb, state definitions generally incorporate the concepts of "harm or substantial risk of harm" or "serious threat or serious harm" to a person younger than 18 years who is not emancipated (Milosavljevic and Brendel 2008). Approximately half of states have some form of emancipation law that may exempt an emancipated or mature minor under the chronological age of 18 years from being subject to a child abuse or neglect report. Physicians should be aware of the specific prevailing standards in the jurisdictions in which they practice regarding the definitions and requirements for reporting. In general, liability attaches to a physician for failure to comply with a mandatory child abuse reporting statute rather than for breaching confidentiality by making a report to child protection authorities (this applies even when a report is ultimately unsubstantiated, provided that the report was made in good faith) (Milosavljevic and Brendel 2008).

Beginning in the 1960s, legislation emerged out of the child protection model to protect vulnerable adults, and by the mid-1970s, federal law was passed to establish adult protective services (Milosavljevic and Brendel 2008). Now, every U.S. jurisdiction identifies physicians as mandated reporters of suspected elder abuse and neglect (Milosavljevic and Brendel 2008). Akin to the jurisdictional variations in definitions of child abuse and neglect, the definition of elder abuse and neglect varies from state to state. That being said, most states use a standard incorporating five common elements: infliction of pain or injury, infliction of emotional or psychological harm, sexual assault, material or financial exploitation, and neglect (Kazim and Brendel 2004). Elder abuse standards may also include self-neglect in recognition of the frequency of waning self-care abilities that accompany age-related physical and cognitive decline (Abrams et al. 2002). Unlike reports of suspected child abuse, elder protection laws may recognize the ability of a competent elder to refuse investigation or intervention by protective services agencies.

The psychosomatic medicine practitioner should be aware of the risk factors and manifestations of elder abuse and neglect, especially since they may be more likely to en-

counter elders at risk due to their presentation with dementia and other mental status changes, as well as when hospitalized for medical consequences of neglect or abuse. As a whole, physicians may be inadequately trained to recognize elder mistreatment, at least in part due to the fact that the manifestations of abuse and neglect may be subtle and may be masked by illness or debility (Alpert et al. 1998; Melton 2002). Simply put, elderly victims of abuse and/or neglect may appear nothing more than frail or sick to the untrained clinician (Kahan and Paris 2003). The psychosomatic medicine physician is in a critically important role to detect elder mistreatment and to intervene to protect vulnerable geriatric patients due to the fact that hospitals and other health care settings may be the only source of help for these individuals. Therefore, practitioners should familiarize themselves with the reporting standards in the jurisdictions in which they practice. As with child abuse reporting, in regard to elder abuse and neglect reporting, physicians are more likely to face legal liability for *failure* to report than for good-faith reporting of suspected abuse and/or neglect, even when reports are “screened out” or found to be unsubstantiated following investigation by elder protective services.

Duties to Third Parties and the Duty to Protect

Since the landmark California Supreme Court Decision in *Tarasoff v. Board of Regents* in 1976, the concept of a duty to protect third parties from physical harm from patients has emerged as a well-known exception to doctor–patient confidentiality (Schouten and Brendel 2004). In this court decision, California’s highest court engaged in an analysis of the complex balance between individual patient privacy and the public interest in preventing harm to hold that psychotherapists have a duty to act to protect third parties when the therapist knows or should know that the patient poses a risk of harm to a third party or parties (*Tarasoff v. Board of Regents* 1976). In the more than three decades since this landmark decision, clinicians and lawmakers alike have debated the relative priority of patient confidentiality and public safety in defining the parameters of the duty, for which situations clinicians will face professional and/or legal responsibility, and even whether the duty to warn or protect would apply in different jurisdictions.

Unlike mandated reporting of abuse and neglect, the duty to protect is not recognized in all jurisdictions (Almason 1997; Ginsberg 2004). It is therefore critical for practitioners to familiarize themselves with the law regarding the duty to protect in the jurisdiction(s) in which they practice. In general, many states have enacted statutory laws characterizing the scope of the duty to protect, and others have narrowed the scope of or eliminated the duty (Appelbaum et al. 1989; Kachigian and Felthous 2004). State laws re-

garding the duty to protect generally limit the situations in which the physician’s duty to protect is triggered.

Statutory methods by which the psychiatrist’s duty to protect and potential liability may be circumscribed include requiring a specific threat to an identified or identifiable victim, a clinician’s knowledge of the patient’s having a past history of violence, and/or a reasonable basis to anticipate violence prior to invocation of the duty to protect. In addition to defining and/or limiting the circumstances in which the duty to protect arises, state laws may also specify what measures mental health clinicians may or must take in order to satisfactorily comply with their duty to protect. These measures often include notifying the police or another law enforcement agency, hospitalizing the patient, or warning the potential victim. The Massachusetts statute is one that both limits the scope of the duty and defines measures by which the duty to protect can be discharged (Duty to warn patient’s potential victims; cause of action [Mass. Gen. Laws Ch. 123, § 36B, 2005]).

One critical aspect of the duty to protect about which the psychosomatic medicine psychiatrist should be aware is that this duty often applies to psychiatrists and other mental health clinicians, but not to nonpsychiatric physicians and clinicians (Brendel and Cohen 2007; Brendel and Schouten 2007). In the setting of providing consultation to medical and surgical services, psychiatrists may be subject to duties to warn and/or protect that do not apply to the physician of record or the primary treatment team and which may create competing and conflicting obligations for the consultant and the consultee. For example, Massachusetts law requires all physicians to keep HIV-related information confidential unless the patient gives written informed consent for release of that information, but also has a statutory duty to protect that applies to psychiatrists and other mental health professionals (HLTV-III test; confidentiality; informed consent [Mass. Gen. Laws Ch. 11 § 70F, 2005]). In the case of an HIV-positive individual who is putting an unknowing sexual partner at risk, nonpsychiatric physicians are bound to confidentiality under the HIV confidentiality statute whereas psychiatrists have competing obligations under the duty to protect and HIV confidentiality laws (Brendel and Cohen 2007).

The complex tension between doctor–patient confidentiality and protecting patient privacy on one side and public protection and welfare on the other, as highlighted in the above example, is not a new one. In fact, the *Tarasoff* court relied on the precedent of mandated reporting of communicable diseases to public health authorities in its reasoning supporting the duty to protect third parties (*Tarasoff v. Board of Regents* 1976). Infectious disease reporting remains a well-established exception to doctor–patient confidentiality, and individual states, as well as the federal

government, have enacted laws about which contagious diseases must be reported—to state public health officials, the Centers for Disease Control and Prevention, or both. Examples of reportable communicable diseases include HIV, varicella, viral hepatitis, severe acute respiratory syndrome, influenza, and syphilis (see, e.g., Averhoff et al. 2006). Reporting requirements vary from jurisdiction to jurisdiction, both in terms of what conditions are reportable and regarding the type and amount of information that must be reported. For example, in the case of HIV, different states vary in what information must accompany a report of a positive test result, including whether the report is anonymized or de-identified and whether partner/spousal notification occurs (Brendel and Cohen 2008; New York State Department of Health 2000, 2003). Physicians should also be aware that both before and following *Tarasoff*, doctors have faced civil liability for failure to disclose a patient's infection status that led to the infection of other individuals, highlighting how critically important it is for physicians to be aware of reporting requirements in the jurisdictions in which they practice (Bradshaw 1993; Gostin and Webber 1998; Liang 2002).

But while clinicians should be aware of the legal and regulatory requirements and constraints applicable to their practice, it is also critical to remember to think and act like clinicians. Simply put, clinicians should resist the tendency to think legally when difficult issues arise and instead act clinically in the setting of an understanding of the law or consultation with appropriate risk management or legal resources (Schouten and Brendel 2009). From the clinical perspective, the starting point for considering the responsibilities to breach confidentiality is the paradigm of doctor–patient confidentiality. The default rule is to protect patient confidentiality and privacy, and breaches for any reason must be carefully weighed and understood. Alternatives to releasing private information (e.g., hospitalization of a patient who has made threats) should be considered before a clinician breaches confidentiality (Beck 1998). In addition, even when a clinician is required to share patient information, only the minimum amount of information necessary to achieve the legal, regulatory, or clinical purpose should be disclosed.

Finally, circumstances may arise in which the consultation psychiatrist is asked to evaluate a patient whose legal status may draw into question the confidentiality of the interview. Examples of these situations include individuals in immigration, police, or correctional custody. In these situations, it is important for the psychiatrist to take steps to maximize the privacy of the interview and also to make the patient aware of the potential limitations on confidentiality inherent in the evaluation given the patient's custodial status. Furthermore, the psychiatrist should follow

standard clinical practice regarding communication with law enforcement officials. Specifically, the clinician should consider all information gathered in the course of the interview as covered by doctor–patient confidentiality and limit contact with law enforcement to providing the minimum necessary to meet any mandated reporting obligations and to ensure the patient's safety. Where clinical sign-out is required to ensure the patient's safety, the psychiatrist should work to identify appropriate clinical personnel within the legal system to provide this pass-off and avoid communicating clinical information through non-clinical personnel (Schouten and Brendel 2009). Finally, where law enforcement officials seek to interview patients, clinicians should continue to maintain their therapeutic fiduciary stance relative to the patient and consider principles of patient autonomy, noninterference with medical care, protection of privacy, and maintenance of professional boundaries in making decisions about the appropriateness of these interviews (Jones et al. 2006).

Health Insurance Portability and Accountability Act

The paradigm of doctor–patient confidentiality often conjures up images of records in locked file cabinets and strict confidentiality for all patient information, especially in the field of psychiatry. As discussed above, however, over time, exceptions to the strict rule of doctor–patient confidentiality as codified by Hippocrates have emerged, recognizing that public safety and welfare considerations at times prevail over the safeguarding of private patient information by physicians. With Congress's passage of the HIPAA in 1996 and subsequent adoption of the regulations promulgated to implement HIPAA, the circumstances in which medical information could be released without the patient's explicit written informed consent was substantially broadened—not just for public safety but also for the purposes of payment and health care operations. Perhaps the most common misconception about HIPAA is that it makes it harder, rather than easier, to release a patient's medical information. As will be further elucidated, rather than promoting privacy, HIPAA has had the opposite effect, expanding the situations in which patient consent is *not* required for release of patient health information. If there is a take-home message about HIPAA, it is simple: the “P” in HIPAA is for portability, not privacy (Brendel and Bryan 2004). The effect of HIPAA has been to increase the circumstances in which patient information can be released without the specific informed consent of the patient (Brendel and Bryan 2004; Brendel 2005; Feld 2005).

With the passage of HIPAA, psychiatrists in particular were concerned about what effect it would have on the protection for often-sensitive psychiatric records, protections

that until the passage of HIPAA were regulated by state law. HIPAA, a federal law, applies to health care providers performing “certain electronic transactions,” and because these functions (e.g., electronic billing, eligibility determinations, claims processing) are performed by hospitals, most if not all psychosomatic medicine psychiatrists are covered by the provisions of HIPAA. HIPAA does not cover all information, but instead governs the management of “protected health information,” which includes not only specific medical information about a mental or physical condition but also patient identifiers such as name or social security number, payment information, and records of treatment or services rendered (HIPAA Privacy Rule 2001).

The provisions of HIPAA most relevant to psychosomatic medicine clinicians relate to disclosure of medical information, patient access to information, and a category of records established by and defined by HIPAA known as “psychotherapy notes.” When lawmakers passed HIPAA, they specifically aimed to improve the “efficiency and effectiveness” of the health care system (HIPAA 1996). In defining the parameters of what information should be considered protected health information under HIPAA, lawmakers engaged in a balancing between the important principles of confidentiality and privacy and the efficient functioning of an increasingly complex health care system, the functioning of which required regular sharing of information between multiple entities. HIPAA’s implementation promoted efficiency by allowing the release of protected health information for treatment, payment, and health care operations purposes without specific informed consent from the patient. This move drew criticism from patient and privacy advocates who believed that the abolition of the consent requirement for release of records would become just the first step in a slippery slope of furthering administrative and operational concerns at the expense of doctor–patient confidentiality—a centuries-old ethical and legal cornerstone of medical treatment (Feld 2005; Friedrich 2001; Gordon 2002).

HIPAA is not a *carte blanche* for release of medical information. Federal regulations do limit disclosure of protected health information under HIPAA in several ways. First, under HIPAA, covered entities (such as hospitals) are required to inform patients of their practices under HIPAA in the form of privacy notices. In addition, patients may request a record of some disclosures of their protected health information. Finally, HIPAA is preempted by federal and state laws that provide greater protection than HIPAA does to protected health information, including records that are considered especially sensitive. For example, under federal law, records from alcohol and substance abuse treatment programs are considered especially sensitive and written informed consent is specially required for

their release. Additionally, state laws vary from jurisdiction to jurisdiction but may require specific written informed consent for release of HIV testing and treatment records as well as records related to domestic violence and sexual assault (Brendel 2005; Brendel and Bryan 2004).

For the psychosomatic medicine psychiatrist pre-HIPAA, distinctions between the handling of medical and psychiatric records often caused confusion. Specifically, psychiatric records were often maintained separately from the general medical record and, even when contained within the medical record, they were subject to limitations on release. For example, at our institution, pre-HIPAA, psychiatric consultation notes contained within the hospital record were redacted before records were released to patients. Post-HIPAA, all psychiatry entries into the medical chart are considered part of the general medical record. The implications of HIPAA’s inclusion of psychiatric records in the general medical chart are several. First, under HIPAA, the records may be released for treatment, payment, and health care operations purposes without specific consent. Second, HIPAA grants patients broad rights of access to their medical records. The practical effect of this broad right of access means that a patient’s access to psychiatric records and psychiatric entries in the medical record may be denied only if a licensed professional makes a determination that release of the records to the patient would harm, endanger the life, or compromise the physical safety of the patient or another person (Brendel and Bryan 2004). It is especially important for psychosomatic medicine clinicians to be aware that patients have the right to access their records and will be allowed to do so—highlighting the need for careful documentation around sensitive issues, use of nonjudgmental terms and avoidance of jargon, and thoughtful formulation, as if the patient were looking over the clinician’s shoulder.

Post-HIPAA, confusion frequently arises among psychiatrists regarding psychotherapy notes. It is critical for practitioners to be aware that while HIPAA affords extra protection for psychotherapy notes in recognition of the sensitive nature of psychiatric treatment, HIPAA’s definition of psychotherapy notes is extremely narrow and does not preclude the patient, or others, from accessing the notes (Maio 2003). Very few notes of psychotherapy sessions, inpatient or outpatient, would qualify as psychotherapy notes under HIPAA, which specifically defines psychotherapy notes as a clinician’s notes that document or analyze the contents of conversations in private counseling sessions and are kept separate from the rest of the patient’s record. In addition, certain information that is more appropriately kept in a medical chart is not subject to the psychotherapy note protection of HIPAA, including medications information, results of tests, diagnosis, prognosis,

progress, and treatment plans and goals (Appelbaum 2002; Brendel and Bryan 2004). Notes that qualify under the psychotherapy notes provision of HIPAA may not be released without specific authorization from the patient. In addition, patients do not have the right to access psychotherapy notes, but there is no prohibition on allowing patients to access their psychotherapy notes. Notwithstanding HIPAA, psychotherapy notes are treated as part of the medical record for legal purposes should the record be subpoenaed for litigation (Schouten and Brendel 2004).

Overall, as discussed above, HIPAA has had the effect of facilitating the release of medical information, in large part by departing from the consent requirement each time a patient's protected health information is released for treatment, payment, or health care operations purposes. In addition, HIPAA recognizes that consent is not required to release information in emergency, mandated reporting, and public safety and monitoring situations (Appelbaum 2002; Schouten and Brendel 2004). Clinicians should also be familiar with two additional points about HIPAA. First, HIPAA sets a floor regarding the minimum requirements for the protection of health information and states may enact laws that are more protective of patient privacy and more permissive of patient access. Second, even though HIPAA permits disclosure of protected health information without specific informed consent in many circumstances, clinicians should still use clinical judgment every time a disclosure is made and limit the information released to the minimum necessary amount to achieve the purpose of the disclosure.

Treatment Consent and Refusal

The psychosomatic medicine psychiatrist is often consulted to assess a patient's ability to understand proposed medical and surgical interventions, especially in settings in which the patient is refusing treatment that the treating clinician has determined to be medically necessary and to have a favorable risk-benefit ratio for the patient. The psychiatrist's threshold clinical determination of a patient's ability to make a decision is a capacity assessment. Capacity refers to an individual's ability to perform a task, such as making a medical decision. Competency is the legal analog of capacity and is presumed for all adults. Hence, clinicians make judgments of capacity and incapacity and judges make determinations of competency and incompetency (Appelbaum and Roth 1981; Brendel and Schouten 2007; Schouten and Brendel 2004; Schouten and Ederheim 2008).

Capacity or incapacity may be global or specific. An example of a globally incapacitated person is an individual in a coma. More commonly, psychiatrists are asked to evalu-

ate task-specific capacity, such as the capacity to leave the hospital against medical advice, a frequently encountered capacity determination in the general hospital. Different tasks and decisions require different abilities and levels of understanding, and therefore the first step in any evaluation of capacity is to ask the question "Capacity for what?" In order to assess the degree to which the patient understands the information relevant to a decision, the psychiatrist must first have an understanding of the type of decision and circumstances the patient is facing (see also Chapter 3, "Ethical Issues").

Capacity Assessment

A patient's decisional capacity depends on an understanding of the underlying illness, proposed interventions, prognosis, and consequences of treatment and nontreatment. The most established method of capacity determination for medical decision making is a practical four-pronged analysis developed by Appelbaum and Grisso (Appelbaum 2007; Appelbaum and Grisso 1988). Under this model, the four factors for consideration in determining decisional capacity are preference, factual understanding, appreciation of the facts presented (i.e., how they relate to the specific individual), and rational manipulation of information. All four elements must be met in order for the individual to demonstrate decisional capacity. In practice, a patient's decisional capacity is rarely questioned when the patient is in agreement with the proposed medical interventions.

In assessing the preference element of capacity, the central facet is the patient's ability to communicate a consistent preference over time. A patient who is unable to demonstrate a stable preference regarding a decision—whether it be due to inability or unwillingness—lacks decisional capacity (though this is not meant to preclude patients' changing their mind). The second element of the four-part capacity evaluation is an assessment of the individual's factual understanding of his or her condition and the proposed treatment. It may be assessed through inquiry about the nature of the patient's illness or condition, the treatment options, the recommended treatment, the prognosis with and without treatment, and the risks and benefits of treatment. If the patient does not demonstrate a factual understanding, it is critical for the evaluator to assess why and also if the patient is capable of gaining a factual understanding. For example, a patient may not have a factual understanding of the relevant information because the primary treaters did not provide the information to the patient. A patient who has never been educated about his or her condition and recommended treatment cannot be expected to know the relevant information. On the other hand, if efforts have been made to inform the pa-

tient of the relevant information and the patient is unable to retain the relevant information, the patient may not be capable of acquiring the requisite information in order to meet the second prong of the capacity evaluation.

The third element in capacity assessment is a determination of whether the patient appreciates the significance of the information presented to him- or herself. Appreciation goes beyond a recitation of the facts and requires a broad perspective of the implications of the medical decision. Factors that may be explored in assessing appreciation include asking the patient about the consequences to him- or herself both of accepting and of refusing the proposed intervention and the consequences of one decision or another on the individual's future.

The fourth, and final, element of the standard capacity assessment for medical decision making requires the patient to demonstrate that his or her decision-making process is a rational one. The focus of inquiry and assessment is not on the final decision the patient makes, but rather on the process that the individual uses to arrive at that decision, taking into account the individual's past preferences and decisions. An often-used example to illustrate the importance of viewing the individual medical decision in the context of the patient's life, beliefs, and previous choices is that of a Jehovah's Witness who is faced with making a decision about whether to accept or refuse a lifesaving blood transfusion. In this case, the individual's decision to refuse the transfusion and face certain death might seem irrational on the surface, but in the context of this individual's faith-based life decisions and belief that accepting the transfusion would be contrary to religious doctrine would normally meet the rationality requirement. Assessing the rationality of the patient's decision-making process is the key element in determining whether seriously mentally ill patients have sufficient capacity for specific medical decisions. For example a chronic schizophrenic patient who refuses cancer chemotherapy because he does not think the side effects worth the limited benefits may well have sufficient capacity to do so even if he is delusional about other areas of his life. However, if the reason he is refusing is that he thinks the doctors are trying to control his mind through the infusion, he would most likely lack capacity. The question of whether mental illness has distorted a patient's thinking sufficiently to preclude capacity can arise in nonpsychotic disorders like major depression as well and can be particularly difficult when the patient has refused lifesaving treatment (Sullivan and Youngner 1994).

Informed Consent

Decisional capacity is a threshold requirement for the ability to give informed consent or refusal for treatment. In other words, a patient who is unable to make consistent

and/or meaningful decisions cannot authorize, or for that matter refuse, proposed medical interventions. The process by which a patient agrees to permit a physician or other treater to do something to or for him or her is informed consent. Informed consent is required before any medical intervention because, in civil law, any unauthorized touching is a battery, including medical intervention. In the treatment context, a patient must therefore give informed consent before any intervention can begin and informed refusal if a treatment intervention is not authorized. Informed consent is an extension of broad principles of individual autonomy and has been a solid cornerstone of medical treatment since the 1960s (Dalla-Vorgia et al. 2001; Mohr 2000).

In hospital settings, informed consent may be equated with having a signed consent form on file. Clinicians should be aware that informed consent is not just signing a form but rather a process characterized by exchange of information, communication, and an active decision by the patient to accept or refuse the treatment. Through this active process, the legal standard of informed consent can be met. Specifically, in addition to decisional capacity, the legal standard for informed consent requires that it must be knowing (or intelligent) and voluntary (Appelbaum et al. 1987; *Salgo v. Leland Stanford Jr. University Board of Trustees* 1957; *Schloendorff v. Society of New York Hospital* 1914). The knowing/intelligent standard varies from jurisdiction to jurisdiction, with two general approaches (Schouten and Edersheim 2008). The first approach to the knowing standard is the reasonable professional standard and considers the information that is required to be presented to the patient in order for informed consent to be what a reasonable practitioner would tell a patient in similar circumstances. A small majority of states use this clinician-centered standard. The second is a patient-centered approach to the knowing requirement, is followed by a substantial minority of states, and defines the information required to meet the knowing standard as the information that an average or reasonable patient would use in coming to a decision. Some states go even further in employing the patient-centered approach and require an inquiry into what information the particular patient would find material or relevant in making a particular decision. This individual patient inquiry is often referred to as the materiality standard (Ihekweumere 2002). Two states use a hybrid approach incorporating both physician and patient focused inquiries in determining the amount of information that must be presented to the patient in order for informed consent to occur (King and Moulton 2006).

As a practical guide to sound clinical practice and risk management, the more information presented to the patient and the more extensive the communication about

that information between the doctor and the patient, the better. That being said, there are six broad categories of information that, if presented to the patient, are generally accepted as meeting the standard of how much information needs to be presented, regardless of the particular jurisdictional standard (King and Moulton 2006):

1. The diagnosis and the nature of the condition being treated
2. The reasonably expected benefits from the proposed treatment
3. The nature and likelihood of the risks involved
4. The inability to precisely predict results of the treatment
5. The potential irreversibility of the treatment
6. The expected risks, benefits, and results of alternative, or no, treatment

There are limits to how much information physicians are required to share in the course of the informed consent process. Overall, the ideal of informed consent is a process incorporating a clear and frank discussion and exchange of information between doctor and patient (King and Moulton 2006). The necessity has been recognized of striking a balance among patients' right to know, fairness to physicians, and public policy considerations of avoiding unreasonable burdens on clinicians (*Precourt v. Frederick* 1985).

The second core element of informed consent is voluntariness. The patient must give consent freely and unencumbered by external coercive forces. A decision made under circumstances that limit the patient's ability to exercise a choice is not voluntary and does not meet the standard for informed consent (Faden and Beauchamp 1986; Keeton et al. 1984). Notwithstanding, distinguishing between voluntary and coerced choices requires a complex and nuanced inquiry (Roberts 2002). For example, patients may be under pressure from family members to make certain treatment decisions, and, in these situations, patients are generally determined to have acted voluntarily from both ethical and legal perspectives (although exceptions do exist) (Grisso and Appelbaum 1998; Mallary et al. 1986). However, individuals who are totally dependent on others for their care are generally (notwithstanding some debate on the issue) deemed unable to give voluntary consent to treatment or research because of the inherent inequality between the patient and the institution. Examples of individuals in this category include nursing home residents and prisoners (Gold 1974; Moser et al. 2004; National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1976, 1978).

There are certain narrow and circumscribed situations in which informed consent is not required for the initiation

of treatment, but these situations are the exception and not the rule (Meisel 1979; Schouten and Brendel 2004; Sprung and Winick 1989). The most common and well-known exception to the informed consent requirement is the emergency exception. For the purposes of exemption from the informed consent requirement, an emergency is a situation in which failure to treat would result in serious and potentially irreversible deterioration of the patient's condition. Invocation of the emergency exception is permissible only until the patient is stabilized, at which time informed consent must be obtained. In addition, the presence of an emergency is not enough to authorize treatment if the physician has knowledge that the patient would have refused the emergency treatment if he or she were able to express his or her wishes. The patient's prior expressed wishes cannot be overridden by an emergency (*Shine v. Vega* 1999).

Two additional narrow exceptions to informed consent are waiver and therapeutic privilege (Meisel 1979; Schouten and Brendel 2004; Sprung and Winick 1989). A competent patient may defer to the clinician or another party, thereby waiving his or her informed consent. In these situations, clinicians should carefully assess and thoroughly document the patient's capacity (Appelbaum et al. 1987). Therapeutic privilege applies when the consent process itself would worsen or contribute to a deterioration in the patient's condition (*Canterbury v. Spence* 1972; Dickerson 1995). In these circumstances, the physician may obtain consent for an intervention from an alternate decision maker. Therapeutic privilege does not apply, however, simply because there is a situation in which providing information to the patient could make the patient less likely to accept the proposed treatment. Over time, the justification for withholding information from a competent patient has narrowed so much that therapeutic privilege is rarely invoked (Bostick et al. 2006). In sum, the default rule is to obtain informed consent for all interventions and to view therapeutic privilege and waiver as two extremely narrow exceptions that should be used in only well-defined and cautiously characterized situations.

Advance Directives and Substitute Decision Making

When a patient lacks capacity to make medical decisions, an alternate decision maker must be identified to authorize medical intervention or to refuse treatment on behalf of the patient. This other person is referred to as a substitute or surrogate decision maker. The surrogate decision maker is charged with making decisions for the patient, and most often for making decisions according to what the patient would have wanted were he or she competent. This standard is known as the substituted judgment stan-

dard. In the case of minors and in some limited circumstances where substituted judgment cannot be applied, the substitute decision maker may be charged with making decisions in the patient's best interest (Schouten and Edersheim 2008).

Substitute decision makers may be either informally or formally appointed. Informal appointment occurs without judicial intervention. An advance directive is one common way of appointing a substitute decision maker. An advance directive is a document prepared and executed by an individual at a time when he or she is competent that either gives instructions to guide decisions or appoints a substitute decision maker should the individual become incapacitated at some time in the future. Two types of advance directives are the health care proxy and the durable power of attorney for health care. Both are characterized by a "springing clause," that is, once crafted, they remain inactive until such time as the patient, or principal, is incapacitated. At the time of incapacity and for the duration of the incapacity, the advance directive "springs" into effect. Should the patient regain capacity at a future time, the advance directive would again become inactive.

Since the passage of the federal Patient Self-Determination Act of 1990, hospitals have been legally required to inquire as to whether patients have an advance directive at the time the patient is admitted to the hospital and additionally required to provide information about advance directives. This law also required the provision of education about advance directives to health care personnel and community members about advance directives (Patient Self-Determination Act final revisions [60 C.F.R. 123, 1995]). Notwithstanding passage of this law, it is estimated that the majority of Americans still do not have advance directives (Brendel and Schouten 2007). In the absence of an advance directive, one of several pathways is generally followed. One legally recognized pathway available in some states is the use of a surrogate decision-making statute. In the absence of an advance directive, these laws give priorities to potential surrogate decision makers based on their relationship to the patient. For example, the Illinois law prioritizes the patient's guardian (if any) and then moves on to the patient's spouse, adult child, and then parent as the order in which a surrogate decision maker should be appointed. At the bottom of the list are more distant blood relatives, followed by close friends and the guardian of the estate (Health Care Surrogate Act 2005).

In the absence of an advance directive and of a state surrogate decision-making law, clinicians often defer decisions to family members at the bedside, especially in situations in which there is little or no disagreement about the course of care, about the patient's wishes, and between family members and when the proposed treatment is well

established and low risk (Brendel and Cohen 2008; Schouten and Edersheim 2008). In situations where there is less clarity about interventions, proposed interventions are more intrusive, and/or there is disagreement between potential surrogate decision makers, the second type of substitute decision maker, or formal substitute decision maker, is more likely to be appointed. Formal surrogate decision makers are court appointed and are most commonly guardians.

Appointment of guardians is governed by state law. Increasingly, states have adopted guardianship laws and standards that derive from model legislation known as the Uniform Probate Code (UPC). Unlike a clinical finding of incapacity triggering the use of an informal advance directive, guardianship is a legal process that may include appointment of an attorney to represent the patient's values and interests, obtaining of independent medical opinions, and a formal court hearing. In addition, the standard for guardianship requires more than a finding of decisional incapacity. For example, UPC-derived state laws generally require three elements for imposition of a guardian: a clinically diagnosed condition, decision-making inability, and functional impairment. In order to obtain a treatment guardian for a patient, courts may look to neurocognitive assessment and functional testing to determine the need for and scope of the guardianship (Massachusetts Probate and Family Court 2009; Massachusetts UPC 2009). Finally, a guardian may be required, even when the treating clinicians do not believe that an intervention is intrusive. One example of a situation like this is the use of antipsychotic medications in Massachusetts (*Rogers v. Commissioner of Department of Mental Health* 1983).

Treatment Refusal and Involuntary Treatment

Consultation psychiatrists frequently become involved when medical inpatients refuse or are uncooperative with particular interventions, or decline treatment altogether. The legal criteria for involuntary medical treatment are based on capacity criteria and, where applicable, surrogate decision making, as discussed above. In other words, authorization for involuntary medical treatment is based on capacity criteria, and authorization for involuntary medical treatment depends on demonstrating that the patient does not have sufficient capacity to refuse treatment; it does not require that the patient's medical condition be life- or limb-threatening.

In contrast, the legal processes and criteria for temporary psychiatric detention and civil commitment do not as closely follow a decisional capacity-based approach (Byatt et al. 2006). Rather, while laws vary by state, the criteria for involuntary psychiatric detention in general require that

the patient have a mental illness and pose a danger to self or to others due to mental illness or be unable to substantially perform self-care or maintain safety due to mental illness. In addition, many jurisdictions follow a bifurcated approach to detention and treatment, meaning that if a patient refuses psychiatric treatment following a psychiatric admission, treatment may proceed only after specific judicial authorization, emergently to prevent imminent harm, and/or with a second psychiatric opinion, depending on the jurisdiction. Some medically ill patients with psychiatric illness may require separate and parallel processes for authorization of medical treatment and for psychiatric admission and/or treatment.

Restraints

The psychiatric-legal issues surrounding the use of physical restraints are complex (Tardiff 1984). As for involuntary medical and psychiatric treatment, the paradigms for use of restraints for medical purposes and for psychiatric purposes are different. In the United States, the Joint Commission (formerly known as the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) and the Center for Medicare and Medicaid Services have issued some guidance regarding the use of physical restraints in medical settings. In general, however, the use of restraints is frequent in medical and surgical hospital settings and is generally allowable to prevent interference with medical care. It is therefore commonplace to encounter physical restraint in inpatient medical settings, especially intensive care units (Glezer and Brendel, *in press*).

Consultation psychiatrists can assist nonpsychiatric colleagues and nurses in determining the risks and benefits of using restraints in general hospital settings. For example, physical restraints may be required in confused, medically unstable patients if chemical restraint is ineffective or contraindicated. If restraints are not used in some patients with delirium or dementia, they may pull out intravenous or arterial lines, endotracheal tubes, or other vital treatment interventions, and this risk often cannot be safely eliminated with sedation alone. Psychiatrists in medical settings can help explore the various options for managing the patient and address the discomfort staff may have in using restraints. It is important to bear in mind that there are clinical and legal risks inherent in using restraints as well as in failing to employ restraints for patient treatment and safety. As a general guideline, the decision about whether to use physical restraints in medical settings should ultimately be determined by what is required to provide necessary medical treatment, and the physician and other clinical staff should document their reasoning for the decision to use physical restraints in the medical record.

In contrast to the use of physical restraints in medical settings, the use of physical restraints on psychiatric units is more limited, and many psychiatric units and facilities have adopted no-restraint policies. Generally, the use of physical restraints in psychiatric settings is legally appropriate only when a patient presents an imminent risk of harm to self or others and a less restrictive alternative is not available.

Discharges Against Medical Advice

Discharges against medical advice (AMA) account for approximately 1% of discharges for general medical patients. AMA discharges commonly occur when patients are experiencing conflict in the doctor-patient relationship, are too anxious about their medical condition or treatment to engage in the treatment, have personal or work pressures to leave the hospital, or have an addictive disorder that has not been adequately diagnosed or treated in the hospital (e.g., nicotine withdrawal or cocaine craving) (Alfandre 2009). Decisions about AMA discharges generally follow the decisional capacity-based model of medical treatment refusal. Specifically, since medical patients are admitted voluntarily to a general hospital, an AMA discharge is akin to a withdrawal of the original consent to hospitalization. Therefore, one role of the consulting psychiatrist is to perform a capacity assessment to determine whether the patient has the requisite capacity to decide to leave the hospital AMA. In addition, the psychiatrist can explore why the patient wants to leave the hospital and, when possible and appropriate, help effect a solution leading to willingness of the patient to remain in the hospital. In other words, the psychiatrist can play a key role in depolarizing a standoff between the patient and the care team.

Care providers often believe that an AMA discharge is an automatic protection from liability (Devitt et al. 2000). Too often, hospital personnel are intent on getting a patient to sign an AMA discharge form, but the form is neither necessary nor sufficient to avoid legal liability. Regardless of whether the patient signs an AMA discharge form, a clear assessment of decisional capacity should be performed, and clear and complete documentation should be made in the medical record of the capacity assessment, the recommendations given to the patient regarding the need for and nature of follow-up care, and the possible risks of premature discharge (Gerbasi and Simon 2003). Medical patients who lack decisional capacity may be kept in the hospital against their will in cases of emergency, until either judicial approval or other authorized surrogate consent can be obtained. Unlike holding a patient involuntarily for psychiatric reasons, involuntary medical hospitalization in these limited circumstances generally does not require a finding of dangerousness to self or to others.

When efforts to convince a competent patient to remain in the hospital fail, a power struggle may ensue and members of the health care team often become angry at the patient. Such anger is not clinically constructive and may contribute to legal liability. For example, some physicians believe that they should refuse to give the departing AMA patient any outpatient prescriptions, thinking that would potentially make them liable for the patient's subsequent clinical course. However, if stopping the medication would endanger the patient (e.g., a beta-blocker after an acute myocardial infarction), it may be both ethical and prudent to give the patient a time-limited prescription, even if the patient wishes to leave the hospital. The patient should be told that he is welcome to return to the hospital if he changes his mind or his symptoms get worse, and robust efforts should be made to secure and convince the patient to accept follow-up care.

Emergency Treatment Requirements and EMTALA

The Emergency Medical Treatment and Active Labor Act (EMTALA), a U.S. federal law enacted in 1986, obligates emergency departments of all hospitals that participate in Medicare to examine patients who seek emergency care and to either stabilize them before discharge or admit or transfer them to another willing facility if medically indicated (Quinn et al. 2002). EMTALA has the effect of preventing health care providers from discriminating against patients who need medical care but are unable to pay. Issues with EMTALA may arise when patients who present to emergency rooms with unstable medical and psychiatric illness are uncooperative with treatment. For example, if a dialysis patient who has been banned from a hospital's outpatient dialysis program because of aggressive behavior toward staff and other patients comes to that hospital's emergency room with severe uremia or hyperkalemia, he or she must be provided with emergent dialysis nonetheless.

Conflicts may also occur between hospitals and between physicians when a patient appears too psychiatrically unstable to be treated in a medical facility and too medically unstable to be transferred to a psychiatric facility. The potential penalties for violations of the law are severe, and as such, in these situations, emergency physicians may admit patients to either a medical or psychiatric setting against the advice of psychiatric and medical colleagues out of fear of EMTALA liability. EMTALA applies only to emergency settings and does not apply to discharges from medical or psychiatric inpatient units, as clarified in 2003 EMTALA rules. However, issues regarding the transfer of psychiatric patients were not addressed in the new rules (Saks 2004).

Malpractice

Like all physicians, the consultation psychiatrist must meet the standard of care in treating patients. The responsibility of the consultant, however, is different than that of the treating physician. Specifically, the consultation psychiatrist's duty is to the consultee, or the physician who requests the consult. The consultant must provide competent consultation to the requesting physician (Brendel and Schouten 2007; Schouten and Brendel 2004). Conversely, the responsibility of the treating clinician is directly to the patient. However, consultants should be cautious in maintaining boundaries between the role of consultant and taking on the role of a treating clinician. For example, if the consultant recommends that the consultee (treating physician) prescribe a medication, the consultant's duty is to provide appropriate recommendations and information to the consultee. But, if the consultant directly enters an order for the medication to be given to the patient, the consultant will generally be held to have assumed a direct treatment role and assumed a direct responsibility to the patient. If the consultant does assume a primary treatment role (and there may be good reasons for the consultant to do so), it is important for the consultant to be cognizant that he or she has assumed the responsibility of a treating psychiatrist, including the responsibility to either monitor and follow-up on the patient's progress or arrange for another clinician to do so.

Physicians—and the psychosomatic medicine psychiatrist is no exception—often fear legal liability and malpractice lawsuits. There is good reason to be concerned, given that defending a malpractice lawsuit, regardless of the outcome, is a personally and professionally burdensome endeavor (Schouten et al. 2008). That being said, the best way to avoid malpractice litigation is to exercise sound clinical judgment, engage in judicious clinical practice, and communicate well with consultees and patients (Schouten et al. 2008). At the same time, familiarity with the legal concept of malpractice and a basic understanding of physicians' responsibilities may help the practitioner contextualize malpractice within the context of treatment and health care delivery.

Malpractice is an area of tort law that covers personal injuries resulting from medical interventions (Brendel and Schouten 2007; Schouten and Brendel 2004; Schouten et al. 2008). To establish a claim of malpractice, four elements must be met. First, a duty must be established, either by the existence of a direct doctor–patient relationship or a consultant–consultee relationship. In some cases, even limited or cursory interactions may be considered by the court to have constituted a doctor–patient relation-

ship. Second, a breach of that duty must have occurred (i.e., a violation of the standard of care). Third, this breach must have directly caused harm to a patient that resulted in the fourth element, or damage to the patient. The legal requirement for malpractice is often summarized as the four *Ds*: duty, dereliction of duty, direct causation, and damage. Malpractice does not require that the physician acted intentionally in causing harm to the patient. Rather, malpractice is an unintentional tort, a tort of negligence, which means that deviation from the accepted standard of care caused damage to the patient.

As a final note, studies of malpractice lawsuits have shown that only a small number of cases involving injury to patients due to medical errors actually lead to malpractice claims or litigation and that defendants prevail in the majority of cases that lead to litigation (Localio et al. 1991; Schouten et al. 2008). Notwithstanding, in a study of paid claims, no medical error was found in up to one-third of claims, highlighting the fact that even error-free practice does not insulate against malpractice liability (Schouten et al. 2008; see also Brennan et al. 1996). As a practical matter, physicians can reduce their risk of malpractice liability by recognizing individual and systemic factors contributing to errors, communicating effectively with colleagues and patients, acknowledging error and preserving relationships, maintaining good records, avoiding overlegalization and focusing on good clinical care, and consulting with colleagues (Schouten et al. 2008).

Conclusion

Issues at the interface of clinical practice and the law may arise frequently in the practice of psychosomatic medicine. Areas in which legal and quasilegal principles emerge include confidentiality and exceptions thereto, HIPAA, capacity determinations, informed consent and refusal, and concerns about malpractice liability. The best rule of thumb is for clinicians to be aware of relevant legal and regulatory provisions in the jurisdictions in which they practice but to leave lawyering to lawyers and, instead, act clinically. At the same time, it is important for the psychiatric consultant to be aware of available legal and risk management resources for consultation when legal issues and concerns arise in the course of treating patients. Finally, it is important for the consulting psychiatrist to be cognizant of his or her role in patients' treatment by maintaining an awareness of his or her role vis-à-vis the patients and to maintain clarity between consultative and direct treatment roles.

Ethical Issues

Donald L. Rosenstein, M.D.

Franklin G. Miller, Ph.D.

ETHICAL ISSUES ARE CENTRAL to both the practice of psychosomatic medicine and the professional identity of its practitioners. Psychiatrists who work in medical and surgical settings routinely perform clinical evaluations and make treatment recommendations with deep moral significance. For example, psychiatrists render opinions about whether medically ill patients can make decisions about their own care, whether they pose a danger to themselves or others, or whether they are appropriate candidates to either donate or receive an organ. These clinical assessments bear directly on patients' autonomy and the course of their medical treatment. Similarly, psychiatrists who provide end-of-life care frequently confront the possibility that medical interventions provided to their patients delay death rather than prolong life. The fact that no clear lines of demarcation exist between these types of clinical considerations and their ethical ramifications makes the practice of clinical ethics in psychosomatic medicine both compelling and challenging. All consulting psychiatrists should be adept at identifying ethical issues related to the practice of psychosomatic medicine and be familiar with laws, ethical rules, principles, and standards that provide guidance in solving moral problems in patient care.

Historically, practitioners of psychosomatic medicine and consultation-liaison psychiatry have been active and influential participants in the ethical life of hospitals, hospice settings, and nursing homes. Many serve as members or chairs of ethics committees, institutional review boards (IRBs), and ethics consultation services (Bourgeois et al.

2006). Even for clinical or research psychiatrists who do not participate in these formal ethics activities, the practice of psychosomatic medicine requires a familiarity with the principles of biomedical ethics.

The routine care of medically ill patients usually requires neither psychiatric consultation nor explicit ethical deliberation. However, when difficulties arise in the provision of clinical care, ethical and psychiatric concerns are often packaged together in partially formulated and emotionally charged requests for help (Lederberg 1997). In some cases, a psychiatric disorder may be inaccurately perceived as an ethical problem. For example, a patient's missed dialysis appointments might be interpreted as refusal of treatment when the patient's absences are actually a result of panic attacks. In this case, proper psychiatric evaluation and clinical intervention may obviate misplaced ethical concerns. Conversely, a legitimate ethical dilemma (i.e., an impasse in the clinical care of a patient because of conflicting moral values) can prompt a misguided request for a psychiatric evaluation (e.g., disagreement between family members and the medical team about the value of continued aggressive medical interventions for a severely ill and clearly incompetent patient). This second example requires careful moral deliberation among the relevant stakeholders rather than a specialist's assessment of the patient's decision-making capacity (DMC). Such cases often require a legal opinion and/or the help of an ethics consultant or committee. Nonetheless, the successful resolution of the ethical issues may not be possible un-

til the presence of psychopathology in the patient, or a systems problem involving the health care team, has been identified and addressed by the psychiatric consultant.

Psychiatrists and ethicists are frequently consulted on the same challenging cases at the same urgent moment. Just as the psychiatrist has been trained to enter carefully into a complex and dynamic health care system, gather information, and formulate the proper questions in the proper sequence, so too must the ethicist. Either consultant may call for a multidisciplinary team meeting to facilitate the critical decision makers talking with one another in the same room rather than through notes in the patient's chart.

Although many of the core skills needed for effective psychiatric intervention are also required for the resolution of ethical dilemmas that arise in the care of medically ill patients, important distinctions exist between the tasks and methods of these two consultative activities. Psychiatric consultation follows the medical model of providing expert advice on diagnosis and therapy. Physicians who request psychiatric consultations are seeking specific answers to specific questions. They want to be told precisely how to manage a certain aspect of their patient's care. Health care professionals often desire the same type of direction from an ethics consultant. However, within the bioethics community, the traditional medical model is one of the least favored approaches to ethics consultation. Instead, most ethics committees and consultation services work to facilitate discussion and conflict resolution between the stakeholders in the case. The purpose of this process-oriented approach is to identify the range of ethically permissible options rather than to provide a single "right answer" or stipulate a specific course of action. The consulting psychiatrist should be able to identify relevant ethical issues that fall outside the scope of the psychiatric question and encourage wider moral deliberation. Similarly, the ethics consultant who can identify unaddressed clinical concerns (e.g., is the patient depressed, anxious, or confused?) can help resolve an apparent ethical problem by bringing the prior clinical questions to the attention of the medical team or psychiatrist.

The purpose of this chapter is to provide a framework for integrating ethical considerations into the practice of psychosomatic medicine. The chapter is organized into two sections. The first section provides an overview of the discipline of ethics and the rules governing the behavior of physicians. The second section includes a case vignette to illustrate the complex interplay among several key clinical and ethical issues encountered in psychosomatic medicine and the process of moral deliberation. The case narrative is interrupted at critical junctures to facilitate a discussion of specific ethical issues as they might unfold in actual practice (e.g., DMC and treatment refusal; involuntary medica-

tion; withdrawal of care). The primary focus of the case is on ethical issues related to the provision of clinical care, but we also discuss the relevant differences between the ethics of clinical medicine and the ethics of clinical research.

We do not cover all ethical issues in psychosomatic medicine. Relevant legal considerations are discussed in Chapter 2 ("Legal Issues"). Specific ethical topics covered elsewhere in this book include physician-assisted suicide in Chapter 9 ("Suicidality"), terminal weaning in Chapter 19 ("Lung Disease"), dialysis decisions in Chapter 21 ("Renal Disease"), transplant candidate and donor issues in Chapter 31 ("Organ Transplantation"), sterilization in Chapter 33 ("Obstetrics and Gynecology"), placebos in Chapter 36 ("Pain"), and palliative care in Chapter 41 ("Palliative Care"). Readers are referred to other sources for ethics topics not covered, including confidentiality (Kimball and Silberman 1978), truth telling (Horikawa et al. 1999, 2000), and the scope of the psychiatric consultant's role in medical settings (Agich 1985).

Overview of the Discipline of Ethics

The discipline of ethics consists of systematic investigation and analysis of moral issues, including judgments concerning deliberation and conduct in specific situations, the identification and application of appropriate moral rules or principles, methods of justifying actions and practices, and the development of moral character. In the field of medical ethics, the focus of inquiry is often morally problematic cases involving complex interactions between health care professionals and patients (or research subjects) in which competing moral considerations are relevant. Ethical inquiry aimed at resolving a problem in patient care, or clinical research, proceeds in accordance with a series of connected steps (Fins et al. 1997). First, the factual contours of the case should be investigated, including the pertinent medical facts, the patient's needs and preferences, legal considerations, institutional contexts, and attitudes and actions of involved professionals. Second, the moral considerations relevant to the case are identified and assessed. This calls for discerning the bearing of specific moral rules and principles on the case and their relative weight in determining what to do when such moral considerations conflict. Third, a decision is made on a plan of action to resolve the moral problem. Finally, the plan is implemented, and its results are evaluated. Typically, all these stages of ethical inquiry take place within a process of discussion among the individuals with a stake in the outcome of the case, which may also include ethics consultation with an ethicist or ethics committee in especially difficult situations.

The most general moral considerations guiding ethical inquiry in medical contexts are the principles of biomedical ethics. The leading conception identifies four such principles (Beauchamp and Childress 2009).

1. *Respect for patient autonomy* requires that professionals recognize the right of competent adult individuals to make their own decisions about health care or research participation. This includes the obligation to obtain informed consent and the right of competent patients to refuse recommended diagnostic interventions or therapy or to decline an invitation to enroll in research.
2. In the therapeutic context, *beneficence* directs professionals to promote the health and well-being of particular patients by offering and providing competent medical care; in research, it directs investigators to produce valuable knowledge with the aim of improving medical care for future patients.
3. *Nonmaleficence* enjoins professionals to avoid harming patients or research subjects. Taken together, beneficence and nonmaleficence underlie the obligation of clinicians to assess the risk-benefit ratios of patient care and research interventions.
4. The principle of *justice* requires that medical care and research are performed in a way that is fair and equitable.

Complex moral problems in medicine are rarely solved by simple application of one of these principles. The specific relevance and weight of principles and subsidiary moral considerations are assessed in the deliberative process of ethical inquiry. An extensive and instructive account of the meaning and application of these principles is presented in *Principles of Biomedical Ethics* by Beauchamp and Childress (2009).

Ethical considerations relevant to the ethical practice of medicine and research are incorporated into various medical oaths (e.g., Hippocratic oath) and codes (e.g., Nuremberg Code, American Medical Association's Code of Medical Ethics; American Medical Association 2001), declarations (Helsinki; World Medical Association 2008) and reports, guidelines, policies, and laws regarding the behavior of physicians. Some of these documents conflict with one another, and some are even internally inconsistent with respect to permissible activities (Miller and Shorr 2002). Indeed, many physicians find their own beliefs at odds with existing laws and policies concerning specific medical practices (e.g., abortion, physician-assisted suicide, use of medical marijuana).

No code of ethics is specific to the practice of psychosomatic medicine. The most relevant professional documents are the American Medical Association's Code of Medical Ethics and the American Psychiatric Association's annota-

tion of this code (American Psychiatric Association 2001). The American Psychiatric Association's annotation goes into substantial detail regarding specific behaviors (e.g., sexual boundary violations, breaches of confidentiality, fee splitting, abandonment of patients) and is directly relevant to all psychiatric practice, including subspecialties. However, certain aspects of the practice of psychosomatic medicine pose ethical challenges that are not specifically addressed by these codes. The following case illustrates several of these difficult issues and suggests a clinically oriented approach to their resolution.

Case Vignette

Mrs. F, a 61-year-old divorced woman, was hospitalized for treatment of advanced breast cancer. She was first diagnosed with breast cancer in her mid-50s and appeared to be free of disease for 5 years after her initial diagnosis. Approximately 6 months ago, she presented with evidence of metastatic disease and received a second course of chemotherapy.

On the day before admission, she went to see her oncologist because of extreme low back pain. Diagnostic imaging identified multiple lesions in her lumbar spine consistent with progressive metastatic breast cancer. Her physician recommended hospitalization for pain management and another course of standard chemotherapy to be followed by radiation therapy. Mrs. F has a history of chronic anxiety and depression and takes paroxetine 20 mg/day and "a couple" of alprazolam "once in a while for nerves."

The morning after her admission, Mrs. F appeared very anxious and short-tempered but was willing to begin chemotherapy. She received intravenous (IV) lorazepam and oral prochlorperazine as part of her chemotherapy regimen. On the third day after admission, her nurse attempted to insert a new IV catheter for the continued administration of chemotherapy. The patient reacted with irritability and pulled her arm away from the nurse. Repeated attempts by the nurse to persuade Mrs. F to allow the IV line to be restarted resulted in an escalation of her anger, and she demanded to be "left alone." She also refused to take any of her oral medications. Psychiatric consultation was requested to determine whether the patient was "competent to refuse treatment."

Informed Consent and Decision-Making Capacity

A patient's refusal of care is a common trigger for psychiatric consultation and raises the related issues of informed consent and the right of competent patients to refuse recommended diagnostic interventions or therapy. Several key points are relevant in the analysis of the case at this point. First, the treatment of a patient without consent can be considered battery (in general, consent makes permissi-

ble what would otherwise be a violation of rights). Second, informed consent is meant to serve the values of patient autonomy and well-being by providing the information that patients need to choose for themselves whether to undergo a course of treatment. Third, a necessary condition for informed consent is DMC.

Consultation requests concerning a patient's ability to make his or her own medical decisions pose two questions. The first requires a *clinical judgment*: does this patient have a medical, neurological, or psychiatric disorder that compromises his or her ability to understand, appreciate, and reason with respect to a decision regarding a recommended diagnostic or therapeutic procedure? The second question requires a *moral judgment*: based on this clinical assessment and other relevant factors, should this person be allowed to authorize or refuse medical care? Competent adults are entitled to refuse medical care or demand the withdrawal of lifesaving treatments if they so desire. Consequently, the assessment of Mrs. F's DMC is a critical next task in her care. Furthermore, because impaired DMC often can be improved, it is important to address the clinical question prior to the ethical one.

The domains of legal competence, the capacity to make autonomous decisions, and the ability to provide informed consent are closely related but distinct from one another (Berg and Appelbaum 2001; Faden et al. 1986; Miller and Wertheimer 2010). In our society, we presume that adults are legally competent to make their own decisions. A judgment that someone is incompetent is made by judicial ruling and is typically based on the ability to make specific decisions at a given point in time (e.g., choices concerning medical care, management of finances, designation of a substitute decision maker, execution of a will). Standards for determining competence vary by jurisdiction but are based in large part on clinical assessments of an individual's cognitive state and DMC. From a legal perspective, a person is either competent to make decisions for himself or herself or incompetent to do so, in which case someone else makes decisions on his or her behalf (see also discussion of DMC in Chapter 2, "Legal Issues").

In contrast to the dichotomous nature of competency determinations, DMC varies along a continuum from being unable to make any meaningful decisions to possessing full capacity for complex decision making. In the medical setting, patients commonly manifest diminished DMC in some domains but retain the ability to make decisions in other domains. For example, a patient may have impaired DMC such that he or she does not understand the procedures, risks, and benefits of a complicated medical intervention, but he or she still may be quite capable of designating a spouse or another loved one to make medical decisions for him or her. Furthermore, the nature of co-

morbid medical and psychiatric illnesses and their treatments is such that DMC often changes over time. Patients with secondary mania, traumatic brain injury, and delirium characteristically manifest fluctuating DMC. Despite the greater prevalence in hospital settings of delirium or comorbid delirium and dementia (Trzepacz et al. 1998), as compared with uncomplicated dementia, the vast majority of published literature on clinical and ethical aspects of impaired DMC has focused on individuals with either stable or progressive cognitive impairment.

The assessment of DMC is particularly challenging in the setting of physical or behavioral communication barriers. Clinical decisions also must be made about patients who are either unable to speak (e.g., due to mechanical ventilation) or unwilling to be interviewed (e.g., due to a personality disorder). The use of written notes or communication boards (often of limited utility because of the patient's fatigue or weakness) and behavioral indicators may allow only tentative conclusions about the patient's DMC. These cases require patience, frequent reassessment, and clinical creativity. Because medically ill patients rarely undergo formal competency evaluations and judicial proceedings, the clinical assessment of DMC carries an extra burden in health care settings to ensure that medical decisions are made by patients with intact DMC or appropriate substitute decision makers for those patients not able to make informed and rational decisions.

Few human activities are as complex and individually determined as how we make decisions. Basic components of DMC include intellectual ability, memory, attention, concentration, conceptual organization, and aspects of "executive function" such as the ability to plan, solve problems, and make probability determinations. Most of the psychiatric literature on DMC has focused on these cognitive functions and used psychometric approaches to the study of subjects with neuropsychiatric illnesses such as dementia, psychosis, major depression, and bipolar disorder (Chen et al. 2002). In contrast, the contributions of mood, motivation, and other influences on risk assessment and decision making have received less attention but have clear implications for the process and quality of informed consent for both clinical procedures and research participation. The extent to which these factors, and less easily quantified concepts such as faith, intuition, trust, or ambivalence, affect the decision-making process is not known. Although much work remains to be done to better understand determinants of decision making, it is clear that focusing exclusively on measures of cognitive impairment is shortsighted.

Medically ill patients are at risk for impaired DMC for multiple reasons. The most common causes for concern are related to the patient's underlying medical problems (e.g., respiratory compromise, hepatic failure, cerebrovas-

cular event, severe pain) or their treatment (e.g., excessive narcotics, high-dose glucocorticoid or cytokine therapy) rather than to a primary psychiatric disorder. In Mrs. F's case, several potential medical causes may account for her treatment-refusing behavior (e.g., delirium due to benzodiazepine withdrawal or selective serotonin reuptake inhibitor withdrawal, inadequate pain control, depression, akathisia). A judgment that Mrs. F is or is not able to refuse treatment would be premature without a careful clinical evaluation of her mental state.

A frequently observed phenomenon on medical and surgical wards is the differential threshold for concern about DMC depending on the degree to which the patient is adherent to medical care. Patients who refuse a diagnostic or therapeutic procedure are often suspected of having impaired DMC and referred for evaluation by psychiatry or neurology. In contrast, decisionally impaired patients who are passive and agreeable with requests from their nurses and physicians rarely engender these same concerns. The diagnosis of delirium, particularly the hypoactive subtype, is often missed in hospital settings (see Chapter 5, "Delirium") and can be very distressing to patients, family members, and health care professionals (Breitbart et al. 2002a). One of several reasons to diagnose and aggressively treat delirium (with or without agitation) is that it may restore DMC and thus allow patients to make important medical decisions for themselves (Bostwick and Masterson 1998).

With respect to determining the adequacy of DMC, it is worth noting that clinicians and ethicists have argued for the legitimate use of a "sliding scale" for assessing competence depending on the consequences for the patient of consent or refusal of treatment (Buchanan and Brock 1990). For example, if Mrs. F urgently needed a lifesaving blood transfusion (low risk and high probability of saving her life), then only a very low threshold of competence would be needed for valid consent. However, in the case as described, Mrs. F is being recommended for a course of chemotherapy for widely metastatic breast cancer, presumably with systemic toxicity and a relatively small prospect of prolonging her survival. Given that risk-benefit scenario, one would want her to show a more sophisticated understanding and appreciation of her circumstances before acting on her decision.

Case Vignette (continued)

Dr. M, a psychiatrist specializing in psychosomatic medicine, visited Mrs. F for a psychiatric examination. She observed that Mrs. F was an older woman who appeared tired and poorly groomed. Her temperature was 38.4°C, and her pulse and blood pressure measurements were slightly elevated. When asked if she understood the purpose of the psychiatric evaluation, Mrs. F replied, "I have nothing to say to you or anyone else. I just want to be left

alone." Mrs. F was irritable and uncooperative with the interview and after a few minutes of complaining about her nursing care insisted that the psychiatrist leave her room. The nursing report indicated that the patient had been increasingly irritable over the past few days and was briefly disoriented the previous evening.

Suspecting that Mrs. F was experiencing delirium, possibly as a result of benzodiazepine withdrawal, Dr. M recommended treatment with a standing order of lorazepam. Dr. M also considered the possibility that paroxetine withdrawal was contributing to the patient's anxiety and agitation. In addition to restarting the paroxetine, orders were written for a multivitamin, folate, thiamine, and a workup for other metabolic, infectious, or structural causes of delirium (including blood tests, a lumbar puncture, and a magnetic resonance image). However, before completion of this workup, the patient struck a nurse and was placed in a harness and wrist restraints.

Physical Restraint and Involuntary Medical Treatment

Physical restraint of patients should be used only when no less restrictive method is available to protect them and staff from harm. The Centers for Medicare and Medicaid Services (U.S. Department of Health and Human Services 2006) and the Joint Commission (2009) require that hospitals have policies on physical restraint and seclusion. Most physicians and nurses are comfortable deciding whether and when a patient's behavior warrants physical restraint. In cases of extreme agitation and violence, nuanced mental status examinations are unnecessary. However, when the underlying neuropsychiatric disorder is not well characterized, the consulting psychiatrist can provide critical information about the justification for restraint and steps to improve the patient's condition. The medical team is looking for an expert opinion as to the patient's degree of self-control and dangerousness. Is there an imminent risk of harm to the patient or staff, and how can that risk be reduced? If the patient is competent and not dangerous, then forcible restraint violates his or her dignity, privacy, and autonomy. On the other hand, if an incompetent and dangerous patient is not restrained, the rights of staff and other patients, and the patient's safety, have been compromised.

It appears that Mrs. F temporarily lost DMC and that the principal concern at this juncture was her safety and that of her caregivers. Occasionally, health care providers question whether it is ethically and legally permissible to physically restrain patients under these circumstances (see Chapter 2, "Legal Issues"). There should be no confusion in this regard: standard of care and legal precedent for acutely agitated and confused patients are to immediately ensure their safety, even if it requires physical restraint. Compas-

sionate care requires that the patient be treated with dignity and respect under such circumstances and that restraint should be continued only for as long as necessary. The critical distinction to be made at this juncture is between competent, informed refusal of care that warrants respect and refusal behavior due to compromised DMC.

A comprehensive workup for delirium often involves invasive diagnostic procedures and may necessitate the use of force to overcome the patient's resistance. Under what circumstances is it permissible to hold a confused patient down for blood tests (e.g., electrolytes, serum drug levels, or blood cultures), a bladder catheterization, or a lumbar puncture? The clinical presentations that prompt such diagnostic interventions range from true medical emergencies to subacute and self-limiting syndromes. This problem has no simple solution. Such decisions require clinical judgments about the necessity of each diagnostic test, its associated risks, and the degree to which the patient's condition is deemed to threaten life or risk permanent serious injury. For minimally invasive testing judged to be of urgent and critical importance, physicians have an obligation to act in the best medical interests of their patients, even if this entails the use of force. At the other end of the spectrum, a relatively high-risk, low-yield diagnostic test in a stable but incompetent patient is substantially more difficult to justify.

Case Vignette (*continued*)

Mrs. F was divorced 15 years ago and since then has lived alone in the same town as her ex-husband. She has one adult son from a first marriage but had not seen him for many years. Attempts to reach the patient's son were unsuccessful, but her ex-husband came to the hospital to visit her. Mrs. F's ex-husband reported that when they were married, they had filled out an advance directive form that made him the holder of a durable power of attorney for her health care decisions. He did not know where that document was or whether it was still considered valid since their divorce.

Durable Power of Attorney and Advance Directives for Health Care

At this point in Mrs. F's hospitalization, the health care team should attempt to identify the most appropriate substitute decision maker for Mrs. F. Involving a spouse, close relative, or friend in medical decision making for incompetent patients shows respect for them. As with competency standards, laws regarding substitute decision makers vary by jurisdiction. The Patient Self-Determination Act of 1991 (Omnibus Budget Reconciliation Act of 1990) was intended to inform patients of their right to direct their own medical care should they become incompetent or oth-

erwise lose the ability to communicate their preferences. These rights include designating a holder of a durable power of attorney for health care decisions. The completion of a living will, or an advance directive for health care, allows patients to specify in writing the medical care they wish to receive under different medical circumstances (e.g., brain death, persistent vegetative state). Although specific laws and customs vary substantially from country to country, some mechanism for surrogate decision making in the medical setting exists in most developed countries (Laurette et al. 2008).

Clinicians and caregivers often make false assumptions about the legal status of family members and significant others when it comes to surrogate decision making. Parents of disabled adults (e.g., patients with mental retardation, autism, psychotic disorders) may erroneously conclude that they automatically remain the patient's legal guardian even after their child's eighteenth birthday. In most of these cases, the parents are the logical and most appropriate choices as legal guardians or surrogate decision makers. However, not all parents of incompetent adult patients have the best interests of their children in mind. Similarly, when an unmarried, incompetent patient has more than one adult child, differences of opinion among the children about what is best for that sick or dying parent are common. Consequently, clinicians should clarify the legal status of their patients' substitute decision makers whenever possible to avoid compromised medical care and its legal ramifications.

Research on the use of advance directives and the behavior of substitute decision makers suggests two important conclusions. First, most individuals are reluctant to put in writing the kind of medical care they would like to receive if they were to become gravely ill and incompetent. Several studies found that only 15%–20% of patients fill out an advance directive for health care or research when given an opportunity to do so (Gross 1998; The SUPPORT Principal Investigators 1995; Wendler et al. 2002). Second, regardless of the expressed wishes of patients, substitute decision makers tend to make decisions according to what they would want to happen to themselves or, alternatively, what they consider to be in the best interests of the patient rather than using a substituted judgment standard (i.e., what the patient would have wanted) when making decisions for someone else (Li et al. 2007; Shalowitz et al. 2006).

Case Vignette (*continued*)

The health care team requested a consultation from the hospital's legal department regarding the most appropriate substitute decision maker for Mrs. F. While attempts were made to contact the patient's son, the clinician in charge of Mrs. F's care obtained permission from the patient's ex-husband to continue the physical re-

straints and complete the diagnostic testing. The medical workup suggested delirium secondary to benzodiazepine withdrawal and a urinary tract infection. Mrs. F was given IV antibiotics, lorazepam, and a low dose of haloperidol to treat her confusion, conceptual disorganization, and agitation.

Two days after treatment with antibiotics, lorazepam, paroxetine, and haloperidol, Mrs. F had a markedly improved sensorium. She was considerably less irritable and was able to complete a detailed psychiatric interview. She was relieved to be able to “think clearly again” and over the course of several sessions developed a trusting relationship with Dr. M. However, as her delirium resolved, she expressed a deepening sadness and sense of hopelessness about her medical condition. She expressed skepticism about the value of more chemotherapy and radiation therapy and reported that what was most important to her at this point was to avoid a painful and lonely death.

Depression in the Medically Ill

In Mrs. F’s case, the aggressive treatment of her delirium had the value of restoring her DMC but left her painfully aware of her progressive cancer and feeling depressed as a consequence. The clinicians caring for her again faced a complex clinical problem that raises ethical issues. Mrs. F was contemplating stopping chemotherapy but was manifesting symptoms of depression. Was her depression influencing her decision making, and, if so, what is the proper response from her health care providers? As discussed earlier, clinical considerations should be explored first and in the service of an ethically desirable outcome for Mrs. F.

It is important to recognize that major depression in the medically ill usually does not render the patient incompetent. To be sure, the presence of depression may well influence the patient’s ability to tolerate uncomfortable symptoms, maintain hope, or assess a treatment’s risk-benefit ratio but not necessarily render him or her unable to make medical decisions for himself or herself (Elliott 1997). Untreated depression has been linked to poor adherence with medical care, increased pain and disability (see also Chapter 8, “Depression”), and a greater likelihood of considering euthanasia and physician-assisted suicide (see also Chapter 9, “Suicidality,” and Chapter 41, “Palliative Care”). Depression produces more subtle distortions of decision making than does delirium or psychosis, but refusal of even lifesaving treatment by a depressed patient cannot be assumed to constitute suicidality or lack of competence (Katz et al. 1995; Sullivan and Youngner 1994). Consequently, although a depressed patient should be strongly encouraged to accept treatment for depression, the decision to override a refusal of medical treatment should be based on whether the patient lacks DMC.

Case Vignette (continued)

Although Mrs. F was moderately depressed, she declined the recommended adjustment of her antidepressant because she had “lived with depression for years, and another dose or another antidepressant would not change anything for me.” She was unwilling to proceed with chemotherapy but did agree to try radiation therapy for palliative treatment of her bone pain. After 4 weeks of radiation therapy, she complained of new chest pain, and it was discovered that she had new bony metastatic lesions in her ribs.

At this point, she asked her oncologist to discharge her to home or hospice. Her oncologist responded that Mrs. F could go home but recommended that she consider enrolling in a Phase I clinical trial of a “very promising” new chemotherapeutic agent. Mrs. F’s ex-husband also encouraged her to enroll in the clinical trial and to “keep fighting as long as possible.”

Differentiating the Ethics of Clinical Research From the Ethics of Medical Care

In some respects, the option of enrolling in a clinical trial is a logical consideration following the failure of standard medical treatment. However, this decision point in Mrs. F’s clinical course warrants a thoughtful exploration of the differences between the practice of medicine and the conduct of clinical research. Clinical medicine aims to provide optimal medical care for particular patients. The risks of diagnostic tests and treatments are justified by the prospect of compensatory medical benefits for the patient. By contrast, clinical research is devoted to answering scientific questions to produce generalizable knowledge. Physician-investigators conduct clinical trials to evaluate experimental treatments in *groups* of patient-subjects, with the ultimate goal of benefiting future patients by improving medical care. The contrast between the group focus of research trials and the individual focus of medical care should not be overstated. Physicians are obligated to practice medicine in the context of a professional standard of care rather than by idiosyncratic judgments about what is best for individual patients. Nonetheless, they are expected to make competent treatment recommendations tailored to the characteristics of their individual patients.

Many patients receive therapeutic benefits from participating in clinical trials, which may even surpass the benefits from standard medical care (Braunholtz et al. 2001). However, clinical trials, especially randomized trials, differ fundamentally from patient care in purpose, characteristic methods, and the justification of risks. Interventions evaluated in these trials are allocated by chance. Double-blind conditions and often placebo controls are used. For scien-

tific reasons, protocols governing clinical trials typically restrict flexibility in dosing of study drugs and use of concomitant medications. Trials often include drug washouts before randomization to establish a drug-free baseline to assess treatment efficacy. Research interventions, such as blood draws, imaging procedures, and biopsies, are often administered to measure trial outcomes. These strictly research interventions pose risks to participants that are not compensated by medical benefits to them but are justified by the potential value of the knowledge to be gained from the trial. Although these differences between research trials and medical care have been frequently noted (Appelbaum et al. 1987; Beecher 1970; Levine 1986; Miller et al. 1998), their ethical significance has not been sufficiently appreciated. Accordingly, clinical trials continue to be conceived from a therapeutic perspective oriented around the physician-patient relationship (Miller and Rosenstein 2003).

Clinical research has changed dramatically in recent years. Two decades ago, most clinical trials were conducted in academic medical centers. Today, they are more likely to be conducted in private practice settings under the direction of clinicians rather than full-time investigators. Increasingly, psychiatrists are being consulted on patients who are either enrolled in or considering a clinical trial. Practitioners of psychosomatic medicine can make several contributions in this context. They may be asked to render an opinion about the psychiatric "appropriateness" of a patient for a clinical trial. Their patients may ask for advice about enrolling in a study. There may be an opportunity to modify the existing study or design a new one that addresses psychiatric aspects of the medical illness or its treatment.

In each of these activities, the consulting psychiatrist is well served by an understanding of the critical aspects of clinical research and how they differ from those related to standard medical care (Emanuel et al. 2000; Miller and Rosenstein 2003). For example, many patients and physicians do not appreciate that the primary purpose of a Phase I trial (what was offered to Mrs. F) is to assess the tolerability and toxicity of a drug rather than to obtain preliminary data on the effectiveness of the drug (Phase II).

Another aspect of research ethics possibly relevant to Mrs. F's case is the issue of research involving subjects considered "mentally disabled" (Rosenstein and Miller 2008). The regulations governing federally funded human subjects research were written more than 20 years ago and mandated additional safeguards for research subjects considered "vulnerable to coercion or undue influence" (U.S. Department of Health and Human Services 1991). Included in this category of vulnerable subjects are the "mentally disabled." These regulations, known as the Common Rule, were clearly intended to prevent the exploitation of individuals for the sake of scientific progress. Unfortu-

nately, the Common Rule does not include a definition of mental disability or of what would constitute the degree of mood, cognitive, or behavioral impairment that would render someone vulnerable in this respect. In practice, a psychiatric consultation often serves as an important additional safeguard by virtue of eliciting an expert opinion about a prospective research subject's DMC and ability to provide informed consent.

The nature of the research protocol, rather than the disorder being studied, also may place research subjects at risk for impaired DMC. Oncology trials in which subjects receive interleukin-2 or interferon-alpha, cytokines associated with central nervous system toxicity, provide examples of protocols that place otherwise competent subjects at risk for losing DMC. In these cases, the concern is less about adequate informed consent on the "front end" of the study than it is about subjects losing their ability to provide adequate consent for continuing participation. For such studies, IRBs can require subjects to appoint a holder of a durable power of attorney as a condition of enrollment. This approach has the advantages of highlighting an important risk of the study (i.e., loss of DMC) and ensuring appropriate initial and ongoing research authorization.

Research Ethics in Psychosomatic Medicine

Guidance on ethical issues raised specifically by research in psychosomatic medicine is needed. For example, obtaining proper authorization for research with individuals who lack DMC is relevant to both research on delirium and research on other conditions in which delirium might develop as a complicating factor. In the case of delirium research, current publication standards for informed consent are variable. Investigators have described research authorization from subjects who provided prospective informed consent (Breitbart et al. 1996). Other articles state that informed consent was obtained from the "subjects or their surrogates" (often without detailing the circumstances of surrogate consent) (Bogardus et al. 2003; Cole et al. 2002; Inouye et al. 1999; Laurila et al. 2002). It also has been argued that prospective IRB review and informed consent are not necessary for studies that involve very little "deviation from (standard) clinical practice" (Breitbart et al. 2002a, 2002b; Lawlor et al. 2000). We contend that this view confuses research with medical care and is inconsistent with the principle of respect for persons and federal regulations for human subjects research (45 CFR 46) (Davis and Walsh 2001). Some reports of delirium research are silent on the issue of IRB review (Lawlor et al. 2000). Finally, we have suggested that published reports of medical and psychiatric re-

search address ethical issues in a more comprehensive fashion (i.e., providing more detail than the standard sentence that the study was approved by a local IRB and that informed consent was obtained from subjects) (Miller et al. 1999; Tanaka 1999).

Case Vignette (*continued*)

After considering the pros and cons of enrolling in the Phase I clinical trial, Mrs. F decided to “face facts and let this thing run its course.” She told her oncologist that she was ready to go home but that she was very afraid the cancer would spread to more of her bones. When she told her oncologist that she would rather end her life than suffer through a painful death, her oncologist responded that he would not do anything to “bring on” Mrs. F’s death and reconsulted Dr. M because of this request for “physician-assisted suicide.”

On psychiatric examination, Mrs. F was judged to be moderately depressed but able to make decisions for herself. She confided that she had cared for her first husband during a “prolonged, excruciating, and undignified” death. She had accepted the inevitability of her death but wished to avoid the kind of experience her first husband had endured. Dr. M then facilitated a discussion between the oncologist and Mrs. F about available options. Mrs. F decided to stop eating and drinking and was discharged to hospice with assurances that she would be kept comfortable while awaiting death. Mrs. F died from terminal dehydration 12 days after her transfer to hospice.

When Patients Express a Wish to Die

Few clinical scenarios generate requests for psychiatric consultation more predictably than when a patient expresses a wish to die. The range of possible meanings underlying this communication is immense, and a comprehensive discussion is beyond the scope of this chapter (see also Chapter 2, “Legal Issues,” Chapter 9, “Suicidality,” and Chapter 41, “Palliative Care”). Is the patient expressing a passive wish to die, planning to commit suicide, rejecting life-sustaining treatments (withdrawal of care), eliciting help in ending his or her life (physician-assisted suicide), or asking to be killed (euthanasia)? Under any circumstances, an expression of suicidal ideation or a request for help with an intentionally arranged death is a complex message that warrants careful clinical assessment.

Muskin (1998) observed that physicians respond to requests to die by focusing predominantly on determinations of the patient’s DMC. He argued persuasively that too often clinicians pay inadequate attention to the underlying meaning and importance of these requests. Although competent subjects have the right to refuse life-sustaining treatments (and in Oregon and Washington in the United States, as well as in Belgium, Luxembourg, and Switzer-

land, request physician-assisted suicide), a compassionate and comprehensive evaluation by the consulting psychiatrist can help frame both the clinical questions and the ethically permissible medical options.

Just as the clinical issues raised by requests to die are frequently reduced to questions of DMC, the ethical analysis of physician-assisted suicide is often characterized as a simple matter of autonomy versus nonmaleficence. Miller and Brody (1995) articulated an important distinction in the debate on physician-assisted suicide. In considering whether physician-assisted suicide was morally justifiable, they explored whether the practice of physician-assisted suicide as a last resort could be compatible with the professional integrity of physicians.

Ultimately, Mrs. F made an informed and deliberate request for a comfortable and dignified death. Her choice of terminal dehydration was a legal option that did not compromise the professional integrity of her caregivers (Ganzini et al. 2003; Miller and Meier 1998).

Medical care at the end of life often identifies important differences in personal and cultural values held by patients, family members, and health care providers. Psychiatrists may be involved in cases in which a member of the health care team has a moral objection to an ongoing or a proposed treatment plan. When a physician’s personal conscience is at odds with a reasonable and legal treatment request from a patient or family member, there should be a mechanism for the transfer of care to another physician. However, it is critical in such cases that the patient not be abandoned in any way before the transfer of care.

Ethics Training in Psychosomatic Medicine

Training in ethics is considered a key component of the educational programs in psychosomatic medicine/consultation-liaison psychiatry fellowships. Recognizing the importance of the interface between psychosomatic medicine and clinical ethics, a task force of the Academy of Psychosomatic Medicine published an annotated bibliography for ethics training (Preisman et al. 1999). Guidelines on ethics, clinical decision making, and professionalism (Roberts and Hoop 2007; Wright and Roberts 2009) and curricula for teaching research ethics in psychiatry (Beresin et al. 2003; Rosenstein et al. 2001) are helpful resources for both students and teachers of psychosomatic medicine. Similarly, a recent analysis of privacy and confidentiality concerns associated with the implementation of the Health Information Portability and Accountability Act is particularly relevant for the practice of psychosomatic medicine (Mermelstein and Wallack 2008). Ethics educa-

tion should be oriented to developing basic competence in identifying ethical issues in the practice of psychosomatic medicine and in deliberation aimed at satisfactory resolution of moral problems in patient care or research.

Conclusion

The relation between psychosomatic medicine and bioethics is rich and unique for historical, conceptual, and practical reasons. The ethical issues considered in this chapter are often discussed in purely theoretical terms. We have illustrated some of the ways in which clinical considerations can color the expression and resolution of these issues as they are encountered at the bedside. All too often, optimal patient care is hampered by the presence of psychiatric symptoms in the patient or systems problems among the health care team or family members. Practitioners of psychosomatic medicine are ideally positioned to facilitate the resolution of both clinical problems and ethical dilemmas as they arise in an increasingly complex health care environment.

Psychological Responses to Illness

Mark S. Groves, M.D.

Philip R. Muskin, M.D.

A CENTRAL TASK OF THE psychiatrist working with the medically ill is to understand patients' subjective experiences of illness to design therapeutic interventions that modulate the patients' behavioral or emotional responses, decrease their distress, and improve their medical outcomes. In outpatient practice or in the general hospital, physicians witness tremendous diversity of emotional and behavioral responses to illness. Some individuals seem able to face devastating illnesses for which no cure is currently available with courage and a sense of humor (Cousins 1983; Druss 1995; Druss and Douglas 1988). Others, facing easily treatable illnesses, have difficulty overcoming intense emotions such as anger, fear, or hopelessness. Clinical experience and research indicate that illness variables such as severity, chronicity, or organ system involvement cannot predict an individual's response to any given medical illness (Lipowski 1975; Lloyd 1977; Sensky 1997; Westbrook and Viney 1982). Rather, it is in the realm of the individual's subjective experience of an illness that one can begin to understand his or her emotional and behavioral responses (Lipowski 1970; Lloyd 1977).

During the past few decades, there has been considerable work in the fields of health psychology and psychiatry attempting to explain the interindividual differences in responses to the stresses of illness (see, e.g., Druss 1995; Geringer and Stern 1986; Kahana and Bibring 1964; Lazarus 1999; Perry and Viederman 1981; Peterson 1974; Strain and Grossman 1975; Verwoerd 1972). In this chapter, we provide a general overview of the stresses that accompany medical illness and hospitalization and review some of the

psychological, emotional, and behavioral responses that these stresses frequently elicit.

The concepts of stress, personality types, coping strategies, and defense mechanisms can be integrated into a framework that illustrates the complexity of an individual's behavioral or emotional responses to illness (Figure 4-1). This framework, adapted from the work of Lazarus and Folkman (Lazarus 1999; Lazarus and Folkman 1984), attempts to integrate the psychodynamic concepts of character style and intrapsychic defenses with other psychological concepts such as stress and coping. The importance of individual subjectivity is emphasized in this model through the placement of coping styles, defense mechanisms, personality types, and the appraised meaning of illness as central mediators of the behavioral and emotional responses to the stresses of medical illness.

In this chapter, we do not focus solely on maladaptive responses to illness or psychopathology. A coping strategy or defense mechanism may be relatively maladaptive or ineffective in one context but adaptive and effective in another (Penley et al. 2002). For example, the maladaptive use of denial by a patient just diagnosed with early breast cancer might lead to a long delay in seeking treatment (Zervas et al. 1993). In contrast, the adaptive use of denial by a man diagnosed with untreatable metastatic pancreatic cancer might enable him to maximize his quality of life in the months before his death (Druss 1995).

Psychiatrists do not see most people who become ill, nor will most patients' responses to their illnesses concern their physicians (Patterson et al. 1993; Perry and Vieder-

FIGURE 4-1. Framework illustrating the complexity of an individual's behavioral or emotional responses to illness.

Source. Adapted from Lazarus 1999; Lazarus and Folkman 1984.

man 1981). That does not mean, of course, that there is no psychological response to the illness. An overt display of emotion may or may not be appropriate for a patient's racial and cultural background. In addition, patients may feel discouraged from expressing their thoughts and feelings about their illness to family members or physicians.

The determination that a psychological response to illness is problematic must be based on the effect the response has on the patient, the patient's adherence to therapeutic plans, and the patient's social functioning.

There is no one correct way to characterize psychological responses to illness. Psychodynamic formulations,

coping styles, and personality types offer different perspectives that may or may not be useful in understanding the response of a particular patient. Therefore, in this chapter we provide an overview of the following topics without subscribing exclusively to any single theoretical framework: 1) the stresses of medical illness and hospitalization; 2) the influences of personality types, attachment styles, coping styles, and defense mechanisms on patients' subjective experiences of illness; 3) denial; 4) emotional responses to illness; and 5) behavioral responses to illness.

Stresses of Medical Illness and Hospitalization

The stresses of medical illness and hospitalization are both very significant and numerous (Strain and Grossman 1975). In their frequently cited study from 1967, Holmes and Rahe surveyed many individuals from various countries, asking them to rate the effect of various events on their lives. These ratings generated a ranked list of life events based on relative effect (Lazarus 1999). In this list of stressors, "personal injury or illness" ranked sixth (after death of spouse, divorce, marital separation, death of close family member, and jail term). Some of the stresses accompanying illness are nearly universal, whereas others vary by illness and are more specific (Druss 1995). In this section, we discuss some of the most common stresses experienced by patients in medical settings.

Apart from medical illness, the hospital environment itself can be stressful (Gazzola and Muskin 2003; Kornfeld 1972). To many, the hospital is a frightening place associated with painful personal or family memories. Hospitalization separates patients from their usual environments and social supports; it is by its very nature isolating. The inpatient is asked to wear a hospital gown, which results in deindividualization, loss of control, and loss of privacy (Gazzola and Muskin 2003). The machines, intravenous lines, blood withdrawals, interactions with strangers, and neighboring ill patients all contribute to the stress of hospitalization regardless of the patient's specific illness. In addition, the hospital demands that the patient be largely dependent on others for the most basic tasks—a change that in itself can be very stressful for many individuals (Kornfeld 1972; Muskin 1995; Perry and Viederman 1981). Perry and Viederman (1981) described three successive (although at times overlapping) tasks that patients facing medical illness must go through: 1) acknowledgment to themselves and others that they are ill; 2) regressive dependency on others for care; and 3) resumption of normal functioning after recovery. Perry and Viederman (1981) proposed that all three tasks bring their own stresses and

must be confronted for the patient to cope successfully with the illness and the hospitalization.

On a nearly universal level, medical illness results in narcissistic injury—that is, it demands that patients reexamine their views of themselves (Strain and Grossman 1975). Although most people would not overtly claim that they are invulnerable to serious medical illness, they may hold such a belief subconsciously. Unconscious fantasies of invulnerability may be unknown until the person is injured or becomes ill. The development of a medical illness shatters any such conscious or unconscious beliefs. The sick patient may feel "defective," "weak," or less desirable to others.

One determinant of the effect of an illness is whether it is acute or chronic (Verwoerd 1972). Although an acute, non-life-threatening illness gives the individual little time to adapt, its effects are short term. Chronic illnesses, however, require the individual to change his or her self-view more permanently. The challenges of chronic illness are ongoing and become a part of daily life for the individual. A change in identity or body image is disorienting and often anxiety producing; the patient's previously held self-concept is disturbed, shaken up, or shattered.

Separation from family or friends in the hospital or at home when one is ill produces isolation, disconnection, and stress (Heiskell and Pasnau 1991; Strain and Grossman 1975). This can precipitate conscious or unconscious fears of abandonment. The stress of separation and fear of abandonment are not only experienced by children. Newly diagnosed with AIDS, a 30-year-old Latina mother of three may fear rejection by her community and abandonment by her parents. Or, after many years of chemotherapy for metastatic thyroid cancer, a 55-year-old bank executive may elect to undergo another course of chemotherapy despite the low likelihood of success rather than seek hospice care because the latter would signify giving up. Although not desirous of more treatment, the patient might fear that his oncologist who had worked with him for a decade would abandon him.

The lack of privacy in the hospital environment or clinic places additional stresses on the patient (Kornfeld 1972). Bodily exposure evokes discomfort. Given only a thin gown to wear, patients may be subjected to repeated examinations by doctors, nurses, and medical students. Exposure of the most private aspects of life can occur (Perry and Viederman 1981). A woman presenting with symptoms of a sexually transmitted disease must give a detailed account of her sexual history, and a young patient brought in with acute chest pain and hypertension is asked about use of cocaine, an illegal drug. For the vulnerable individual, such experiences of exposure can evoke feelings of shame and thus require the clinician to be tactful and

empathic to put the patient at ease and maintain a therapeutic alliance.

Beyond simple exposure, the medical environment often involves experiences of bodily invasion that are very stressful for the patient (Gazzola and Muskin 2003). From the more invasive experiences of a colonoscopy, the placement of a nasogastric tube, or tracheal intubation to ostensibly more benign procedures such as a fine-needle biopsy of a breast lump or a rectal examination, the fear and discomfort of such interventions are often not fully recognized by the physician for whom such procedures have become routine. Individuals certainly vary in their fears; for example, the victim of repeated physical or sexual abuse might be especially fearful of such experiences and require the doctor to use greater care and psychological preparation than usual.

Pain should not be overlooked as a profound stressor that should be dealt with aggressively (Heiskell and Pasnau 1991). Even the most highly adapted patient with effective coping skills and strong social support can be taxed to the limit by extreme pain. Psychiatrists are frequently asked to evaluate patients for depression and hopelessness. On discovering inadequately treated pain, the consultant can facilitate increased pain control, sometimes leading to full remission of hopelessness and depression without any additional intervention. Like pain, sleep disturbances are extremely common in the medically ill, with significant psychological effects. A patient's outlook, emotional expression, and ability to cope may shift dramatically when insomnia is remedied.

When illness leads to disability—whether due to pain, physical limitations, or psychological effects—the disability is an additional stressor that can have a profound effect on the patient's regular activities of daily life (Westbrook and Viney 1982). What was previously routine and required no conscious planning can become tremendously challenging, both psychologically and practically. For example, on the acute rehabilitation unit, patients are assisted in their efforts to learn to walk again. What was previously automatic has become incredibly difficult and requires new techniques, assistive devices, and the help of others. Disabilities frequently preclude the possibility of an immediate return to work. For many this is a significant loss because it removes the natural opportunities to feel productive, which had provided a sense of accomplishment. For many people, feelings of accomplishment, productivity, and usefulness are important for their self-image. Thus, self-esteem is damaged when they lose this important source of gratification.

Although only a small proportion of medical illnesses signify the imminent or near approach of death and force affected individuals to confront their mortality directly,

even minor illnesses can evoke a sense of the fragility and impermanence of life (Perry and Viederman 1981). Psychiatrists for the medically ill are often called to consult on patients who are experiencing anxiety or conflicts facing death (or patients whose illnesses evoke these difficulties in caregivers). Patients may refuse to give do-not-resuscitate orders despite clear evidence that resuscitation would be futile because they equate do-not-resuscitate orders with suicide, which is morally unacceptable to them (Sullivan and Youngner 1993). Facing mortality—whether in the near future or later—can force a person to reflect deeply on life and can shatter previously held dreams of the future. This can stir up regrets and evoke numerous emotions, as described in the work of Elisabeth Kubler-Ross (1969). The various emotions evoked by medical illness are discussed later in this chapter.

Attachment Styles, Personality Types, Coping Styles, and Defense Mechanisms

There is great individual variation in responses to an environmental stressor such as receiving a diagnosis of cancer (Heim et al. 1993). Models of human behavior that involve only environmental stress and reflexive behavioral responses cannot account for this variation in responses and are therefore considered to have limited utility and explanatory power. Richard Lazarus (1999) has reviewed the historical transition in health psychology and other disciplines from the traditional stimulus → response model to the more contemporary stimulus → organism → response model, which emphasizes the importance of understanding individuals' *subjective* experiences. Only through understanding individuals' subjective experiences can the interindividual differences in reactions to a stressor be accounted for.

Although the stressors of a situation and the behavioral responses of the patient may be readily identified by the medical team, the subjective experiences of the patient by their very nature are more elusive and require inquiry. Psychiatrists are often asked to evaluate patients with problematic behavioral or emotional reactions to the hospital setting or to their illnesses. Medical doctors usually can identify the stressors involved—for example, the need for emergent amputation in a 55-year-old diabetic patient with a gangrenous toe. The stated reason for consultation often also identifies the behavioral or emotional responses judged to be problematic, such as displaying anger and threatening to sign out against medical advice. Consulting psychiatrists seek to understand patients' subjective experiences of illness to explain their emotional and behavioral

responses and to design interventions to help patients (and their caregivers).

Research investigating subjective variables that influence an individual's response to a given stressor generally has focused on four main areas: attachment styles, personality types, coping styles, and defense mechanisms. These areas are addressed separately in this section.

Attachment Styles

Attachment theory is another fruitful way of examining patients' interactions with the health care setting and their physicians. John Bowlby (1969) developed a theory that emphasized the effect of early interactions with primary caregivers on an individual's internal relationship schemas. Attachment theory has recently been applied to psychosomatic medicine.

Four predominant attachment styles have been described in the literature (a secure style and three insecure styles: preoccupied, dismissing, and fearful; Bartholomew and Horowitz 1991). Several instruments have been developed to assess individuals' predominant styles, such as the Relationship Questionnaire (Griffin and Bartholomew 1994) and the Adult Attachment Interview (Main 1991). Each attachment style implies a view of self and other formed from early life experiences with caregivers; these internal relationship models are stable and enduring over time; thus, they would logically affect patients' experiences, behaviors, and expectations in the doctor-patient relationship. The individual with a secure attachment style is hypothesized to have experienced consistently responsive caregiving in early life and therefore has a positive expectation of others and comfort in depending on others for care. Inconsistently responsive caregiving is proposed as the environmental antecedent to a preoccupied attachment style, characterized by increased effort on the part of the individual to elicit caregiving and a positive expectation of others, with a negative view of self. These individuals may be particularly vulnerable to consciously or unconsciously exaggerated illness behavior or high medical use (Ciechanowski et al. 2002b).

The dismissing attachment style is thought to derive from early experiences with consistently unresponsive caregivers. As an adaptation to such an environment, these individuals come to dismiss their need for others, value being "self-reliant" to an extreme, and have difficulty trusting others. They develop a positive view of themselves as independent and self-reliant and have a negative expectation of others. Individuals with dismissing attachment styles would therefore be averse to reaching out to others or disclosing their emotional experiences. They avoid engaging in psychotherapy but once engaged benefit from the experience (Fonagy et al. 1996).

Hostile, rejecting, or abusive caregiving early in life is thought to originate the fearful attachment style, characterized by negative views of self and others and a desire for support but fear of rejection and difficulty trusting others. These individuals often alternate between help-seeking and help-rejecting behaviors and frequently demand care but are often nonadherent and miss appointments. Individuals may show characteristics of more than one attachment style, but identification of the predominant style can be useful.

Ciechanowski and colleagues' research studies of patients in a specialty diabetes clinic with various attachment styles serve as excellent examples of the richness of the application of this theory to the health care setting and patient-physician interactions. They found that dismissing and fearful attachment styles are associated with worse diabetes self-care, lower adherence to hypoglycemic agents, and higher blood glucose levels. They describe the difficulty such patients have in trusting and depending on others, which affects their interactions with physicians in our fragmented health care system (Ciechanowski and Katon 2006; Ciechanowski et al. 2001). They proposed that awareness of a patient's predominant attachment style can inform understanding of patient-physician dynamics. Skilled clinicians can use this understanding to alter their approach to patients to facilitate patient engagement and treatment adherence.

Other studies have found that attachment style is an important factor associated with 1) frequency of follow-up in a pain management specialty clinic (Ciechanowski et al. 2003); 2) symptom reporting in primary care, health care costs, and utilization (Ciechanowski et al. 2002b); 3) symptom perception or somatization (Ciechanowski et al. 2002b); and 4) medically unexplained symptoms among hepatitis C patients (Ciechanowski et al. 2002a). Reviews, such as Hunter and Maunder (2001) and Thompson and Ciechanowski (2003), provide a more detailed introduction to this rich area of research, particularly applicable to psychosomatic medicine research and clinical practice.

Personality Types

It is important to distinguish between the concepts of personality type or character style and personality disorder. As noted at the outset, we do not focus on psychopathology in this chapter. Personality types may be understood as existing on a continuum with respective personality disorders (Oldham and Skodol 2000). In addition, most patients do not fit exclusively into one type but may show characteristics of several personality types. Although the most accurate and complete understanding of personality may be achieved through a dimensional model, the characterization of discrete personality types is useful in high-

lighting differences and providing vivid prototypical examples. Much of the literature on personality types consists of contributions from psychodynamic psychiatry. Although this rich literature continues to be tremendously useful for psychiatrists working in the medical setting, it is unfortunately often ignored because of the current emphasis on biological and descriptive psychiatry. In recognition of Kahana and Bibring's (1964) classic and still relevant paper, "Personality Types in Medical Management," we have organized our discussion around the seven personality types they described (altering their terms to fit with more commonly used modern descriptions): 1) dependent, 2) obsessional, 3) histrionic, 4) masochistic, 5) paranoid, 6) narcissistic, and 7) schizoid. Kahana and Bibring's paper is so valuable because of the rich descriptions of these various personality types and the manner in which each type determines the individuals' subjective experiences of the meaning of illness.

Under conditions of stress, an individual's characteristic means of adapting to situations are heightened (Heiskell and Pasnau 1991; Kiely 1972). When confronted with the stress of a medical illness requiring hospitalization, the mildly obsessional patient might appear overly rigid or controlling. Similarly, a moderately dependent individual may appear "clingy" or excessively needy amid the acute stresses of hospitalization. Patients with extreme forms of these personality types can frustrate caregivers, often evoking intense negative emotions. It is important to recognize these countertransference responses because they can be diagnostically useful tools. The negative emotions that patients with these extreme personality types evoke in the physicians and nurses may result in responses from the caregivers that aggravate the situation (Muskin and Epstein 2009).

In another classic paper, "Taking Care of the Hateful Patient," Groves (1978) characterized four types of patients who most challenge physicians: dependent clingers, entitled demanders, manipulative help-rejecters, and self-destructive deniers. Groves also described the typical countertransference responses to each type and provided helpful tips on the management of these challenging patients. In this subsection, we integrate Groves's astute observations and descriptions of these four types with the seven personality types described by Kahana and Bibring.

Table 4-1 summarizes each of the seven personality types described in detail in the following subsections—their characteristics, the meaning of illness to each type, frequent countertransference responses evoked among caregivers, and tips on management—drawing on the contributions of Geringer and Stern (1986), Groves (1978), Kahana and Bibring (1964), Muskin and Haase (2001), and others.

Dependent

The dependent patient is needy and demanding, is seemingly unable to independently solve problems or self-soothe, and continually asks for help from others. Patients with a dependent personality may initially evoke positive feelings from their physicians and are more likely to adhere to treatment recommendations (Bornstein 1994). The physician may enjoy feeling needed or powerful, much as a parent might feel toward a child. The dependent patient, however, can feel "sticky" or seem to have insatiable needs (Miller 2001), making it difficult for the caregiver to leave the room or end an interview. Such patients typically have limited frustration tolerance. Historically described as "oral" personalities, the extreme of this personality type corresponds to a DSM-IV-TR diagnosis of dependent personality disorder and sometimes borderline personality disorder (American Psychiatric Association 2000; Geringer and Stern 1986).

For the patient with a dependent personality, illness evokes an increased desire for care from others. Illness stimulates the patient's fear of abandonment (Perry and Viederman 1981). The person may feel that no one cares about him or her or may frantically cling to caregivers. Extremes of this personality style fit Groves's (1978) description of dependent clingers. These patients evoke aversion in their caregivers. The caregiver becomes overwhelmed by the patient's neediness, may feel manipulated, and may wish to avoid the patient, thus confirming the patient's fear of abandonment (Groves 1978). Tips on managing patients with this personality style, whether in a mild form or at the extreme, include appropriate reassurance that they will be taken care of, setting firm limits regarding what needs will be met, and setting a specific schedule of visits (e.g., 20 minutes three times a week) to establish clear expectations regarding the doctor's time and availability (Miller 2001; Perry and Viederman 1981). For the over-demanding patient, it can be helpful to convey tactfully that behaviors such as incessantly ringing the call bell may have an opposite effect than what is intended and can lead caregivers to avoid the patient (Perry and Viederman 1981).

Obsessional

Individuals with an obsessional personality style are meticulous and orderly and like to feel in control. They place a strong emphasis on rationality, can be self-righteous at times, and are concerned with issues of right and wrong. These patients may be emotionally reserved and focus on details, sometimes to such an extent as to miss the broader picture. Ritual and regularity of schedule are important to them (Miller 2001). They are easily frustrated by the unpredictability of the hospital environment. Patients at the

TABLE 4-1. Personality types

Type	Characteristics	Meaning of illness	Countertransference responses	Tips on management
Dependent	Needy, demanding, clingy Unable to reassure self Seeks reassurance from others	Threat of abandonment	Positive: doctor feels powerful and needed Negative: doctor feels overwhelmed and annoyed; may try to avoid patient	Reassure within limits Schedule visits Mobilize other supports Reward efforts toward independence Avoid tendency to withdraw from patient
Obsessional	Meticulous, orderly Likes to feel in control Very concerned with right/wrong	Loss of control over body/emotions/impulses	May admire When extreme: anger—a “battle of wills”	Try to set routine Give patient choices to increase sense of control Provide detailed information and “homework” Foster collaborative approach/avoid “battle of wills”
Histrionic	Entertaining Melodramatic Seductive, flirtatious	Loss of love or loss of attractiveness	Anxiety, impatience, off-putting Erotic; finds patient attractive	Strike a balance between warmth and formality Maintain clear boundaries Encourage patient to discuss fears Do not confront head-on
Masochistic	“Perpetual victim” Self-sacrificing martyr	Ego-syntonic Conscious or unconscious punishment	Anger, hate, frustration Helplessness, self-doubt	Avoid excessive encouragement Share patient’s pessimism Deemphasize connection between symptoms and frequent visits Suggest that patient consider treatment as another burden to endure, or emphasize treatment’s positive effect on loved ones
Paranoid	Guarded, distrustful Quick to blame or counterattack Sensitive to slights	Proof that world is against patient Medical care is invasive and exploitative	Anger, feeling attacked or accused May become defensive	Avoid defensive stance Acknowledge patient’s feelings without disputing them Maintain interpersonal distance; avoid excessive warmth Do not confront irrational fears
Narcissistic	Arrogant, devaluing Vain, demanding	Threat to self-concept of perfection and invulnerability Shame evoking	Anger, desire to counterattack Activation of feelings of inferiority, or enjoyment of feeling of status of working with an important patient	Resist the desire to challenge patient’s entitlement Reframe entitlement to foster treatment adherence Take a humble stance, provide opportunities for patient to show off, offer consultations if appropriate
Schizoid	Aloof, remote Socially awkward Inhibited	Fear of intrusion	Little connection to patient Difficult to engage	Respect patient’s privacy Prevent patient from completely withdrawing Maintain gentle, quiet interest in patient Encourage routine and regularity

extreme end of the spectrum with this personality style might meet DSM-IV-TR criteria for obsessive-compulsive personality disorder.

Patients with an obsessional personality style will generally want a lot of information from their physicians regarding their medications, diagnoses, tests, and so forth. The physician may be pleased by the patient's desire to learn about his or her illness and its treatments. Under extreme stress, however, the patient may become increasingly rigid and inflexible, and at times the obsessional patient's only way to feel a sense of control is by refusing treatment or procedures (Kahana and Bibring 1964). A defiant refusal of procedures frequently leads to psychiatric consultation. For example, the obsessional patient who is frustrated by the unpredictability of his hospital care and is angry after hours of fasting for an endoscopy that is subsequently canceled may refuse to allow a phlebotomist to draw his blood the following morning or refuse the second attempt to send him to the endoscopy suite. Conflicts between the extremes of compliance and defiance are common for these individuals.

Illness is experienced by the obsessional patient as a loss of control over the body, and it evokes a fear of loss of control over emotions or impulses (Heiskell and Pasnau 1991; Kahana and Bibring 1964; Miller 2001). When an inflexible or obstinate patient with this personality style confronts the physician, the physician may be tempted to engage in a battle of wills or try to exert greater control over the patient's treatment. Such a response, however, becomes counterproductive and often provokes the patient to resist even harder as in a tug-of-war. Instead, it may be helpful to offer detailed explanations of the procedures and tests and the reasons they are necessary. This emphasizes a collaborative approach, encouraging patients to participate actively in their care. Wherever possible, it is helpful to give patients choices and input into their care. This makes the patient a partner, not an opponent (Gazzola and Muskin 2003). Giving patients information, assigning them "homework," and providing opportunities for their input on decisions, when appropriate, will enable them to feel more in control of their care and will decrease anxiety and interpersonal friction (Muskin and Haase 2001).

Histrionic

Patients with a histrionic personality style can be entertaining, engaging, and at times seductive. This can be charming at times, or it can be uncomfortable or embarrassing for physicians (Miller 2001). Histrionic patients crave attention, approval, and admiration and tend to avoid anxiety-provoking situations through the use of denial. Illness in the patient with a histrionic personality style is experienced as a threat to the patient's masculinity

or femininity (Geringer and Stern 1986). Illness activates such patients' fear of loss of love or attractiveness (Kahana and Bibring 1964; Strain and Grossman 1975).

The physician treating the histrionic patient should try to strike a balance between warmth and formality. Maintaining clear boundaries is essential, but an overly formal style will activate the patient's fear of loss of attractiveness or lovability (Heiskell and Pasnau 1991; Miller 2001). Encouraging the patient to discuss his or her fears will help bring to consciousness the anxiety that the patient is attempting to avoid. It is important, however, not to push patients too hard—a supportive and patient stance that gently encourages patients to voice fears when ready will be most helpful. "Confronting denial" head-on usually is counterproductive, as discussed in greater detail later in this chapter.

Masochistic

Patients with a masochistic personality style seem to be perpetual victims and readily recount their woes, experiencing themselves as self-sacrificing martyrs. One typically finds that such patients had miserable, abusive childhoods in which the experiences of physical illness paradoxically may have been bright spots, the only times they may have felt truly loved or cared for by parents or others (Heiskell and Pasnau 1991). The experience of illness, in part, provides reassurance to these patients that they will be able to maintain the attention and care of their physicians. Kahana and Bibring (1964) concretize this wish in the unspoken statement "You have to love me because I suffer so terribly." The patient may feel that the illness (consciously or unconsciously) is punishment for real or fantasized wrongdoings. Other patients may hold an unconscious wish to defeat their physicians (Douglas and Druss 1987; Heiskell and Pasnau 1991). The masochistic personality style can be particularly resistant to change.

Patients with the masochistic personality style may present with somatoform or factitious disorders. When the masochistic patient has no response (or a negative response) to treatment, or the physician's attempts to offer reassurance have no effect, the physician may become extremely frustrated. Encouragement and reassurance may actually have a paradoxical effect, provoking the patient to feel more pessimistic and leading to a worsening of symptoms. Those with an extreme version of this personality style have been described as "help-rejecters" (Groves 1978). They evoke feelings of irritation, depression, self-doubt, and hopelessness in their caregivers, who themselves may believe that such patients engineer their own misfortunes. The idea that someone could obtain psychological benefit from suffering is a concept that is difficult to understand, especially for physicians and other health care professionals.

Managing the patient with a masochistic personality should involve regularly scheduled follow-up visits irrespective of symptoms. It is important to deemphasize the connection between severity of symptoms and frequency of physician contact (Perry and Viederman 1981). Rather than encourage and reassure these patients, it is useful to acknowledge the patients' suffering and to "share their pessimism" (Groves 1978). It is sometimes of benefit for the physician to express to the patient an understanding that the illness and medical treatments are yet another burden for the patient to endure (Gazzola and Muskin 2003). It can also be helpful to emphasize the treatment's potential positive effect on others dear to the patient. This may reframe the treatment as another opportunity for the patient to suffer for the benefit of others (Heiskell and Pasnau 1991).

Paranoid

The paranoid patient is not generally a favorite of the physician. This patient maintains a guarded, distrustful stance; is quick to blame; and readily feels attacked (Heiskell and Pasnau 1991). Patients with a paranoid style do not forgive easily and may maintain lists of grievances. When these patients feel slighted, they tend to counterattack. It may not take much to provoke them because they are extremely sensitive to anything experienced as a slight. When ill, patients with a paranoid personality style may blame others, and they may conceive of the illness as proof that the world is against them. They are prone to feeling hurt, invaded, or exploited by seemingly innocuous medical procedures (Miller 2001). Stress increases such patients' tendency to be suspicious, guarded, or controlling. This results in a request for psychiatric consultation because these patients evoke feelings of anger in their caregivers. They refuse procedures or tests, threaten to sign out against medical advice, and accuse the staff of doing things against them.

The physician assigned the task of treating a patient with this personality style often feels accused. If the physician is not aware of this, it can lead to defensive countertransference (Kahana and Bibring 1964). This may appear as a temptation to argue with the patient or as an attempt to prove the patient wrong. Taking a defensive stance will be counterproductive and can in essence prove the paranoid patient right; a defensive response will only increase the patient's paranoia. A more helpful approach is to acknowledge the patient's feelings without dispute or agreement, explaining in detail the justification for the treatments. Irrational fears often should not be confronted head-on or challenged; the patient will judge caregivers more on their actions and predominant emotional stance than on their words. Avoiding excessive warmth is helpful,

as is maintaining sufficient interpersonal distance (Heiskell and Pasnau 1991). A calm, firm, direct stance is preferable to an angry, defensive stance or an intrusive, overly warm stance.

Narcissistic

Patients with a narcissistic personality style are typically easily recognized. Arrogant, devaluing, vain, and demanding, these patients can often be identified by one's immediate reaction. The narcissistic patient frequently begins the interview inquiring about the physician's title and rank. The patient may refuse to be examined by medical students, residents, or junior faculty members. These patients will devalue those believed to be inferior to them and will idealize the few people perceived to be highest in status. At the extreme, some patients will meet the criteria for narcissistic personality disorder. The patient's self-experience is frequently not validated by actual status in the world.

Narcissistic patients will experience an illness as a threat to their self-concept of perfection and invulnerability (Heiskell and Pasnau 1991; Kahana and Bibring 1964). Under such a threat, the patient's characteristic defense of grandiosity will be heightened. The physician or caregiver who is angered by the patient's devaluations and entitlement will be strongly tempted to put the patient in his or her place (Miller 2001). The psychiatric consultant who is called to assist in the management of a narcissistic patient may hear angry staff members say, "Who does he think he is? He's no better than anyone else!" and hear them put down the patient. Groves (1978) described patients at the extreme of this style as "entitled demanders," noting the intense feelings of anger and the desire to counterattack that these patients can evoke in their caregivers. The narcissistic patient can activate the physician's own feelings of inferiority, adding to the desire to avoid or attack the patient. The "power" of narcissistic VIP patients can be very seductive to physicians, who may be tempted to cater to the unreasonable demands with the fantasy of some special status.

Managing patients with a narcissistic personality can be challenging. Resisting the desire to challenge the patient's entitlement is crucial in forming a therapeutic alliance. According to Groves (1978), "Entitlement is the patient's religion and should not be blasphemed." Although it is counterintuitive, the physician should not reflexively support the patient's entitlement but should reframe it in such a way as to foster the patient's adherence to the treatment regimen and working with the team. Frequent use of phrases such as "You deserve the best" can be very helpful (Muskin and Haase 2001). Taking a humble stance can be effective: "Understandably, Mr. Jones, you want the best care and certainly deserve no less—unfortunately, although we strive to provide you with the best care possible, we

aren't perfect. We ask your indulgence to work with us so that we can give you the care that you deserve." Such statements can at times have a dramatic effect if delivered genuinely. Judicious use of "narcissistic strokes"—that is, providing opportunities for the patient to brag or show off—can assist in building rapport. Appropriate acknowledgment of mistakes made by the team and offering consultation by specialists can also assist in the management of these challenging patients. If the patient feels recognized as someone unique and special, he or she will feel reassured and will have less need to make demands (Heiskell and Pasnau 1991). The psychiatric consultant can assist members of the team not to take the patient's devaluations personally but instead to understand them as the patient's frantic efforts to maintain self-esteem. If the caregivers can avoid feeling personally attacked, they will find it easier to work with these patients and will be less likely to engage in a counterattack.

Schizoid

Patients with a schizoid personality are seen as aloof, remote, and socially awkward or inhibited; they frequently avoid obtaining medical care until it is absolutely necessary (Kahana and Bibring 1964; Miller 2001). The physician charged with the care of the schizoid patient will find it difficult to build rapport or engage the patient in treatment.

At one end of the spectrum of this personality style are schizoid and avoidant personality disorders (Geringer and Stern 1986). These two personality disorders are distinguished in part by the apparent interest in social contact. The patient with schizoid personality disorder seems uninterested in social contact, whereas the patient with avoidant personality disorder desires social contact but avoids it out of fear of rejection. In the consultation setting, similar management tips apply to either of these two personality disorders and to patients who fall within this spectrum. In general, illness and hospitalization evoke a fear of intrusion and intense anxiety (Geringer and Stern 1986; Heiskell and Pasnau 1991). The physician should respect the patient's need for privacy but should prevent the patient from withdrawing completely (Gazzola and Muskin 2003). Maintaining a quiet, gentle interest in the patient and encouraging a regular, expectable routine can reassure the patient that he or she is safe and will not be intruded on (Miller 2001). Typically, such patients have a fragile sense of self and therefore warrant gentle care but care at a distance.

Summary of Personality Types

These seven prototypical personality styles cannot claim to capture every patient, and many patients fit into multiple categories. Understanding the common features of each

style can aid the consulting psychiatrist. Knowing how each personality style experiences illness will inform interactions with such patients. Close monitoring of one's countertransference can also assist in identifying the patient's predominant personality style (e.g., feeling inferior with narcissistic patients or feeling attacked by paranoid patients). Knowledge of these personality types can assist the psychiatric consultant in educating the medical team about the proper management of these challenging patients and in assisting them not to react in counterproductive ways. At times, through understanding of the patient's personality style, the consulting psychiatrist is able to achieve rapid and remarkable therapeutic effects by choosing an appropriate intervention. Such effective interventions are impressive to nonpsychiatric physicians and staff members and confirm the utility of psychodynamic understanding in the psychiatric care of the medically ill.

Coping Styles

In the previous subsection, we illustrated how taking into account personality types can explain some of the individual variation in response to the stressors of illness. How individuals cope is another rich area of investigation (Jensen et al. 1991; Lazarus 1999; Penley et al. 2002), and problems in coping with illness have been shown to be a frequent reason for psychiatric consultation (Strain et al. 1993). Health psychologists have developed the concepts of appraisal (the assignment of meaning or value to a particular thing or event) and coping (Lazarus and Folkman 1984). An extensive body of literature developed over the past few decades has examined these processes among patients in health care settings. This psychological literature is often underrecognized by the psychiatric and medical communities but is extremely useful and can complement psychodynamic perspectives.

Coping can be defined as "thoughts and behaviors that the person uses to manage or alter the problem that is causing distress (problem-focused coping) and regulate the emotional response to the problem (emotion-focused coping)" (Folkman et al. 1993, pp. 409–410). A comprehensive review of the literature on the many defined coping strategies in medical illness is beyond the scope of this chapter. The reader is referred to the excellent reviews by Lazarus (1999) and Penley et al. (2002). Some important empirical generalizations that have emerged from decades of research on coping are discussed in this section (Lazarus 1999).

Use of Multiple Coping Styles in Stressful Situations

Folkman and colleagues (1986) identified eight categories of coping styles in a factor analysis of the Ways of Coping Questionnaire–Revised: 1) confrontative coping (hostile or aggressive efforts to alter a situation), 2) distancing (at-

tempts to detach oneself mentally from a situation), 3) self-controlling (attempts to regulate one's feelings or actions), 4) seeking social support (efforts to seek emotional support or information from others), 5) accepting responsibility (acknowledgment of a personal role in the problem), 6) using escape-avoidance (cognitive or behavioral efforts to escape or avoid the problem or situation), 7) planful problem solving (deliberate and carefully thought-out efforts to alter the situation), and 8) conducting positive reappraisal (efforts to reframe the situation in a positive light) (Penley et al. 2002). Research has shown that patients use multiple coping strategies in any given situation (Lazarus 1999). Individuals often prefer or habitually use certain strategies over others, but generally multiple strategies are used for a complex stressful situation such as a medical illness or hospitalization. People use some trial and error in the selection of coping style (Lazarus 1999).

Coping as a Trait and a Process

Preferred coping styles are commonly tied to personality variables; sometimes they can be viewed as traits as well as processes (Heim et al. 1997; Lazarus 1999). Therefore, it is useful to ask patients how they previously dealt with very stressful situations. This can provide useful information for the physician because patients are likely to use strategies in the present that are similar to those they used in the past, whether they were effective or not.

Research on women with breast cancer at various stages of illness has found that coping strategies may change as the nature of the stressor changes (Heim et al. 1993, 1997). For example, on initial detection of breast cancer, a woman may seek social support from her friends and spouse to cope with the uncertainties of her situation. Later, after lumpectomy and staging, she might shift her primary coping strategy to planful problem solving—a plan to follow up regularly for chemotherapy and to adhere fully to her oncologist's prescription of tamoxifen.

Problem-Focused Coping Versus Emotion-Focused Coping

One way to organize various coping styles is whether they are problem focused or emotion focused. Research has shown that patients will tend to choose problem-focused coping strategies when they appraise the situation as being changeable or within their control (Folkman et al. 1993; Schussler 1992). In conditions considered out of their control, patients may choose emotion-focused coping styles (Folkman et al. 1993; Schussler 1992). In the medical setting, consulting psychiatrists can help change the patient's appraisal of the situation and encourage the patient to choose more adaptive coping styles. For example, if a patient newly diagnosed with diabetes mellitus misperceives

high blood glucose as being unchangeable or out of his control, he might choose an emotion-focused coping strategy such as avoidance or denial. In educating this patient about how treatable hyperglycemia can be, the physician could encourage the patient to change his coping strategy to a problem-focused strategy such as making dietary changes or increasing exercise.

Variations in Usefulness of Coping Strategies Over Time

Coping is a powerful mediator of how a patient responds emotionally to a given stressor (Folkman and Lazarus 1988; Lipowski 1970). Coping strategies also have been reported to have different effects on health outcomes—some positive, others negative (see Penley et al. 2002 for a meta-analysis on this research). Although some coping strategies may be considered more effective than others, they vary in usefulness depending on the situation. A strategy that is initially effective in dealing with a stressor may no longer be effective when the nature of the stressor changes (Penley et al. 2002). The discussion of maladaptive versus adaptive denial under "Denial" later in this chapter illustrates this point.

Relation Between Coping Styles and the Meaning of Illness

Lipowski (1970) described eight "illness concepts": 1) illness as challenge, 2) illness as enemy, 3) illness as punishment, 4) illness as weakness, 5) illness as relief, 6) illness as strategy, 7) illness as irreparable loss or damage, and 8) illness as value. Lipowski proposed that a patient's choice of coping strategy is partially dependent on the underlying illness concept. In a study of 205 patients with chronic physical illness, the descriptors "illness as challenge" and "illness as value" were found to be related to "adaptive coping and mental well-being." Conversely, "illness as enemy," "illness as punishment," and "illness as relief" were associated with psychological symptoms and maladaptive coping (Schussler 1992).

Defense Mechanisms

Anna Freud (1948), in *The Ego and the Mechanisms of Defense*, first described the psychoanalytic term *defense mechanism* in the literature. Defense mechanisms are automatic psychological processes by which the mind confronts a psychological threat (e.g., the fear of death or deformity) or conflict between a wish and the demands of reality or the dictates of conscience. This psychoanalytic concept has a rich history that is beyond the scope of this chapter. Although there is some overlap of the concept of coping with that of defenses, the psychological concept of coping is more behavioral; it involves action (e.g., seeking social support, or pro-

ductive problem solving) and is generally a conscious experience. Defenses are usually conceptualized as intrapsychic processes that are largely out of the individual's awareness. In *The Wisdom of the Ego*, George Vaillant (1993) emphasized the usefulness of the concept of defenses:

Our lives are at times intolerable. At times we cannot bear reality. At such times our minds play tricks on us. Our minds distort inner and outer reality so that an observer might accuse us of denial, self-deception, even dishonesty. But such mental defenses creatively rearrange the sources of our conflict so that they become manageable and we may survive. (p. 1)

He further noted that

[a] clearly understood nomenclature of defenses not only enables us to understand adaptation to stress; it also offers us a means of uncoding, of translating if you will, much of what seems irrational in human behavior. (p. 28)

A basic understanding of the concept of defense and various defense mechanisms can provide the psychiatrist in the medical setting with another lens through which to examine a patient and to predict or explain the patient's emotional or behavioral responses to medical illness.

Vaillant (1993) identified several aspects of defenses:

1. *Defenses are generally outside of awareness of the individual or unconscious.* They enable the mind to "play tricks on" the individual to lessen distress or conflict.
2. *Defenses by nature distort inner and outer reality.* As is emphasized below, the degree of this distortion varies among defense mechanisms, as does the focus of the distortion: some defenses distort a ward-off internal drive or desire, whereas others distort the external reality or interpersonal situation.
3. *Defenses can appear strange or overt to the observer while going unnoticed by the subject.* The psychiatrist must decide whether directing the patient's awareness to his or her use of certain defenses is indicated.
4. *Defenses are creative.* The mind creates a new perception distinct from reality.
5. *Defenses involve psychological conflict.* Through them the mind attempts to manage the often conflicting demands of inner wishes, conscience, other people, and reality.
6. *Defenses are adaptive and are not all pathological.* Some defenses are more adaptive than others, and the use of defenses is an inherent property of the mind.

Vaillant (1993) proposed a hierarchy of defense mechanisms ranked in four levels of adaptivity: psychotic, immature (or borderline), neurotic, and mature. This hierarchy is

based on the degree to which each defense distorts reality and how effectively it enables the expression of wishes or needs without untoward external consequences. Patients often use many different defense mechanisms in different situations or under varying levels of stress. When a patient inflexibly and consistently uses lower-level defenses, this is often consistent with a personality disorder. Table 4-2 lists major defense mechanisms grouped into four levels.

The *psychotic defenses* are characterized by the extreme degree to which they distort external reality. Patients in psychotic states usually employ these defenses; psychotherapy is generally ineffective in altering them, and anti-psychotic medication may be indicated.

The *immature defenses* are characteristic of patients with personality disorders, especially the Cluster B personality disorders such as borderline personality disorder. Vaillant (1993) emphasized how many of these defenses are irritating to others and get under other people's skin. "Those afflicted with immature defenses often transmit their shame, impulses and anxiety to those around them" (p. 58).

In contrast to the immature defenses, the *neurotic defenses* do not typically irritate others and are more privately experienced—they are less interpersonal and often involve mental inhibitions. They distort reality less than do immature or psychotic defenses and may go unnoticed by the observer. With appropriate tact and timing, neurotic defenses can be effectively interpreted in exploratory psychotherapy when it is considered appropriate by the treating psychiatrist. "Over the short haul, neurotic defenses make the user suffer; immature defenses make the observer suffer" (Vaillant 1993, p. 66).

The *mature defenses* "integrate sources of conflict...and thus require no interpretation" (Vaillant 1993, p. 67). The use of mature defenses such as humor or altruism in the confrontation of a stressor such as medical illness often earns admiration from others and can be inspirational. Such mature defenses are not interpreted by the psychiatrist but are praised. These defenses maximize expression of drives or wishes without negative consequences or distortion of reality.

Denial

Denial is an important and complex concept and a common reason that physicians request psychiatric consultation. Weisman and Hackett (1961) defined *denial* as "the conscious or unconscious repudiation of part or all of the total available meanings of an event to allay fear, anxiety, or other unpleasant affects" (p. 232). It is to be distinguished from a lack of awareness due to a cognitive deficit such as anosognosia or from the limited insight of a patient with chronic

TABLE 4-2. Defense mechanisms

Mature defenses	
Suppression	Consciously putting a disturbing experience out of mind
Altruism	Vicarious but instinctively gratifying service to others
Humor	Overt expression of normally unacceptable feelings without unpleasant effect
Sublimation	Attenuated expression of drives in alternative fields without adverse consequences
Anticipation	Realistic planning for inevitable discomfort
Neurotic defenses	
Repression	Involuntary forgetting of a painful feeling or experience
Control	Manipulation of external events to avoid unconscious anxiety
Displacement	Transfer of an experienced feeling from one person to another or to something else
Reaction formation	Expression of unacceptable impulses as directly opposite attitudes and behaviors
Intellectualization	Replacing of feelings with facts/details
Rationalization	Inventing a convincing, but usually false, reason why one is not bothered
Isolation of affect	Separating a painful idea or event from feelings associated with it
Undoing	Ritualistic "removal" of an offensive act, sometimes by atoning for it
Immature defenses	
Splitting	Experiencing oneself and others as all good or all bad
Idealization	Seeing oneself or others as all-powerful, ideal, or godlike
Devaluation	Depreciating others
Projection	Attributing unacceptable impulses or ideas to others
Projective identification	Causing others to experience one's unacceptable feelings; one then fears or tries to control the unacceptable behavior in the other person
Acting-out	Direct expression of an unconscious wish or impulse to avoid being conscious of the affect, and thoughts that accompany it
Passive aggression	Expressing anger indirectly and passively
Intermediate denial	Refusal to acknowledge painful realities

TABLE 4-2. Defense mechanisms (continued)

Psychotic defenses	
Psychotic denial	Obliteration of external reality
Delusional projection	Externalization of inner conflicts and giving them tangible reality—minimal reality testing
Schizoid fantasy	Withdrawal from conflict into social isolation and fantasizing

schizophrenia. Psychiatrists are often called to see a patient "in denial" about a newly diagnosed illness and may be asked to assess the patient's capacity to consent to or refuse certain treatments. As discussed in this section, denial can be *adaptive*, protecting the patient from being emotionally overwhelmed by an illness, or *maladaptive*, preventing or delaying diagnosis, treatment, and lifestyle changes.

Denial seems to be a very personal response that is prone to a double standard: we are often capable of—even comfortable with—ignoring our own denial but consider other people's denial abnormal. A smoker may minimize his risk of lung cancer, noting that only a small percentage of smokers get the disease, yet simultaneously criticize his son's obesity as a risk factor for diabetes. Physicians urge their patients to adopt healthy lifestyles yet may routinely overwork and get too little sleep (see Gaba and Howard 2002).

Psychiatrists are most likely to be called on when the patient's denial makes the physician uncomfortable, but health care providers sometimes use the term *denial* loosely and inaccurately (Goldbeck 1997; Havik and Maeland 1988; Jacobsen and Lowery 1992). A physician's statement that a patient is "in denial" may refer to various situations: 1) the patient rejects the diagnosis, 2) the patient minimizes symptoms of the illness or does not seem to appreciate its implications, 3) the patient avoids or delays medical treatment, or 4) the patient appears to have no emotional reaction to the diagnosis or illness (Goldbeck 1997). The first task of the psychiatric consultant is to determine specifically what the referring physician means by "denial."

The severity of denial varies by the nature of what is denied, by the predominant defense mechanisms at work (e.g., suppression, repression, psychotic denial), and by the degree of accessibility to consciousness (Goldbeck 1997). Patients who use the mature defense of *suppression* in confronting an illness are not truly in denial. Rather, they have chosen to put aside their fears about illness and treatment until a later time. Their fears are not deeply unconscious but are easily accessible if patients choose to access them. These patients typically accept treatment, face their ill-

nesses with courage, and do not let their emotions overtake them. Such “denial” is considered adaptive (Druss and Douglas 1988). Many authors have proposed that some denial is perhaps necessary for very effective coping with an overwhelming illness (see discussions in Druss 1995; Ness and Ende 1994; Schussler 1992; Wool 1988).

In contrast to suppression, the patient using *repression* as a defense is generally unaware of the internal experience (e.g., fear, thought, wish) being warded off. Repressed thoughts or feelings are not easily accessible to consciousness. Such a patient may feel very anxious without understanding why. For example, a 39-year-old man whose father died of a myocardial infarction at age 41 may become increasingly anxious as his 40th birthday approaches without being aware of the connection.

When it is more severe and pervasive, denial can result in patients flatly denying they are ill and not seeking medical care. If they are already in care, they decline treatment or are nonadherent. Repeated attempts by the medical team to educate them about their illness have no effect. Extreme denial may be severe enough to distort the perception of reality, sometimes described as *psychotic denial*. Most patients with pervasive denial of illness are not psychotic in the usual sense of the word and should be distinguished from those who are. The latter usually have a psychotic illness such as schizophrenia and may pay no attention to signs or symptoms of illness or may incorporate them into somatic delusions. Psychotic patients who deny illness usually do not conceal its signs; others often readily recognize they are ill. In contrast, nonpsychotic patients with pervasive denial often conceal signs of their illness from themselves and others. For example, a nonpsychotic woman with pervasive denial of a growing breast mass avoided medical care and undressing in front of others and kept a bandage over what she regarded as a bruise. Although pregnancy is not a medical illness, a dramatic example of pervasive (sometimes psychotic) denial is the denial of pregnancy (see Chapter 33, “Obstetrics and Gynecology”).

Strauss et al. (1990) proposed a new DSM diagnosis—maladaptive denial of physical illness—to describe patients whose denial of illness is maladaptive. How does one determine whether denial is adaptive or maladaptive? For the woman with a growing breast tumor, denial is clearly maladaptive because it has prevented her from receiving potentially lifesaving treatment. In other situations, denial may be quite adaptive. In determining the adaptivity of a patient’s denial, it is important to answer the following questions (Goldbeck 1997):

- Does the patient’s denial impair or prevent the patient from receiving necessary treatment or lead to actions

that endanger the patient’s health? If so, then the denial is deemed maladaptive. In cases in which no effective treatment is available, the denial might be judged as adaptive to the extent that it decreases distress and improves quality of life, or it may be maladaptive if it prevents critical life planning (e.g., a single parent with little support and a terminal illness who has made no plans for his or her young children).

- Which component of denial—denial of the facts of illness, denial of the implications of the illness, or denial of the emotional reaction to illness—does the patient show? The latter two components of denial are not as maladaptive as the first component and may be adaptive in some situations. Denying the full implications of a disease, such as inevitable death, might be adaptive because it facilitates hope and improved quality of life. Likewise, denial of certain emotional reactions to the illness such as fear or hopelessness might enable a patient to stay motivated through a completed course of treatment.
- Is the denial a temporary means of “buying time,” to accept gradually a diagnosis so that the immediate effect is not so overwhelming, or has the denial been so protracted that it has prevented adaptive action? Many patients are unable to accept a diagnosis immediately, and denial may be a way for them to adjust at their own pace to their emotional distress in a period of gradual acceptance. In many situations, this would be considered adaptive.

Even when denial is adaptive for the patient, it may bother physicians or other caregivers. The following case vignette illustrates this point.

Case Vignette

A psychiatric consultation was requested for a 24-year-old man who was quadriplegic after a gunshot wound to the spine. The physician was insistent that the patient’s denial be “broken through” because the patient was convinced that he would walk again. The patient had a thorough understanding of his condition and maintained that his hard work and faith would restore his physical abilities. The physician was concerned that the patient might commit suicide when he realized that there was no chance of recovery of function. Instead of forcing the patient to face the prognosis, the consultant recommended that the physician offer the patient training in the skills necessary to maintain himself in his current state because recovery, in whatever form it took, would take a considerable amount of time. The patient continued to cooperate with physical therapy, learned how to use a motorized wheelchair, and discussed the plans for his living arrangements. The physician felt comfortable with this approach because it was “realistic.”

All too often, physicians misjudge patients as being in denial. This tends to occur with three types of patients: 1) patients without an overt emotional reaction to an illness or a diagnosis, 2) patients whose reactions differ from those expected by their caregivers, and 3) patients who have been inadequately informed about their illness. The absence of an overt reaction to medical illness is a style of psychological response. Although it is not evident to an observer, individuals may actually be aware of their emotions and thoughts about their illness. Some physicians have a tendency to misjudge patients as being in denial who do not express an expected emotional response or who seek alternative treatments instead of those recommended by the physician (Cousins 1982). An obsessional middle-aged accountant in the coronary care unit, for example, may be acutely aware of his condition and may be quite concerned about it, yet he may not express any of the fears or anxiety that his caregivers would expect, appearing calm and hopeful. This patient is not denying his illness but may be considered to be doing so by caregivers because he "looks too relaxed and in too good a mood."

One must ensure that patients are fully informed about their illness and treatment before assessing patients as being in denial. Gattelari et al. (1999) found that a portion of patients judged by their caregivers to be using denial were in reality relatively uninformed about the details of their illness or its prognosis. On the contrary, some patients who say that they have not been informed have in fact been repeatedly educated by their health care professionals and really are in denial.

Studies of the effect of denial on medical outcomes have found both beneficial and adverse effects. The literature has several methodological limitations, including sometimes failing to clearly define how denial was measured, treating denial as an all-or-nothing phenomenon, and using a lack of observable negative affect as a primary indicator of denial (problematic for the reasons discussed earlier). The use of different measures of denial and distinct patient populations makes comparisons across studies very difficult (Goldbeck 1997).

Some studies have reported positive effects of denial of physical illness on outcome. Hackett and Cassem (1974) found that "major deniers" in coronary care units after myocardial infarction had a better outcome than did "minor deniers." Levenson et al. (1989) found that among patients with unstable angina, "high deniers" had fewer episodes of angina and more favorable outcomes than did "low deniers." Other studies suggest that denial is useful for specific clinical situations such as elective surgery (Co-

hen and Lazarus 1973) and wound healing (Marucha et al. 1998). Denial was associated with better survival rates in a small study of patients awaiting heart transplantation (Young et al. 1991).

Other research studies have found a mixed or negative effect of denial on medical outcome. "Major deniers" have shorter stays in the intensive care unit but are more likely to be noncompliant after discharge (Levine et al. 1987). Greater denial was associated with a worse medical outcome but decreased mood symptoms and sleep problems in patients with end-stage renal disease (Fricchione et al. 1992). Denial may be counterproductive in asthma patients (Staudenmeyer et al. 1979). Croog et al. (1971) noted lower treatment adherence among deniers in their large sample of myocardial infarct patients. In a study of women scheduled for breast biopsy, those with a history of habitual use of denial were observed to have been more likely to delay medical evaluation (Greer 1974).

When denial is present and is assessed as maladaptive, interventions usually should be directed toward the underlying emotions provoking the denial (e.g., fear). Direct confrontation of denial generally should be avoided because it is counterproductive (Ness and Ende 1994; Perry and Viederman 1981). For example, a 17-year-old adolescent who is newly diagnosed with diabetes mellitus may not want to accept this diagnosis and the need for changes in his lifestyle because of his painful memories of seeing other family members suffer through complications of diabetes. The physician may be tempted to frighten the patient into compliance with a statement such as, "If you don't change your diet, measure your blood sugar, and take insulin regularly, you will wind up with complications just like your mother's." Such statements are usually counterproductive because they increase anxiety, which is driving the patient's use of denial in the first place. Instead, a gentle, empathic, and nonjudgmental stance is more effective (Ness and Ende 1994). Diminishing the intensity of negative affects such as anxiety through psychopharmacological or psychotherapeutic interventions also can be helpful because these affects may be driving the patient's need for denial.

In addition, the consulting psychiatrist should consider whether a patient's maladaptive denial is fostered by particular interpersonal relationships, such as those with family members, friends, a religious community, physicians, or other caregivers (Goldbeck 1997). In such cases, interventions aimed solely at the individual patient's denial without addressing the reinforcing interpersonal relationships are likely to be unsuccessful.

Emotional Responses to Medical Illness

Psychiatrists in the medical setting are frequently called on to help a patient manage emotional responses to illness and hospitalization (e.g., anger, fear, grief, shame). Usually the patient's emotional response is identified in the consultation request. For example, "Please come see this 25-year-old man just diagnosed with testicular cancer who is angry and refusing treatment." The young man's internist cannot understand why this patient would refuse the very course of therapy needed to treat (and possibly cure) his testicular cancer. With an understanding of the patient's subjective experience of his illness, his predominant coping styles, and his prominent defense mechanisms, the consulting psychiatrist can help the patient and the internist to understand the patient's anger, facilitating an alliance within which treatment is more likely to be accepted.

Because every patient is unique, empathic listening to a patient's story of his or her illness will identify the predominant emotional response, which is a potential clue to the subjective meaning of illness for that patient (Lazarus 1999). Core relational themes for the most common emotions (Lazarus 1999) can serve as hypotheses about the meaning of the illness for the patient (Table 4-3). An illness can evoke multiple emotional responses simultaneously or sequentially. The illness may have multiple meanings, and the meanings may change over the course of the illness. The predominant emotional response should not be the sole focus of the psychiatrist's attention (although it may demand the most attention). For example, the 25-year-old man just diagnosed with testicular cancer is markedly angry and refuses treatment. One can hypothesize that it might be because he feels frightened, weakened, or emasculated or that he fears castration. In viewing the physician as the bearer of bad news, the patient is not only angry about receiving a cancer diagnosis but also angry with his physician. Accepting and attempting to understand the patient's anger aids the psychiatrist in giving this man permission to express his feelings while tactfully helping him to see that he can do so without forgoing his own treatment. The patient's refusal of treatment also may be determined by fear of what the treatment will involve. The psychiatrist might also work with the oncologist and his response to the patient's anger. Education by the physicians about the treatment options and the high likelihood of cure could dramatically shift the patient's emotional and behavioral responses and evoke relief and hope. Assisting the patient in naming his emotional responses and understanding *why* they are present can help the patient feel understood. This can facilitate the acceptance of an indi-

TABLE 4-3. Core relational themes underlying affective responses

Anger	A demeaning offense against me and mine
Anxiety	Facing uncertain, existential threat
Fright	An immediate, concrete, and overwhelming danger
Guilt	Having transgressed a moral imperative
Shame	Failing to live up to an ego ideal
Sadness	Having experienced an irrevocable loss
Happiness	Making reasonable progress toward the realization of a goal
Envy	Wanting what someone else has
Relief	A distressing goal-incongruent condition that has changed for the better or gone away
Hope	Fearing the worst but yearning for better

vidualized treatment plan that appropriately involves medication, psychotherapy, psychoeducation, or other interventions.

Anger

Anger is a common emotional response to medical illness and may be the most difficult emotional response for physicians to confront. This is particularly true when the anger is directed toward them or is expressed as treatment refusal. Patients with paranoid, narcissistic, borderline, or antisocial personality styles or disorders are particularly likely to express anger in the face of medical illness (Muskin and Haase 2001). Common reflexive reactions include counterattacking or distancing oneself from the patient. The psychiatrist who is skilled in psychosomatic medicine will convey appropriate empathy along with necessary limit setting for the angry patient. Many maneuvers are possible, such as a tactful redirection of the patient's anger toward more productive targets (e.g., away from refusal of treatment and toward planning with the oncologist to attack the illness through potentially curative chemotherapy). Helping the team respond appropriately to the patient is just as important. Viewing expressed anger as natural and diffusing the intensity of affect can help to reestablish collaborative relationships with the patient.

Anxiety and Fear

Some degree of anxiety is likely to be experienced universally by patients in the medical setting (Lloyd 1977). The

degree of anxiety varies tremendously by individual and by situation. Patients with premorbid anxiety disorders are more likely to experience severe anxiety when confronted with medical illness. The patient with a dependent personality style may experience acute anxiety on hospitalization when faced with separation from his or her support system. The obsessional patient is likely to become anxious if the treatment plan or diagnosis remains unclear. The intrusiveness of the medical setting may evoke anxiety in the schizoid patient.

Psychotherapies, education about the illness and treatments, and judicious use of medication can greatly diminish the patient's anxiety (Perry and Viederman 1981). Although fear (usually involving a specific threat or danger) and anxiety (the feeling of nervousness or apprehension experienced on facing uncertain threats) are distinct emotions, their management is similar. It is important to elicit what the patient fears specifically—pain, death, abandonment, disfigurement, dependence, disability, and so forth. Blanket reassurance is usually ineffective and may actually be detrimental because the patient may perceive it as not empathic, superficial, false, or patronizing. Empathy and reassurance tailored to the patient's specific fears can offer significant relief (Perry and Viederman 1981).

Sadness

Situations in which people experience a loss evoke sadness (Lloyd 1977). Medical illness can lead to multiple types of loss: loss of physical function or social role, loss of ability to work, loss of the pursuit of a goal or dream, or loss of a part of one's body. Internal losses of organs or organ functions can be as significant as external losses such as amputation of a limb. Patients with untreated mood disorders may be more likely to develop clinically significant depression in the face of medical illness. Sadness may be the primary manifestation of an adjustment disorder, which is common in medically ill patients (Strain et al. 1998). Drawing an analogy to the process of mourning is often appropriate and helps to normalize the patient's sadness (Fitzpatrick 1999). A fact not well appreciated in medical settings is that mourning a loss takes time. It is important for the physician to convey a sense of appropriate hope. Describing true examples of other patients' positive outcomes in similar situations can often be helpful. Even when the patient's sadness represents a normal grieflike reaction, physicians are often tempted to prescribe antidepressant medication, desiring to make the patient feel better. In such cases, the psychosomatic medicine specialist can redirect the treatment plan to interventions that are more likely to be helpful, such as psychotherapy, pastoral

care, and—often most important—more time speaking with the primary treating physician.

Guilt

Some patients experience illness as a punishment for real or imagined sins. Clarifying that illness is not the patient's fault—and thereby confronting the guilt—is a helpful technique. Patients also may experience guilt related to earlier or current illness-promoting behaviors such as smoking cigarettes, nonadherence to medication regimens, or risky sexual practices. Education of family members can be critical if they blame the patient inappropriately for the illness. If the patient is religious, counseling from a hospital chaplain or the appropriate clergy member should be considered.

Shame

Illness is universally experienced as narcissistic injury to some degree. Narcissistic patients are more susceptible to experiencing shame in the face of medical illness. Patients who view their illness as a result of earlier behaviors—such as contracting HIV through impulsive sexual liaisons or developing lung cancer after a long history of smoking—may experience shame in the medical setting. It is important for physicians to take a nonjudgmental stance and avoid blaming patients for their illnesses. Critical, disapproving responses are counterproductive, heighten patients' shame, and frequently lead to treatment avoidance. For example, the noncompliant diabetic patient who is repeatedly admitted to the hospital for diabetic ketoacidosis frustrates her doctors and nurses. They are often tempted to scold the patient, thinking that this is necessary to avoid colluding with her acting-out and failure to take her disease seriously. Such responses are typically humiliating for the patient, are ineffective in motivating behavior change, and often worsen the vicious cycle of noncompliance.

Behavioral Responses to Illness

Patients' behavioral responses to illness vary tremendously within a spectrum ranging from maladaptive to adaptive. Adaptive responses may simply warrant encouragement or praise. Psychiatrists in the medical setting are often asked to see patients whose behavioral responses to illness or hospitalization are maladaptive and are interfering with their treatment. In understanding the patient's subjective experience, personality style, defense mechanisms, and coping strategies, one can design therapeutic interventions to help change the patient's responses to more adaptive behaviors. This section highlights a few of the common behavioral responses to illness.

Adaptive Responses

Support Seeking

Facing a new medical illness or hospitalization can be highly taxing for even the most well-adapted individual. Patients who are fortunate enough to have well-developed social support networks can benefit greatly from support from friends and family. Patients with conflicts about dependency might have more difficulty with this task, and psychotherapy can normalize this need and assist patients in reaching out to others. Referral to patient support groups also can be helpful for many patients; they can learn from the experiences of others facing the same illness and can feel less alone or alienated from other people. Information about self-help organizations can be obtained from various sources on the Internet, such as Dr. John Grohol's "Psych Central" Web site (<http://psychcentral.com>) and the "Self-Help Group Sourcebook Online" of the American Self-Help Group Clearinghouse (<http://mentalhelp.net/selfhelp>).

Altruism

Altruistic behavior such as volunteering to raise money for breast cancer, becoming a transplant advocate who meets with preoperative patients and shares experiences with them, or participating in an AIDS walkathon can represent a highly adaptive response to illness. One of the common stresses of illness is the effect on an individual's self-esteem and sense of productivity. Through helping others, patients feel a sense of purpose and gratification that can help improve their mood. Generally, the consulting psychiatrist needs only to support and encourage such behaviors. For many patients with severe illnesses, voluntary participation in research can have the same effect. Particularly for those with terminal illness, participation in research can provide a sense of purpose and hope by contributing to the potential for new treatment options in the future.

Epiphany Regarding Life Priorities

Although no one would generally claim that a medical illness is beneficial for the affected individual, it often helps patients regain perspective on what is most important to them in life. Normal daily hassles of living may no longer seem as stressful, and some patients facing a serious illness experience an epiphany and dramatically change their lives for the better. Patient narratives of the life-affirming effects of illness and stories of personal growth abound in literature (Druss 1995). At times, the consultation psychiatrist can witness and support a patient through a personal transformation. A 47-year-old male executive recently diagnosed with a myocardial infarction may dramatically change his diet, embark on a new exercise regimen, and reconfigure his role at work to reduce emotional stress. Sim-

ilarly, a woman newly diagnosed with HIV who commits herself to taking her medications regularly, seeks treatment for substance use, and rejoins her church also exemplifies this phenomenon.

There are wonderful opportunities for effective psychotherapy in the medically ill. Patients are under tremendous stress when faced with serious medical illness, and the usual distractions of their daily lives no longer dominate their thoughts. Sometimes a therapeutic alliance can form and work can progress more rapidly than is typical in other settings (Muskin 1990). The regression imposed on patients by the medical illness may set the stage for psychological gains that would take much longer in typical outpatient psychotherapy.

Becoming an Expert in One's Illness

For the obsessional patient in particular, learning as much as possible about the illness can be adaptive and can give the individual a greater sense of control. Although the information itself may not be positive, patients often find that reality can seem more manageable than their imagined fears. However, this response to illness is not appealing to all patients. Some will prefer to put their trust in their physicians and prefer not to know everything. The psychiatrist, armed with an understanding of the patient's personality style, characteristic coping styles, and defense mechanisms, will be able to know whether increased information and knowledge might reduce the patient's distress and augment a sense of control.

Maladaptive Responses: Nonadherence to Treatment Regimens

Treatment nonadherence is more common than most physicians recognize. Estimates suggest that up to 50% of patients fail to adhere to their prescribed medication regimens (Sackett and Haynes 1976). Patients typically overestimate their own adherence to the treatment, and physicians are often unaware of their patients' lack of adherence (Levenson 1998). Physicians working in all medical settings witness the negative effects of nonadherence, and psychiatrists are called frequently to see problem patients who are repetitively noncompliant. For such cases, the consulting psychiatrist is often cast in the role of disciplinarian, detective, or magician; medical colleagues may expect the psychiatrist's interventions to bring rapid change to the patient's adherence patterns. Although it is possible in some cases, this scenario is typically unrealistic. It is possible to undertake interventions that improve patient adherence when the underlying factors accounting for nonadherence are correctly identified and addressed.

Patients do not fully adhere to treatment regimens for numerous reasons. Psychiatric disorders and psychological

motivations are not the only factors that may be involved. Other factors, such as cost, side effects, and treatment complexity, may play a role. It is important to determine the degree of a patient's nonadherence and its context. Is the patient occasionally or consistently nonadherent? Is the nonadherence specific to a certain medication or type of recommendation (e.g., dieting), or is it more generalized across different treatments and different physicians? Identifying the context of nonadherence can provide clues to the underlying factors involved when the patient cannot directly give the reasons for nonadherence. In this section, we identify some of the most common reasons for treatment nonadherence and offer 11 general principles for management of this common clinical problem.

Psychologically Motivated Factors for Nonadherence

Perry and Viederman (1981) outlined several distinct psychological reasons that patients do not adhere to treatment recommendations. One reason they discuss is nonadherence to defend against humiliation (Perry and Viederman 1981). Rather than accept the stigma of his illness, a patient with HIV might stop his medications, which remind him daily of his illness. Active empathic work to counteract the illness concepts that cause shame can diminish this motivation for treatment nonadherence.

Another psychological motivation for nonadherence is to counteract a feeling of helplessness (Perry and Viederman 1981). An adolescent with newly diagnosed diabetes mellitus who is struggling with a developmentally appropriate desire to gain autonomy may believe that the only way to feel autonomous and in control is to rebel against her parents and caregivers by not taking insulin. Such nonadherence also may be motivated by the wish to be healthy like her peers.

Anger toward the treating physician or toward the illness or diagnosis itself may be another psychological motivator for treatment nonadherence, whether the anger is appropriate to the situation or is a product of character pathology. Various degrees of denial also may be involved. Specific interventions for clinical situations in which anger and denial are primary motivators for nonadherence were discussed earlier in this chapter in the section "Denial" and in the subsection "Anger" under "Emotional Responses to Medical Illness."

Patients' trust in the physicians recommending their treatment is an important determinant of their likelihood of complying with the treatment regimen. Physicians must earn their patients' trust through building rapport and direct, honest communication. Patients with psychotic disorders or significant character pathology might have particular difficulty placing trust in their caregivers. Mistrust

and paranoia may play a role in these patients' noncompliance with treatment regimens.

Comorbid Psychiatric Disorders and Nonadherence

Comorbid psychiatric disorders also may lead to treatment nonadherence. Mood disorders are particularly common. Depressed patients may not have the motivation, concentration, or energy required to comply fully with treatment recommendations. They might even stop treatment as an indirect means of attempting suicide. Manic patients may believe that they no longer need treatment, may abuse substances, or may become disorganized or psychotic. Psychotic disorders, anxiety disorders, substance use disorders, and cognitive disorders are other psychiatric conditions that often play a role in treatment nonadherence. Therefore, a thorough psychiatric history and comprehensive review of symptoms are essential parts of the evaluation of the noncompliant patient.

Other Factors in Nonadherence

Nonadherence may be due to reality factors rather than psychological motivations. Cost of treatment, side effects (whether feared or experienced), and complicated or inconvenient medication dosing schedules are treatment-specific factors that should be considered. Other practical barriers, such as difficulties with transportation, inflexible and lengthy work schedules, or child care responsibilities, may preclude consistent keeping of appointments (Levenson 1998).

A lack of information about the illness or its treatment should always be ruled out as a factor in nonadherence. Patients should understand their illness, their treatment options, and the reasons that treatment is necessary. Patient education should always be provided in the patient's primary language to ensure full understanding. To assess patient understanding, physicians should ask patients to repeat and to explain in their own words what they have been told about their illness. If possible, family members should be involved in the education. Written materials or visual materials may be helpful tools in patient education.

Incongruities between the health beliefs of patients and their physicians can also account for nonadherence and should be identified (Gaw 2001). Physicians of all disciplines must make an effort to understand their patients' cultural and religious backgrounds, paying particular attention to patients' beliefs and values about health and illness. Physicians should attempt to elicit their patients' explanatory models about diseases and the effects of treatments. When possible, attempts can be made to explain treatment plans within patients' explanatory models for illness and treatment. Conversely, at the least, mutual ac-

knowledge and acceptance of the differences between the explanatory models of the physician and the patient may facilitate treatment adherence and build doctor-patient rapport. When they feel that their caregivers accept and understand their cultural, health, or religious beliefs, patients will be more likely to volunteer information about their use of alternative or herbal treatments.

Interventions to Increase Treatment Adherence

The following general principles may assist the physician in facilitating greater patient adherence to treatment regimens (Becker and Maiman 1980; Chen 1991; Gaw 2001; Levenson 1998):

- ♦ Ask patients directly about their adherence, maintaining a nonjudgmental stance. Design a collaborative plan to increase adherence. Normalizing statements and questions—such as “Many patients find it difficult to take their medications on a regular basis. Have you had this experience?”—are more effective in eliciting information about treatment adherence than questions such as “You’ve been taking your medication regularly, right?”
- ♦ Ensure that patients are fully informed about their illness and treatments.
- ♦ Rule out cognitive deficits (e.g., mental retardation or dementia) because they may play a role in nonadherence.
- ♦ Uncover any underlying psychological motivating factors for nonadherence, and address them specifically.
- ♦ Diagnose and treat any comorbid psychiatric disorders.
- ♦ Minimize treatment-related factors for nonadherence, such as side effects and cost and complexity of treatment regimens, when possible.
- ♦ Identify, acknowledge, and contend with any cultural reasons for nonadherence.
- ♦ Avoid shaming, scolding, or frightening the patient. Scolding patients or scaring them with statements such as “If you don’t take your medications, you could have a heart attack and die!” is almost always counterproductive (Heiskell and Pasnau 1991). Such statements may shame patients or inflate their fears and can increase the likelihood that they will not return for treatment.
- ♦ Use positive reinforcement as a motivator when possible because it is generally more effective than negative reinforcement at facilitating behavior change.
- ♦ Involve family members in facilitating patient treatment adherence when they are “on board” with the treatment plan.
- ♦ Attend to doctor-patient rapport, and build an effective treatment alliance.

Maladaptive Responses: Signing Out Against Medical Advice

A common reason for urgent psychiatric consultation in the medical hospital is a patient threatening to sign out against medical advice. Of all hospital discharges in the United States, 0.8%–2% are against medical advice (Hwang et al. 2003; Jeremiah et al. 1995; Weingart et al. 1998). Often the psychiatrist is asked to assess the decisional capacity of a patient who wants to sign out against medical advice. Legal aspects of this important assessment are discussed in Chapter 2, “Legal Issues.” The patient’s threat to sign out is usually not truly motivated by a primary desire to leave but more often reflects another agenda, intense affect, or interpersonal friction with physicians or nursing staff. In some cases, it is a means of expressing anger or frustration toward caregivers (Albert and Kornfeld 1973).

The motivations for signing out against medical advice vary significantly and are similar to those motivating treatment nonadherence. Among the more common motivations are 1) anger with caregivers or dissatisfaction with the treatment received (whether legitimate or partly due to character pathology); 2) overwhelming fear or anxiety; 3) substance craving or withdrawal (sometimes due to the medical team’s inadequate use of prophylactic medications such as benzodiazepines or nicotine patches); 4) delirium or dementia; 5) psychosis or paranoia; 6) desire to leave the hospital to attend to outside responsibilities (e.g., child care, work, court dates, or a pet at home alone); and 7) impatience with discharge planning or feeling well enough to leave. In a classic study of patients threatening to sign out against medical advice, the most common underlying motivations were overwhelming fear, anger, and psychosis or confusion (Albert and Kornfeld 1973). In most cases, there had been a progressive increase in the patient’s distress that had not been recognized or addressed adequately for days before the threat to sign out (Albert and Kornfeld 1973).

Among interventions, *empathic listening* to the patient’s frustrations is critical, in that it provides an opportunity for the patient to ventilate frustrations and to feel understood. Empathic listening will often have a dramatic de-escalating effect and will enable the team to re-engage the patient in treatment. The psychiatrist can also intervene in assisting the team to achieve a better understanding of the patient’s behavior and to diminish the patient’s feelings of anger and frustration. Other guidelines for intervention are the following:

- ♦ Understand the threat as a communication—Does the patient really want to leave, or is he or she expressing frustration, anger, anxiety, or another affect?
- ♦ If the patient is justifiably angry, apologize on behalf of the system or hospital.

- ♦ Avoid scare tactics or direct confrontation of denial because these techniques are generally counterproductive.
- ♦ Design interventions with an understanding of the patient's personality type.
- ♦ Diagnose and treat any comorbid psychiatric disorders.
- ♦ Involve social supports (if they are allied with the treatment plan).
- ♦ Ensure that the patient is adequately informed about the illness and its need for treatment.
- ♦ Assess the patient's capacity to sign out, if indicated (discussed further in Chapter 2, "Legal Issues").
- ♦ When patients still sign out against medical advice, encourage them to return for treatment if they change their mind.

Conclusion

How does one integrate these various theoretical concepts into the consultation process? How do the psychological responses to illness guide the consultant to use his or her time efficiently, understand the situation, and make useful suggestions? We are aware of no magic formula, but we believe that experienced consultants use their knowledge of human behavior and concepts such as attachment styles, personality types, coping styles, and defense mechanisms to understand their patients and to intervene. Opportunities abound in the medical setting for psychiatric interventions, which can dramatically modify patients' psychological responses to illness. The key to these interventions lies in the development of an understanding of the patient's subjective experience of illness. A curious inquiry into the internal experience of a patient facing medical illness and the appropriate conveyance of empathy is a rewarding experience. We hope the framework, concepts, and guidelines presented in this chapter will prove useful in assisting psychiatrists who have chosen to work with patients in medical settings.

PART II

Symptoms and Disorders

Delirium

Paula T. Trzepacz, M.D.

David J. Meagher, M.D., M.R.C.Psych., M.Sc.

Maeve Leonard, M.B., M.R.C.Psych.

DELIRIUM IS AN ACUTE neuropsychiatric disorder that occurs commonly among patients in all health care settings, especially among the elderly and those with preexisting brain lesions or cognitive impairment. It is a disorder of impaired consciousness with inattention, information processing deficits and sleep–wake cycle disruption. Delirium is characterized by generalized impairment of cognition, with inattention as its cardinal feature, but also involves a range of noncognitive symptoms affecting motor behavior, sleep–wake cycle, thinking, language, perception, and affect. It characteristically has an acute onset (hours to days) and a fluctuating course (waxing and waning symptom severity over a 24-hour period), often worsening at night. It may be preceded by a prodromal phase of 2–3 days of malaise, restlessness, poor concentration, anxiety, irritability, sleep and thought disturbances, and nightmares. Delirium has been called *acute organic brain syndrome* and *acute brain failure* because of its breadth of cognitive and behavioral symptoms. Because delirium alters consciousness, it causes broader impairment than do most other psychiatric disorders. Table 5-1 highlights delirium's characteristic features.

Normal consciousness is not easy to define. "At its least, normal human consciousness consists of a serially time-ordered, organized, restricted, reflective awareness of self and the environment. Moreover, consciousness is an experience of graded complexity and quantity" (Schiff and Plum 2000, p. 438). Consciousness is graded in levels, although it can be abruptly lost during coma, general anesthesia, or deep sleep. Consciousness involves intact attentiveness, awareness of both internal states and the external

environment, and intact wakefulness—which enable thinking, working memory, intention, perception, cognition, and affect in higher cortical and limbic regions. Consciousness is accompanied by a desynchronized electroencephalogram (EEG) with fast-wave activity.

Delirium is an alteration of consciousness graded along a continuum between normal at one end and stupor and coma at the other end. Delirium must be distinguished from other brain states in which consciousness is lost or even more grossly impaired. Coma and stupor entail loss of consciousness and complete failure of arousal, without an intact sleep–wake cycle. Precise delineation between severe hypoactive delirium and stupor can be difficult. Vegetative states include arousal and intact sleep–wake cycles, but with complete absence of awareness of self or environment due to a disconnection between higher cortical regions and the brain stem/diencephalic areas. Minimally conscious state (MCS) is characterized by partial preservation of consciousness and an intact sleep–wake cycle, but intention is absent, and there is inconsistent ability to follow commands, visually track, verbalize (intelligibly), or gesture (Giacino et al. 2002). MCS can progress to delirium in patients who recover (see Figure 5-1).

Emergence from coma usually involves a period of delirium before normal consciousness is achieved. A prospective study of medical intensive care unit (ICU) patients found that 89% of survivors of stupor or coma progressed to delirium (McNicoll et al. 2003), whereas the small number who progressed directly to normal consciousness without delirium tended to have had drug-induced comatose states (Ely et al. 2004a).

TABLE 5-1. Signs and symptoms of delirium**Diffuse cognitive deficits**

Inattention

Disorientation (time, place, person)

Impaired memory (short- and long-term; verbal and visual)

Visuoconstructional impairment

Executive dysfunction

Temporal course

Acute or abrupt onset

Fluctuating severity of symptoms over 24-hour period

Usually reversible

Subclinical syndrome may precede and/or follow

Psychosis

Perceptual disturbances (especially visual), including illusions, hallucinations, metamorphoses

Delusions (usually paranoid and poorly formed)

Thought disorder (tangentiality, circumstantiality, loose associations)

Sleep-wake disturbance

Fragmented throughout 24-hour period

Reversal of normal cycle

Sleeplessness

Motor behavior

Hyperactive

Hypoactive

Mixed

Language impairment

Word-finding difficulty/dysnomia/paraphasia

Comprehension deficits

Altered semantic content

Severe forms can mimic expressive or receptive aphasia

Altered or labile affect

Any mood can occur, usually incongruent to context

Anger or increased irritability common

Hypoactive delirium often mislabeled as depression

Lability (rapid shifts) common

Unrelated to mood preceding delirium

felt like I was sitting in front of a TV set while an invisible stranger clicked the remote control nonstop through the channels—it was all imagery and tone, without any sense.”

Delirium is often a brief, transient state when a patient emerges from general anesthesia, an overdose of medication, concussion following a mild traumatic brain injury (TBI), or seizure. Football players who sustain a head injury during a game are removed to the sidelines until the disorienting effects of concussion resolve sufficiently, although repeated injuries increase the severity of subsequent brain effects (Collins et al. 2002).

Most deliria are considered reversible, but in the elderly, cognitive impairment and previously undiagnosed dementia may be found at longer-term follow-up after recovery from delirium. Delirium occurring in patients with serious medical illness frequently remits completely, as illustrated in studies finding that 67%–85% of deliria in hospitalized patients with cancer resolved completely with treatment (Breitbart et al. 2002; Ljubicavljovic and Kelly 2003). Leonard et al. (2008) found that even in terminally ill palliative care patients, delirium was reversible in about 27%.

Delirium is considered a syndrome and not a unitary disorder because a wide variety of underlying etiologies can cause it. Identification of these etiologies, often multiple or occurring serially over time, is a key part of clinical management. Despite these varied etiologies and physiology, delirium symptoms are characteristic and thus may represent dysfunction of a final common neural pathway that includes perturbations of the various brain regions responsible for the abnormal cognition, thinking, sleep, and behaviors (see section “Neuropathogenesis” later in this chapter).

Recent work conceptualizes three core domains of delirium: cognitive, circadian, and higher-level thinking. The *cognitive* domain is comprised primarily of inattention along with other cognitive impairments, the *circadian* domain of sleep-wake cycle disturbance and possibly motor activity abnormalities, and the *higher-level thinking* domain of a combination of semantic language, thought process, and executive function impairments based on research findings that these are the most frequent, consistent, and differentiating symptoms (J.G. Franco et al. 2009; Meagher et al. 2007; Trzepacz et al. 2001c). Furthermore, these deficits in these three domains corresponded to independently diagnosed delirium in post-TBI acute recovery patients, predicting delirium with 97% accuracy (Kean et al., in press).

Unlike most other neuropsychiatric disorders (except Lewy body dementia and subdural hematoma), delirium symptoms typically fluctuate in intensity over any 24-hour period. Symptom fluctuation is measurable (Gagnon et al. 2004a, 2004b) and is an important indicator of delirium emphasized in DSM-IV and DSM-IV-TR (American Psy-

English teacher and marathon runner Jon Stableford experienced delirium after emerging from coma due to sepsis, acute respiratory distress syndrome (ARDS), and heart and renal failure (Stableford 2009): “I learned that the perspective provided by my family can be transient, that hellish fears can still lurk in the lonely hours between visits. My first week of consciousness seemed disjointed and chaotic. I

Disorders of Consciousness

FIGURE 5–1. Disorders of consciousness.

chiatric Association 1994, 2000). This fluctuation is also a key differentiating feature from dementia. During this characteristic waxing and waning of symptoms, relative lucid or quiescent periods often occur, frustrating accurate diagnosis and complicating research severity ratings. In milder cases, such periods involve a significant diminution of delirium symptoms or even a seeming resolution. The underlying reason for this fluctuation in symptom severity is poorly understood—it may relate to shifts in levels of neurotransmitters such as acetylcholine, which supports consciousness; thalamic sensorimotor gating; or fragmentation of the sleep–wake cycle, including daytime rapid eye movement (REM) sleep.

Although not nearly as well studied, the symptom profile of delirium in children appears to be similar to that in adults (Prugh et al. 1980; Turkel et al. 2003, 2006). In the only study of delirium phenomenology in children and adolescents in which a standardized instrument was used, Turkel et al. (2003) retrospectively described 84 consecutively evaluated delirium patients (ages 6 months–19 years) and found scores comparable to those in adults, with the only difference being fewer delusions and hallucinations in younger children. Turkel et al. (2006) also compared delirium symptoms across the life cycle and, despite differences in methodologies, considered them qualitatively to be largely similar. Prugh et al. (1980) noted the importance of educating nursing staff about the difference between visual hallucinations and imaginary friends. Documentation of delirium symptoms in preverbal children or non-communicative adults is difficult. In these patients, more reliance on inference and observation of changed or un-

usual behaviors—for example, inferring hallucinations or recording sleep–wake cycle changes—is needed.

Delirium symptoms in adults across the age range are comparable, although the co-occurrence of another cognitive disorder is particularly likely in the elderly as compared with younger adults, usually related to dementia. How the presence of a comorbid dementia alters the phenomenological presentation of delirium in the elderly is not well studied, but existing data suggest that delirium overshadows the dementia symptoms (see section “Differential Diagnosis” later in this chapter). Likewise, diagnosing delirium in mentally retarded patients can be challenging.

One of the challenges for both clinicians and delirium researchers is the myriad of terms applied to the delirious state. Historically, acute global cognitive disturbances have been labeled according to the setting in which they occurred or the apparent etiology for the confusional state, resulting in the many names (see Table 5–2) that exist in practice and the literature. Little evidence supports these as separate entities, and, as such, *delirium* has been adopted as the accepted umbrella term to denote acute disturbances of global cognitive function as defined in both DSM-IV and ICD-10 (World Health Organization 1992) classification systems. Even though the term *delirium* has been used since classical Greek medical writings, different terms unfortunately continue to be used by nonpsychiatric physicians (e.g., *ICU psychosis*, *hepatic encephalopathy*, *toxic psychosis*, *posttraumatic confusion*). These terms inappropriately suggest the existence of independent psychiatric disorders for each etiology rather than recognize delirium as a unitary syndrome. Terms such as *acute brain failure* and

TABLE 5-2. Terms used to denote delirium

Acute brain failure	Cerebral insufficiency	Organic brain syndrome
Acute brain syndrome	Confusional state	Posttraumatic confusion
Acute brain syndrome with psychosis	Dysergastic reaction	Reversible cerebral dysfunction
Acute dementia	Encephalopathy	Reversible cognitive dysfunction
Acute organic psychosis	Exogenous psychosis	Reversible dementia
Acute organic reaction	Infective-exhaustive psychosis	Reversible toxic psychosis
Acute organic syndrome	Intensive care unit (ICU) psychosis	Toxic confusion state
Acute reversible psychosis	Metabolic encephalopathy	Toxic encephalopathy
Acute secondary psychosis	Oneiric state	

acute organic brain syndrome highlight the global nature and acute onset of cerebral cortical deficits in patients with delirium, but they lack specificity in regard to other cognitive mental disorders. The term *delirium* subsumes these many other terms, and its consistent use will enhance medical communication, diagnosis, and research.

Little work has been done with the use of daily delirium ratings to better understand the temporal course of this syndrome. In a study of 432 medical inpatients 65 years or older, Rudberg et al. (1997) found that 15% had delirium, and 69% of those had delirium for only a single day. Mean delirium scores on day 1 were significantly higher (i.e., worse) in those whose delirium occurred for multiple days compared with those whose delirium lasted for 1 day, suggesting a relation between severity and duration in delirium episodes. Systematically monitoring adult bone marrow transplant patients, Fann et al. (2005) found delirium to be more severe in episodes that lasted 3 days or longer. Delirium is common after TBI and can be particularly persistent. The severity of delirium at 1 month post-TBI predicts occupational dysfunction at 1 year (Nakase-Richardson et al. 2007).

Delirium continues to be underrecognized and underdiagnosed. It is commonly misdiagnosed as depression by nonpsychiatric physicians and nurses (Nicholas and Lindsey 1995). Misdiagnosis of delirium is more likely when delirium is hypoactive in presentation and when patients are referred from surgical or intensive care settings (Armstrong et al. 1997). Van Zyl and Davidson (2003) reviewed charts of 31 delirious patients who were referred for psychiatric consultation and found that delirium or a synonym was noted in 55% of the structured discharge summaries and in none of the unstructured summaries, for an overall rate of 16%. Missed cases were denoted as dementia (25%), a functional psychiatric disorder (25%), or no diagnosis noted (50%) (Johnson et al. 1992).

Nondetection of delirium was associated with poorer outcome, including increased mortality, in a study in emergency department patients (Kakuma et al. 2003). In contrast, explicit recognition of delirium was associated with better outcomes in the form of shorter inpatient stays and lower mortality (Rockwood et al. 1994). Detection can be improved to some extent by providing formal educational programs, for example, to house staff (Rockwood et al. 1994). Personal attitudes are important among nursing staff, who often play a key role in identifying and reporting symptoms because the symptoms fluctuate, especially at night (McCarthy 2003). Detection is a challenge in ICU settings, where the sickest patients are at the highest risk for delirium. Ely et al. (2004b) distributed a survey to 912 physicians, nurses, respiratory therapists, and pharmacists attending international critical care meetings and found that 72% thought that ventilated patients experienced delirium, 92% considered delirium a very serious problem, and 78% acknowledged that it was underdiagnosed. Yet only 40% routinely screened for delirium and 16% used a specific tool for assessment. Rincon et al. (2001) reported that critical care unit staff underdiagnosed delirium (and other psychiatric disorders), and used psychotropic medications without any clear documentation of targeted diagnoses.

ICU populations have delirium prevalence rates ranging from 40% to 87% (Ely et al. 2001c). Delirium in the ICU is understudied and neglected in part because it is "expected" to happen during severe illness, and medical resources are preferentially dedicated to managing the more concrete "life-threatening" problems.

With pressure to reduce acute hospital length of stay, elderly patients are discharged, often to nursing homes, before delirium resolves. Kiely et al. (2003) studied 2,158 patients from seven Boston, Massachusetts, area skilled nursing facilities and found that 16% had a full-blown delirium. In general, such facilities are even less well equipped and

staffed to diagnose and manage delirium than are acute care hospitals.

Consequences of Delirium

Delirium can have a profound effect on a patient's morbidity and mortality as well as on his or her caregivers and loved ones. Delirious patients have difficulty comprehending and communicating effectively, consenting to procedures, complying with medical management (e.g., removing intravenous lines, tubes, or catheters), benefiting from many therapies, and maintaining expected levels of self-hygiene and eating. They also are at risk for inadvertent self-harm because of confusion about the environment or in response to hallucinations or paranoid delusions. Delirium-recovered patients were uncomfortable discussing their delirium episodes—even to the extent of denial—because they feared that it meant that they were “senile” or “mad” (Schofield 1997). Breitbart et al. (2002) prospectively interviewed and rated 101 cancer patients with a resolved delirium episode, their spouses, and their nurses (see Figure 5-2). About half (43%) of the patients recalled their episode, with recall dependent on delirium severity (100%

of patients with mild delirium vs. 16% of patients with severe delirium recalled the episode). Mean distress levels were high for patients and nurses but were highest for spouses. However, among patients with delirium who did not recall the episode, the mean distress level was half that of those who did recall. The experience of the delirium was frightening and stressful for all involved, but for somewhat different reasons—for patients, the presence of delusions; for nurses, the presence of perceptual disturbances or overall severe delirium; and for spouses, the low ability to function was predictive of distress level. Spouses perceived the delirium as indicating a high risk for death and loss of the loved one, contributing to anticipatory bereavement.

Medical complications, including decubitus ulcers, feeding problems, and urinary incontinence, are common in patients with delirium (Gustafson et al. 1988). Effects on hospital length of stay, “persistence” of cognitive impairment, increased rate of institutionalization, and reduced ambulation and activities of daily living (ADL) level have been reported as consequences in elderly patients with delirium.

The Academy of Psychosomatic Medicine (APM) Task Force on Mental Disorders in General Medical Practice

FIGURE 5-2. Relationship of delirium severity to patient recall of the episode, and comparison of delirium-related distress levels, in cancer patients with a resolved delirium episode and their families and caregivers.

(A) Percentage of patients who recalled their episode, by delirium severity. (B) Mean distress levels of patients, spouses or caregivers, and nurses (rated on a 0-4 rating scale).

(Saravay and Strain 1994) reviewed studies finding that comorbid delirium increased hospital length of stay 100% in general medical patients (R.I. Thomas et al. 1988), 114% in elderly patients (Schor et al. 1992), 67% in stroke patients (Cushman 1988), 300% in critical care patients (Kishi et al. 1995), 27% in cardiac surgery patients, and 200%–250% in hip surgery patients (Berggren et al. 1987). The APM task force noted that delirium contributed to increased length of stay via medical and behavioral mechanisms, including the following: decreased motivation to participate in treatment and rehabilitation, medication refusal, disruptive behavior, incontinence and urinary tract infection, falls and fractures, and decubiti.

Significantly increased length of stay associated with delirium has been reported in many studies in the 1980s and 1990s, and a meta-analysis of eight studies (Cole and Primeau 1993) supported statistically significant differences in length of stay between delirium and control groups. Ely et al. (2004a) found that delirium duration was associated with length of stay in both the medical ICU and the hospital ($P < 0.001$) and was the strongest predictor of length of stay even after adjustment for illness severity, age, gender, and days of opioid and narcotic use. McCusker et al. (2003a) studied elderly medical inpatients and found significantly longer length of stay for those with incident, but not prevalent, delirium.

K. Franco et al. (2001) identified the increased costs associated with delirium in a prospective study of 500 elective surgery patients older than 50 years. Delirium occurred in 11.4% of the patients during postoperative days 1–4, and these patients had higher professional, consultation, technical, and routine nursing care costs. Milbrandt et al. (2004) compared costs associated with having at least one delirium episode in 183 mechanically ventilated medical ICU patients and nondelirious control subjects after controlling for age, comorbidity of illness, degree of organ dysfunction, nosocomial infection, and hospital mortality. Median ICU costs per patient were \$22,346 for delirious and \$13,332 for nondelirious patients ($P < 0.001$), and total hospital costs were \$41,836 and \$27,106 ($P = 0.002$), respectively; more severe delirium cases resulted in higher costs than did milder ones.

Decreased independent living status and increased institutionalization during follow-up after a delirium episode were found in many studies of elderly individuals (Cole and Primeau 1993; George et al. 1997; Inouye et al. 1998). Reduction in ambulation and/or ADL level at follow-up is also commonly reported (Francis and Kapoor 1992; Gustafson et al. 1988; Inouye et al. 1998; Minagawa et al. 1996; Murray et al. 1993). Delirium also has an effect in nursing home settings, where incident cases are associated with poor 6-month outcome, including behavioral decline,

initiation of physical restraints, greater risk of hospitalization, and increased mortality (Murphy 1999). Even subsyndromal delirium is reported to increase index admission length of stay and postdischarge dysfunction and mortality after adjustment for age, sex, marital status, previous living arrangement, comorbidity, dementia status, and clinical and physiological severity of illness (Cole et al. 2003b).

In nursing home patients, better cognitive function at baseline was associated with better outcome from delirium (Murphy 1999), supporting the notion that impaired brain reserve is an important predelirium factor that needs to be taken into account in any longitudinal outcome assessments. Longitudinal cognitive assessments of postcardiotomy patients who had normal preoperative Mini-Mental State Examination (MMSE) findings compared elderly with middle-aged and younger adults and found that delirium was not a predictor of persistent cognitive impairment at 3-month follow-up, even though it was associated with deficits at the time of discharge from the hospital, and only the elderly group had worse cognitive function at 3 months, whereas the other two groups were similar to the elderly nondelirious control subjects (Monk et al. 2008).

Epidemiology

Delirium can occur at any age, although it is particularly understudied in children and adolescents. Most epidemiological studies have focused on the elderly, who are at higher risk to develop delirium than are younger adults. This is likely because of age-related changes in the brain, including decreased cholinergic functioning, often referred to as *reduced brain reserve*. The frequent occurrence of central nervous system disorders (e.g., stroke, hypertensive and atherosclerotic vessel changes, tumor, dementias) in the elderly further increases their vulnerability to delirium). Improving our understanding and treatment of delirium is thus a considerable health care challenge, especially in countries whose population is aging at a dramatic rate.

Most studies of delirium incidence and prevalence report general hospital populations consisting of either referral samples or consecutive admissions to a given service. Specific patient populations, such as elderly patients who require emergent hip surgery, liver transplant candidates, and hospitalized TBI patients, may be responsible for disparate rates reported in studies. In addition, not all studies use sensitive and specific diagnostic and measurement techniques, risking overestimates or underestimates of the true occurrence of delirium.

Diagnosis is an issue for epidemiological studies. Substantial differences in rates can occur—for example, when DSM-III (American Psychiatric Association 1980), DSM-III-R (American Psychiatric Association 1987), DSM-IV,

and ICD-10 criteria were used, only 25% of the patients with delirium received accurate diagnoses by all four systems (Laurila et al. 2003). Lesser diagnostic emphasis on disorganized thinking in the DSM-IV criteria accounted for that system's greater sensitivity and inclusivity (but lower specificity) in comparison with the other systems, whereas ICD-10 criteria were the least inclusive (Cole et al. 2003a). Laurila et al. (2004) concluded that DSM-IV criteria are most inclusive, whereas ICD-10 criteria are overly restrictive. The Confusion Assessment Method may underestimate or overestimate occurrence of delirium when used alone (see section "Diagnosis and Assessment" later in this chapter).

Fann (2000) reviewed prospective studies of delirium in hospitalized patients to report an incidence from 3% to 42%, and prevalence from 5% to 44%. A review of prospective cohort and cross-sectional studies of general medical inpatient settings found prevalence of delirium at admission from 10% to 31%, incidence of new delirium per admission from 3% to 29% and occurrence rate per admission between 11% and 42% (Siddiqi et al. 2006). Table 5-3 describes prospective incidence and prevalence studies of delirium in which DSM diagnostic criteria or rating scales were used. These studies were done in medical, surgical, palliative care, institutional care, intensive care, and community settings, and most focused on geriatric patients.

Prevalence rates for delirium in studies that have been conducted in community-based settings have found highly variable frequencies of delirium (<0.05%–44%) but have involved considerably different methodologies from exclusion of patients with known dementia (Andrew et al. 2006) to the use of the Organic Brain Syndrome scale in settings as diverse as nursing homes along with an emergency hospital (Sandberg et al. 1998). When admitted to a hospital, 10%–15% of elderly patients have delirium, and another 10%–40% receive diagnoses of delirium during the hospitalization. A clinical rule of thumb seems to be that, on average, approximately one-fifth of general hospital patients have delirium sometime during hospitalization. Terminally ill cancer patients have a very high incidence of delirium, with rates from 28% to 42% on admission to a palliative care unit and up to 88% before death (Lawlor et al. 2000a). Also, up to 50% of adults undergoing stem cell transplantation have delirium in the postoperative month (Beglinger et al. 2006; Fann et al. 2002).

In a prospective cohort study of older medical ICU patients, McNicoll et al. (2003) found delirium in 31% on admission and an overall prevalence, and delirium incidences of 62% during the ICU stay and 70% during the entire hospitalization. In addition, 30% had evidence of prior dementia, and these patients were 40% more likely to become delirious, even after controlling for comorbidity, baseline functional status, severity of illness, and invasive proce-

dures. In a prospective study of 275 consecutive mechanically ventilated medical ICU patients that used daily ratings over 5,353 patient days, 51 (18.5%) were comatose; of the remaining 224 patients, 183 (82%) had a delirium at some point during the hospitalization, with a median duration of 2.1 days (Ely et al. 2004b). Delirious patients had numerically higher admission mean comorbidity and critical illness severity scores compared with those who never became delirious, but mean ages were comparable.

Frail elderly individuals living in nursing facilities studied for 3 months during and after an acute medical hospitalization had a high incidence of delirium of 55% at 1 month and 25% at 3 months, which persisted until death or hospitalization in 72% (Kelly et al. 2001).

Thus, irrespective of the diversity of incidence and prevalence rates reported among studies, delirium is very common in medical and institutional settings where its rates generally exceed those for any other serious psychiatric disorder.

Risk Factors

Delirium is particularly common during hospitalization when a confluence of both predisposing (moderating) and precipitating (mediating) factors is present. Several patient, illness, pharmacological, and environmental factors have been identified as being relevant risk factors for delirium. Although some factors are more relevant in certain settings, age, preexisting cognitive impairment, severe comorbid illness, and medication exposure are particularly strong predictors of delirium risk across a range of populations (Inouye et al. 1999). Dementia in older persons is a common risk factor. Korevaar et al. (2005) found the most important independent risk factors in elderly medical inpatients for having a prevalent delirium were premorbid cognitive impairment, functional impairment, and an elevated urea nitrogen level. Terminal illness is a risk factor for delirium (Lawlor et al. 2000a). In stem cell transplant patients, pretransplant risk factors included lower cognition on the Trail Making Test B; higher serum levels of urea nitrogen, magnesium, or alkaline phosphatase; and lower physical functioning (Fann et al. 2002).

Stress-vulnerability models for the occurrence of delirium have been long recognized. Henry and Mann (1965) described "delirium readiness." More recent models of causation involve cumulative interactions between predisposing factors and precipitating insults (Inouye and Charpentier 1996; O'Keeffe and Lavan 1996). Baseline risk is a more potent predictor of delirium likelihood—if baseline vulnerability is low, patients are very resistant to the development of delirium despite exposure to significant precipitating factors, whereas if baseline vulnerability is high, delirium is

TABLE 5-3. Prospective studies of delirium incidence and prevalence

Study	N	Sample	Delirium ascertainment	Design	Findings
Erkinjuntti et al. 1986	2,000	Medical inpatients, age ≥ 55 years	SPMSQ, DSM-III criteria on interview and chart review	Prospective	Prevalence 15%
Cameron et al. 1987	133	Medical inpatients, ages 32-97 years	DSM-III criteria on interview	Prospective	Prevalence 14%, incidence 3%
Gustafson et al. 1988	111	Femoral neck fracture patients, age ≥ 65 years	OBS Scale, DSM-III criteria on interview	Prospective	Prevalence 33%, incidence 42%
Rockwood 1989	80	Medical inpatients, age ≥ 65 years	DSM-III criteria on interview	Prospective	Prevalence 16%, incidence 11%
Francis et al. 1990	229	Medical inpatients, age ≥ 70 years	DSM-III-R criteria on interview and chart review	Prospective	Prevalence 16%, incidence 7%
Johnson et al. 1990	235	Medical inpatients, age ≥ 70 years	DSM-III criteria on interview	Prospective	Prevalence 16%, incidence 5%
Folstein et al. 1991	810	Community sample	DSM-III criteria on interview	Cross-sectional	Prevalence 0.4% (1.1%, age ≥ 55)
Williams-Russo et al. 1992	51	Bilateral knee replacement surgery patients receiving postoperative fentanyl	DSM-III-R criteria on interview and chart review	Prospective	Incidence 41%
Jitapunkul et al. 1992	184	Medical inpatients, age ≥ 60 years	DSM-III-R criteria on chart review	Prospective	Prevalence 22%
Snyder et al. 1992	42	Acquired immunodeficiency syndrome inpatients	DSM-III-R criteria on interview	Prospective	Prevalence 17%
Schor et al. 1992	325	Medical and surgical inpatients, age ≥ 65 years	DSI	Prospective	Prevalence 11%, incidence 31%
Leung et al. 1992	569	Male medical inpatients, ages 12-99 years	DSM-III criteria on interview	Prospective	Prevalence 9.5%
Kolbeinson and Jonsson 1993	331	Medical inpatients, age ≥ 70 years	MSQ, MMSE, and DSM-III-R criteria on interview	Prospective	Prevalence 14%
Rockwood 1993	168	Geriatric medical inpatients, mean age = 79 years	DRS, DSM-III-R criteria on interview	Prospective	Prevalence 18%, incidence 7%
Marcantonio et al. 1994a	1,341	Noncardiac surgery patients, age ≥ 50 years	CAM, medical records, nursing intensity index	Prospective	Incidence 9%

TABLE 5-3. Prospective studies of delirium incidence and prevalence (continued)

Study	N	Sample	Delirium ascertainment	Design	Findings
Pompei et al. 1994	432	Medical and surgical inpatients, age ≥ 65 years	Digit Span, Vigilance "A" Test, CAC, CAM, DSM-III-R criteria on interview	Prospective	Prevalence 5%, incidence 10%
Pompei et al. 1994	323	Medical and surgical inpatients, age ≥ 70 years	CAM	Prospective	Prevalence 15%, incidence 12%
Kishi et al. 1995	238	Critical care medical unit patients	DSM-III-R criteria on clinical evaluation	Prospective	Incidence 16%
Fisher and Flowerdew 1995	80	Elective orthopedic surgery inpatients, age ≥ 60 years	CAM	Prospective	Incidence 18%
Inouye and Charpentier 1996	196	Medical inpatients, age ≥ 70 years	CAM	Prospective	Incidence 18%
	312	Medical inpatients, age ≥ 70 years	CAM	Prospective	Incidence 15%

	131	Acute general medical ward	CAM	Prospective	Incidence 15.2%
Nakase-Thompson et al. 2004	171	Acute brain injury rehabilitation unit	DSM-IV, DRS	Prospective	Incident 66%

Note. CAC = Critical Assessment of Confusion; CAM = Confusion Assessment Method; CRS = Confusion Rating Scale; DRS = Delirium Rating Scale; DSI = Delirium Symptom Interview; ICU = intensive care unit; MDAS = Memorial Delirium Assessment Scale; MMSE = Mini-Mental State Examination; MSQ = Mental Status Questionnaire; OBS = Organic Brain Syndrome; SPMSQ = Short Portable Mental Status Questionnaire.

likely even in response to minor precipitants (Inouye and Charpentier 1996). Tsutsui et al. (1996), for example, found that in patients older than 80 years, delirium occurred in 52% after emergency surgery and 20% after elective procedures, whereas no cases of delirium were noted in patients younger than 50 years undergoing either elective or emergency procedures. Kalisvaart et al. (2006) reported that delirium was four times more common in urgent than elective hip surgery patients, with cognitive impairment and age other important risk factors. In addition to the elderly, children are considered at higher risk for delirium, possibly related to ongoing brain development.

Up to two-thirds of the cases of delirium occur superimposed on preexisting cognitive impairment (Wahlund and Bjorlin 1999) which has been reported to increase risk ninefold, making it the strongest risk factor for prevalent delirium (Korevaar et al. 2005). The absence of dementia can be considered an important predictor of recovery (Cole et al. 2007). Delirium is 2.0–3.5 times more common in patients with dementia compared with control subjects without dementia (Erkinjuntti et al. 1986; Jitapunkul et al. 1992). Delirium risk appears to be greater in Alzheimer's disease of late onset and dementia of vascular origin as compared with other dementias, with this increased risk perhaps reflecting the relatively widespread neuronal disturbance associated with these conditions (Robertsson et al. 1998). Voyer et al. (2006) described an association between prior cognitive impairment, low functional autonomy, and benzodiazepine and narcotic use with increased delirium severity in older institutionalized patients admitted to an acute care hospital.

O'Keeffe and Lavan (1996) stratified patients into four levels of delirium risk based on the presence of three factors (chronic cognitive impairment, severe illness, elevated serum urea) and found that the risk of delirium increased as these factors accumulated. Similarly, Inouye and Charpentier (1996) developed a predictive model that included four predisposing factors (cognitive impairment, severe illness, visual impairment, dehydration) and five precipitating factors (more than three medications added, catheterization, use of restraints, malnutrition, and any iatrogenic event). These factors predicted a 17-fold variation in the relative risk of developing delirium. Uremia increases the permeability of the blood–brain barrier, allowing many larger molecules, such as drugs, to enter the brain when they ordinarily would not.

Although the value of reducing risk factors appears self-evident, many may simply be markers of general morbidity; therefore, studies showing preventive effect are important (see subsection “Prevention Strategies” later in this chapter). Some risk factors are potentially modifiable and thus are targets for prevention, although cumulative

microstructural effects of aging are not reversible. Thiamine deficiency is an underappreciated cause of and risk factor for delirium in pediatric intensive care and oncology patients (Seear et al. 1992) and nonalcoholic elderly patients (O'Keeffe et al. 1994).

Medication exposure is probably the most readily modifiable risk factor for delirium, implicated as a cause in 20%–40% of cases. Polypharmacy and drug intoxication and withdrawal may be the most common causes of delirium (Hales et al. 1988; Trzepacz et al. 1985). Benzodiazepines, opioids, and drugs with anticholinergic activity have a particular association with delirium (T.M. Brown 2000; Marcantonio et al. 1994b). Many drugs (and their metabolites) can unexpectedly contribute to delirium as a result of unrecognized anticholinergic effects. Ten of the 25 most commonly prescribed drugs for the elderly had sufficient *in vitro* anticholinergic activity identified by radioreceptor assay to cause memory and attention impairment in nondelirious elderly subjects (Tune et al. 1992). Therefore, drug exposure must be minimized, especially when facing high-risk periods such as the perioperative phase. Although opioids are associated with delirium, Morrison et al. (2003) found in a prospective study of older patients undergoing hip surgery that delirium was nine times more likely in those patients deemed to have undertreated pain.

The temporal relation between exposure to risk factors and development of delirium requires further study. Postoperative delirium (excluding emergence from anesthesia) appears most frequently at day 3. A large multicenter study found age, duration of anesthesia, lower education, second operation, postoperative infection, and respiratory complications to be predictors of postoperative cognitive impairment (Moller et al. 1998).

Low serum albumin is an important risk factor at any age and may signify poor nutrition, chronic disease, or liver or renal insufficiency. Hypoalbuminemia results in a greater bioavailability of many drugs that are transported in the bloodstream by albumin, which is associated with an increased risk of side effects, including delirium (Dickson 1991; Trzepacz and Francis 1990). This increased biological drug activity occurs within the therapeutic range and may not be recognized because increased levels of free drug are not separately reported in most assays. Serum albumin was identified by discriminant analysis, along with Trail Making Test B and EEG dominant posterior rhythm, as sensitively distinguishing delirious from nondelirious liver transplant candidates (Trzepacz et al. 1988b).

Nicotine withdrawal has been implicated as a potential risk factor in the development of delirium, especially in heavy smokers unable to continue their habit during hospital admission. Klein et al. (2002) reported a single case of

delirium in such a patient who responded quickly to a transdermal nicotine patch.

The study of genetic factors relevant to delirium has lagged behind other neuropsychiatric conditions and the bulk of work to date has explored candidate genes that regulate factors relevant to alcohol metabolism in alcohol withdrawal delirium. Among these, studies of dopamine receptor genes have produced varied results, with the positive studies (Sander et al. 1997; Wernicke et al. 2002; Wodarz et al. 2003) matched by equivalent negative studies (Kohnke et al. 2005, 2006a; Limosin et al. 2004). Positive associations have been reported for alcohol withdrawal delirium incidence for polymorphisms in genes coding for glutamate receptor (Preuss et al. 2006), tyrosine hydroxylase (Sander et al. 1998), brain-derived neurotrophic factor (BDNF) (Matsushita et al. 2004), and NAD(P)H-quinone oxidoreductase-2 (Okubo et al. 2003), while negative findings have been found in relation to monoamine oxidase A (MAO-A) (Kohnke et al. 2006b), catechol-*O*-methyltransferase (COMT) (Tihonen et al. 1999), neuropeptide Y (Kohnke et al. 2002), and cholecystokinin (Okubo et al. 2000). Two studies of cannabinoid receptors have produced conflicting findings (Preuss et al. 2003; Schmidt et al. 2002).

Genetic factors may increase risk for delirium from medical causes. Some studies have found that the apolipoprotein E (APOE) $\epsilon 4$ allele is associated with an increased risk of delirium in ICU patients (Ely et al. 2007) and poorer prognosis (longer episode duration or nonrecovery) (Adamis et al. 2007b; Ely et al. 2007). Dopaminergic gene polymorphisms may also play a role (Van Munster et al. 2009). While genetic risk factors are a promising avenue for further research, the results to date are inconclusive because of insufficiently powered studies and other methodological issues (Adamis et al. 2009).

Delirium and Mortality

Delirium appears to be associated with high morbidity and mortality both short- and long-term, especially in the elderly. Reported mortality rates during the index hospitalization for a delirium episode have ranged from 4% to 65% (Cameron et al. 1987; Gustafson et al. 1988). Methodological inconsistencies and shortcomings affect the interpretation of many studies of mortality risk associated with delirium. Some earlier studies do not compare patients who have delirium with control groups. Many studies include patients with comorbid dementia, and many earlier studies do not control for severity of medical comorbidity (admittedly difficult to measure). In addition, many early studies do not address the effects of advanced age as a separate risk factor, and specific delirium rating instruments were rarely used. The effect on reducing mortality risk by treatment

for the delirium itself, a potential confound, is also not reported in most studies. Attention to whether the sample is incident or prevalent, identification of referral biases, and indication of whether follow-up mortality rates are cumulative to include the original sample are also important issues that vary across study designs. Not all studies have reported a higher mortality rate after delirium (Adamis et al. 2007a; Francis and Kapoor 1992; Inouye et al. 1998).

More recent prospective studies in medically hospitalized patients have found that delirium significantly increases mortality risk, even after controlling for multiple potential confounding factors such as medical comorbidity, demographics, dementia status, and ADL (Curyto et al. 2001; Ely et al. 2004a; Inouye et al. 1998; Leslie et al. 2005; McCusker et al. 2002). Other studies have shown a similar increase in mortality associated with delirium in nursing facilities (Kelly et al. 2001; Marcantonio et al. 2005). Mortality risk may be increased even years later (Curyto et al. 2001). The number of days of delirium is a significant predictor of later mortality (Gonzalez et al. 2009; Pisani et al. 2009). Delirium that is persistent is especially likely to predict poorer prognosis (Cole et al. 2009) and increased mortality (Kiely et al. 2009). Dementia plus delirium appears to carry a higher mortality risk than either diagnosis alone (Bellelli et al. 2007). Longer duration of delirium increases long-term mortality in the elderly, whether measured as number of delirium days in the ICU after controlling for moderating factors (Pisani et al. 2009) or as number of delirium hours in the medically ill (Gonzalez et al. 2009).

Longer-term follow-up of emergency department elderly who were sent home found that delirium increased mortality even after adjustment for age, sex, functional level, cognitive status, comorbidity, and number of medications (Kakuma et al. 2003). However, those with delirium undetected by the emergency department staff had the highest mortality whereas those with detected delirium had comparable long-term mortality to the nondelirious. The latter suggests that detection and intervention may be important determinants in mortality rates, although, in contrast, studies of systematic intervention in delirious patients have failed to show a reduction in mortality or subsequent institutionalization (Cole et al. 1994, 2002; Pitkala 2006).

It is not known whether increased mortality is attributable to the effects of underlying etiologies of delirium; to indirect effects on the body related to perturbations of neuronal, endocrine, and immunological function during delirium; or to damaging effects on the brain from neurochemical abnormalities associated with delirium (i.e., similar to glutamate surges after stroke). Additionally, patients with delirium cannot fully cooperate with their medical care or participate in rehabilitative programs during hospitalization. Their behaviors can directly reduce the effective-

ness of procedures meant to treat their medical problems (e.g., removing tubes and intravenous lines, climbing out of bed), which adds to morbidity and possibly to further physiological injury and mortality.

So-called subsyndromal delirium may also be associated with adverse outcomes including increased mortality (Cole et al. 2003b; Levkoff et al. 1992; Marcantonio et al. 2002, 2005), reduced independent living status (Marcantonio et al. 2002), and increased need for postdischarge institutional care (Bourdel-Marchasson et al. 2004). Cole et al. (2003b) prospectively observed that the more delirium symptoms present, especially on admission, the worse the prognosis as evidenced by longer inpatient stays, poorer cognitive and functional status as well as greater subsequent mortality at 12-month follow-up.

Thus, although the mechanism is not understood, the presence of delirium does indeed appear to be an adverse prognostic sign that is associated with an increased risk for mortality, extending well beyond the index hospitalization, even after controlling for other known risk factors like age, medical problems and low function at baseline. To what extent aggressive treatment of both the delirium and its comorbid medical problems would reduce morbidity and mortality is not well studied. There is increasing interest in measuring biological markers of inflammation and other disturbed pathophysiology that may ultimately assist in disentangling the reason for the association between delirium and mortality risk.

Delirium Reversibility and Long-Term Cognitive Impairment in the Elderly

The traditional concept of delirium is of a disorder that is usually reversible, and this attribute has been one of the key characteristics used to distinguish delirium from dementia. In Bedford's (1957) landmark study of delirium, approximately 5% of the patients were still "confused" at 6-month follow-up. Epidemiological reports indicate that a subset of delirium symptoms can persist for months in approximately one-quarter of elderly delirium cases (Marcantonio et al. 2005; McCusker et al. 2003b; Siddiqi et al. 2006). A significant percentage of patients develop enduring cognitive deficits, so-called long-term cognitive impairment (LTCI). A range of studies have documented the occurrence of longer-term cognitive deficits after an index episode of delirium (see Jackson et al. 2004 and MacLulich et al. 2009 for detailed reviews), but it is methodologically challenging to determine causality and distinguish among the many potential causes of LTCI including moderating and mediating factors rather than the delirium itself (see Figure 5-3).

It remains unclear to what extent persistent cognitive difficulties represent ongoing or recurrent delirium symptoms or reflect the development of neuropsychological impairments that differ in character from acute delirium. Zaubler et al. (2009) found that the pattern of neuropsychological impairment at 3 months was unrelated to delirium. Furthermore, Jones et al. (2006) found cognitive impairments in nondelirious ICU patients that persisted following discharge. Both of these findings strengthen the causality argument toward the medical morbidity and not the delirium.

Preexisting cognitive impairment predicts both the risk for delirium and its severity (J.G. Franco et al., in press; Voyer et al. 2007), as well as predicting specific cognitive symptoms of delirium (Voyer et al. 2006). Delirium severity is associated with degree of prior cognitive impairment in the elderly, as well as with baseline low functional autonomy level (i.e., instrumental activities of daily living [IADL]) (Voyer et al. 2007). Ongoing or recurrent delirium symptoms occur in older patients discharged home or to nursing homes before the index delirium episode has resolved (Levkoff et al. 1992, 1994; Rockwood 1993). More recent neuropsychological and longitudinal reports highlight the importance of preexisting moderating factors.

Importantly, both the delirium and LTCI may be caused by another condition, such as an underlying medical illness, brain injury (e.g., hypoxic, traumatic), or a preexisting undiagnosed dementia (Koponen et al. 1994). In such cases, delirium is a marker for risk of future cognitive deterioration. Zaubler et al. (2009) found that greater intraoperative regional oxygen desaturation in frontal lobes as measured by cerebral oximetry predicted a fivefold risk of postoperative delirium, which supports hypoxia as a possible common denominator for both delirium and LTCI, independently.

However, there is the possibility that delirium itself, once precipitated, might be neurotoxic in vulnerable patients, which is an intriguing notion, as it would mean that delirium is an important potentially modifiable risk factor for dementia—the inverse of the current understanding of dementia as a risk factor for delirium. This conclusion is suggested by Fong et al. (2009), who found that the rate of cognitive decline in patients with Alzheimer's disease who had developed delirium was accelerated threefold compared with the rate of decline in those who had not experienced delirium.

Many studies have related persisting cognitive difficulties to "diminished brain reserve" associated with preexisting dementia that has progressed over time (Camus et al. 2000; Koponen et al. 1994; Rahkonen et al. 2000; Rockwood et al. 1999). Thus, persistent deficits may instead reflect an underlying disorder and not the delirium. Comorbid dementia may go unrecognized at the time of the

FIGURE 5-3. "Persistent cognitive deficits" following delirium episode: possible mechanisms.

Source. Reprinted from Trzepacz PT, Meagher DJ: "Neuropsychiatric Aspects of Delirium," in *The American Psychiatric Publishing Textbook of Neuropsychiatry and Behavioral Neurosciences*, 5th Edition. Edited by Yudofsky SC, Hales RE. Washington, DC, American Psychiatric Publishing, 2008, pp. 445–517. Copyright 2008, American Psychiatric Publishing, Inc. Used with permission.

delirium index episode in part because it is challenging to adequately assess for preexisting dementia retrospectively. More focal neuropsychological deficits also increase risk for delirium. Several investigators have found that preexisting executive dysfunction and/or attentional difficulties, even in the absence of dementia, predicted delirium (L.J. Brown et al. 2009; I.R. Katz et al. 2001; Lowery et al. 2007; Osse et al. 2008; Rudolph et al. 2006; Smith et al. 2009). Thus, undetected preexisting cognitive deficits may both predict delirium and become manifest as LTCI.

Very interesting are studies that suggest there may be subtypes of delirium with differing vulnerability to poor prognosis. Among elderly delirium survivors there are no significant differences in cognition, function, or institutional status between delirium-recovered and nondelirious groups at 6 and 12 months, after adjustment for multiple moderating and mediating factors (Cole et al. 2008). Following major noncardiac surgery in cognitively normal patients, those with delirium were more likely than age-matched control subjects to have cognitive deficits at discharge but not at 3-month follow-up, when cognitive impairment was instead predicted by baseline IADL (Monk et al. 2008). Furthermore, among the three age groups (young: 18–39 years; middle-aged: 40–59 years; and elderly: 60-plus years), only the elderly group had worse cognitive function than nondelirious control subjects at 3 months.

Although the likelihood of developing both delirium and LTCI is increased in patients with preexisting cognitive deficits, a number of prospective studies have demonstrated that LTCI may occur in patients who appear cogni-

tively intact prior to experiencing delirium (Benoit et al. 2005; Bickel et al. 2008; Dupplis and Wikblad 2004; Fann et al. 2002; Gruber-Baldini et al. 2003; Kat et al. 2008; Lundstrom et al. 2003). However, these studies did not employ the most sensitive assessment methods (usually the MMSE), making it difficult to be sure patients did not have preexisting cognitive deficits.

In summary, whether delirium itself causes irreversible damage remains controversial because of the difficulties disentangling the effects of acute medical burden and preexisting brain damage particularly in those with advanced age. Studies to date have many methodological issues that include a predominance of elderly subjects who are prone to cognitive disorders, inclusion of relatively small sample sizes, use of insensitive screens like the MMSE in lieu of neuropsychological testing, lack of delirium severity measures, inadequate control for baseline cognitive impairment, and other confounders (e.g., severity of illness, exposure to medications), variable length of follow-up, and need to better account for delirium subtype, etiology, severity, and duration, all of which have implications for outcome. These studies do increase awareness that a delirium episode, especially in an older person, is a harbinger of physiological damage in the body and brain that may result from an otherwise unrecognized process which is possibly hastened by the medical or surgical event associated with a delirium episode. Whether the brain sustains enduring damage from the delirium is not discernible at this time, although evidence that delirium is a marker and risk factor for LTCI appears convincing.

Clinical Features

Phenomenology

The classic descriptive study of 106 “dysergastic reaction” (i.e., delirium) patients by Wolff and Curran (1935) is still consistent with current conceptions of delirium phenomenology as a complex neuropsychiatric syndrome that includes a wide range of cognitive and noncognitive disturbances that are of relatively acute onset and fluctuate over the course of an episode. Inconsistent and unclear definitions of symptoms and underuse of standardized symptom assessment tools have hampered subsequent efforts to describe delirium phenomenology or to compare symptom incidences across studies and etiological populations. Moreover, the temporal course of its phenomenological complexity can only be captured by longitudinal studies which are almost entirely lacking. A recent longitudinal study of delirium symptoms in TBI patients using cognitive tests and the sleep–wake cycle item on the Delirium Rating Scale–Revised–98 (DRS-R-98; Trzepacz et al. 2001c) over five ratings found a highly individualized pattern for recovery of each symptom (Abell et al. 2009).

Despite across-study inconsistencies for symptom frequencies, certain symptoms occur more often than others, consistent with the proposal that delirium has core symptoms irrespective of etiology (Trzepacz 1999b, 2000). Multiple etiologies for delirium may “funnel” into a final common neural pathway (Trzepacz 1999b, 2000), so that the phenomenological expression becomes similar despite a breadth of different physiologies. Some symptoms represent core elements of the syndrome (e.g., inattention, sleep–wake cycle disturbances, motor activity changes) while other features are more variable in presentation (e.g., psychosis, affective changes) reflecting the influence of particular etiological underpinnings, comorbidities, exposure to medical

treatments for delirium, or individual patient vulnerabilities. Candidates for core symptoms include attention deficits, memory impairment, disorientation, sleep–wake cycle disturbance, thought process abnormalities, motor alterations, and language disturbances, whereas associated or noncore symptoms would include perceptual disturbances (illusions, hallucinations), delusions, and affective changes (Trzepacz 1999b) (see Table 5–4). Relationships between symptoms have received limited study, except through factor analyses of cross-sectional data (J. G. Franco et al. 2009; N. Gupta et al. 2008). These studies indicate some striking similarities regarding which symptoms clustered together typically with 2–3 factor solutions with a composite cognitive and one or more neurobehavioral factors.

Historically, the term *clouding of consciousness* has been used to describe the characteristic cognitive impairment of delirium with diminished capacity to engage with and grasp the external environment. However, a disturbance of consciousness is a better descriptor of delirium as a disorder than as a symptom of it. A disproportionate disturbance of attention has been emphasized as the principal cognitive disruption of delirium, and is the cardinal symptom required for diagnosis of delirium according to current classification systems. However, although inattention correlates highly with other elements of cognitive disturbance (Meagher et al. 2007), it does not account for the breadth of delirium symptoms.

Attention is impaired in all of its aspects such that delirious patients have difficulty in their ability to mobilize, shift, and sustain attention, reflected in apparent distractibility and poor environmental awareness during interview as well as with formal testing (Lipowski 1990). Inattention is a consistent feature, crucial to diagnosis, but also highly prevalent in patients who have subsyndromal or mild delirium (Marquis et al. 2007).

TABLE 5–4. Frequency of phenomenological manifestations in delirium using the Delirium Rating Scale–Revised–98

Core features	Noncore features
Attentional deficits (97%–100%)	Perceptual disturbances (50%–63%)
Disorientation (76%–96%)	Delusions (21%–31%)
Short-term memory deficits (88%–92%)	Affective changes (43%–86%)
Long-term memory deficits (89%–96%)	
Sleep–wake cycle disturbances (92%–97%)	
Thought process abnormalities (54%–79%)	
Visuospatial impairment (87%–96%)	
Motor alterations (24%–94%)	
Language disturbances (57%–67%)	

Source. From N. Gupta et al. 2008.

Patients with delirium also exhibit more generalized cognitive disturbance typically impacting upon short- and long-term memory, orientation, comprehension, vigilance, visuospatial ability, and executive function. Crystallized intelligence is unaffected, however (L.J. Brown et al. 2009). Memory impairment occurs often in delirium, affecting both short- and long-term memory, with particular disruption of recent memory due to diminished capacity to incorporate new experience. Patients are often amnesic for some or all of their delirium episodes (Breitbart et al. 2002). Trzepacz et al. (2001b) found a high correlation between short- and long-term memory items in delirious patients, with attention correlating with short-term memory but not with long-term memory. This is consistent with normally needing to pay attention before information can enter short-term (working) memory, and then selected data from working memory are stored in long-term memory.

Disorientation to time, place, and identity of others is a common feature that is often used as a screen for disturbed cognition in clinical settings but is fraught with potential for inaccuracy in detection due to its fluctuating nature. Visuospatial disturbances impair patients' ability to function in hospital environments. The constructional apraxia measured by performance on the Clock Drawing Test is sensitive to cognitive impairment in general but lacks specificity for delirium (Adamis et al. 2005).

Disorganized thinking is also a prominent feature that was previously emphasized in diagnosis (DSM-III-R) and that ranges from tangentiality and circumstantiality to loose associations. In one study, 21% of the patients with delirium exhibited tangentiality or circumstantiality, while 58% had loose associations (Trzepacz et al. 2001b).

Speech and language disturbances in delirium include abnormal semantic content, dysnomia, paraphasias, impaired comprehension, dysgraphia, and word-finding difficulties. In extreme cases, language resembles a fluent dysphasia. Incoherent speech or speech disturbance is reported commonly. Various forms of dysgraphia (spelling errors, angled and jagged writing, and disturbances of constructional praxis) have been advocated for delirium detection (Baranowski and Patten 2000) but overall writing disturbances appear to be nonspecific in nature (Patten and Lamarre 1989).

Disturbances of the sleep-wake cycle are reported in over 90% of patients with delirium, and the severity and type of disturbances range from napping and nocturnal insomnia to much more severe disturbances (including fragmentation, cycle reversal) which differ considerably from the milder sleep disturbances common in nondelirious hospitalized elderly. The prominence of sleep-wake cycle disturbances has prompted some to advocate delirium as a disorder of sleep and/or circadian rhythms (Mat-

sushima et al. 1997). The extent to which sleep-wake cycle disturbance confounds the hyperactive-hypoactive subtyping of delirium is not known.

Disturbances of motor behavior are almost invariable in delirium (Camus et al. 2000; A.K. Gupta et al. 2005; Meagher et al. 2008c) and include three patterns: hyperactive, hypoactive, and mixed presentations that shift between hyper- and hypoactivity. Often, motor disturbances are characterized as psychomotor behaviors (including hyperalertness, wandering, and uncooperativeness, or hypersomnolence, disinterest, and unawareness) that encompass nonmotor symptoms that may or may not have any specificity for delirium. The relevance of these patterns to clinical subtyping of delirium is discussed below.

Psychotic features such as perceptual disturbances (e.g., hallucinations and delusions) are less frequent than core symptoms (Eriksson et al. 2002; Webster and Holroyd 2000). A retrospective study of 227 patients with delirium found that 26% had delusions, 27% had visual hallucinations, 12% had auditory hallucinations, and 3% had tactile hallucinations (Webster and Holroyd 2000), while O'Keefe et al. (2005) found that 70% of elderly dementia-free patients with delirium had delusions, misperceptions, or both during delirium. Psychosis is more common in hyperactive presentations but also occurs in hypoactive patients (Breitbart et al. 2002; Meagher et al. 2000). The type of perceptual disturbance and delusion distinguishes delirium from functional psychoses such as schizophrenia (Cutting 1987). Clinically, the occurrence of visual (as well as tactile, olfactory, and gustatory) hallucinations heightens the likelihood of delirium, although primary psychiatric disorders occasionally present with visual misperceptions. Visual hallucinations range from patterns or shapes to complex and vivid animations (Trzepacz 1994). Persecutory delusions that are poorly formed (not systematized) are the most common type in delirium, although other types occur (e.g., somatic or grandiose). Delusional content involves misidentifications, themes of imminent danger, or of bizarre happenings in the immediate environment (Cutting 1987).

Affective lability is typical of delirium and can take many forms (e.g., anxious, apathetic, angry, dysphoric); it reflects a loss of control of emotional expression. In a study of psychiatric consultation referrals for suspected mood disorder who actually had delirium, 24% experienced suicidal thoughts, 52% had frequent thoughts of death, and 32% felt there was no point in taking medications (Farrell and Ganzini 1995). These findings highlight the importance of careful monitoring of mental state in delirious patients. Recent work has highlighted the frequency of more sustained disturbances of mood that complicate differentiation from hypomania in agitated cases and depression in hypoactive presentations (Leonard et al. 2009).

Motor Subtypes

It is not known whether there are meaningful subtypes of delirium based on clinical profiles. The most common proposed subtype has been defined according to alterations in motor activity. Altered motor activity in physically unwell patients with cognitive disturbance has been recognized for over two millennia, with the terms *lethargicus* and *phrenitis* used by the ancient Greeks to denote profiles of decreased and increased activity, respectively. Lipowski (1990) championed the use of “hyperactive” and “hypoactive” as labels for delirium subtypes, before adding a third “mixed” category to account for the observation that many patients experience elements of both within short time frames.

Subsequent work using a range of methodologies applied to a range of populations and treatment settings indicates that subtypes defined by motor presentation have similar neuropsychological and EEG profiles while differing in relationship to a variety of important clinical parameters, including frequency of presence of nonmotor symptoms, etiology, pathophysiology, detection rates, treatment experience, duration of episode, and outcome (Meagher 2009).

One of the most important implications of the different motor presentations of delirium is their impact upon accurate detection. The highly visible and often compelling behavioral disturbances of hyperactive patients tend to attract the attention of clinical staff, but in patients with hypoactive delirium, the frequent absence of overt distress or disturbance causes them to more likely be missed (Inouye et al. 2001) or misdiagnosed as depression.

Symptom fluctuation and acuity of onset are especially evident in hyperactive and mixed cases. Delusions, hallucinations, mood lability, speech incoherence, and sleep disturbances may be somewhat more frequent in hyperactive patients (Meagher and Trzepacz 2000; Ross et al. 1991) but are present in many patients with hypoactive presentations (Breitbart et al. 2002). Studies suggest that delirium occurring in the context of metabolic disorders or organ failure is more frequently hypoactive in presentation while that due to substance intoxication or withdrawal is more typically hyperactive (A. K. Gupta et al. 2005; Meagher et al. 1998; Morita et al. 2001; Ross et al. 1991).

The motor subtypes of delirium occur at differing frequencies in different populations. Hypoactive subtype is reported at higher frequency in palliative care and ICU populations, while psychiatric consultations are more likely to be requested for patients with relatively more hyperactivity. ICU patients have high rates of the mixed subtype. Detailed longitudinal study of delirium symptoms is necessary before any definitive conclusion can be reached regarding the stability of motor subtypes. Mixed

cases may reflect different impacts over time of multiple etiological effects on motor behavior or may be a hybrid state; some evidence suggests that mixed types occur in more severe delirium (Meagher 2009).

Few treatment studies in delirium have attempted to assess response for different motor subtypes, and they are small and do not paint a clear or consistent picture (Boettger et al. 2007a, 2007b; Liu et al. 2004; Platt et al. 1994, 2002). Overall, the relationship between motor subtype and treatment remains uncertain, but existing studies do suggest that hypoactive patients may also benefit when given antipsychotic treatment.

A range of studies have linked psychomotor profile and motor subtypes to outcome of delirium. The balance of the evidence suggests that hypoactivity is associated with a relatively poorer prognosis, but such differences may reflect differences in underlying causes, recognition rates, and/or treatment practices. Meagher et al. (1996), for example, found that psychotropic medication and supportive environmental ward strategies were more frequently used in the management of patients with hyperactive subtype.

An important methodological issue is that clinical checklist methods of motor subtyping do not focus solely on motor activity but instead include various “psychomotor” symptoms (verbal, affective, sleep, psychotic) that have a questionable phenomenological relationship to motor activity levels (Meagher and Trzepacz 2000). Therefore, Meagher et al. (2008c) studied motor and psychomotor symptoms in a study of delirious patients and nondelirious control patients and on the basis of these analyses developed a new pure motor disturbance clinical subtyping method, the Delirium Motor Subtype Scale (DMSS). DMSS items differentiated delirious subjects from control subjects (Meagher et al. 2008b; see Table 5–5). This scale is recommended for clinical use to replace nonvalidated psychomotor schema that include many nonmotor items. Unlike traditional psychomotor checklists, this scale has been demonstrated to have concurrent validity with objectively measured motor activity recorded via electronic actigraphy (Godfrey et al. 2009; Leonard et al. 2007b; Meagher et al. 2008a). Figure 5–4 depicts the percentage of time spent per hour in dynamic activity for patients with hyperactive, hypoactive, and mixed motor delirium, highlighting the differences among these subtypes (Godfrey et al. 2010).

Diagnosis and Assessment

Diagnosis

The diagnosis of delirium is made according to diagnostic systems where the cardinal symptom is inattention or clouded/impaired level of consciousness or both. Inatten-

TABLE 5-5. Delirium Motor Subtype Scale (DMSS)

- A. **HYPERACTIVE SUBTYPE** if definite evidence in the previous 24 hours (and this should be a deviation from predelirium baseline) of at least two of the following:
- (1) Increased quantity of motor activity: Is there evidence of excessive level of activity (e.g., pacing, fidgeting, general overactivity)?
 - (2) Loss of control of activity: Is the patient unable to maintain levels of activity that are appropriate for the circumstances (e.g., remain still when required)?
 - (3) Restlessness: Does the patient complain of restlessness or appear agitated?
 - (4) Wandering: Is the patient wandering (i.e., moving around without clear direction or purpose)?
- B. **HYPOACTIVE SUBTYPE** if definite evidence in the previous 24 hours (and this should be a deviation from predelirium baseline) of two or more of the following:
- (1)* Decreased amount of activity: Does the patient engage in less activity than is usual or appropriate for the circumstances (e.g., sits still with few spontaneous movements)?
 - (2)* Decreased speed of actions: Is the patient slow in initiation and performance of movements (e.g., walking)?
 - (3) Reduced awareness of surroundings: Does the patient show a relative absence of emotional reactivity to the environment (i.e., show a passive attitude to his or her surroundings)?
 - (4) Decreased amount of speech: Does the patient have a reduced quantity of speech in relation to the environment (e.g., answers are unforthcoming or restricted to a minimum)?
 - (5) Decreased speed of speech: Does the patient speak more slowly than usual (e.g., long pauses and slowing of actual verbal output)?
 - (6) Listlessness: Is the patient less reactive to his/her environment (e.g., responses to activity in surroundings are slow or reduced in amount)?
 - (7) Reduced alertness/withdrawal: Does the patient appear detached or lacking in awareness of his or her surroundings or their significance?
- *At least one of either decreased amount of activity or speed of actions must be present.
- C. **MIXED MOTOR SUBTYPE** if evidence of both hyperactive and hypoactive subtype in the previous 24 hours.
- D. **NO MOTOR SUBTYPE** if evidence of neither hyperactive nor hypoactive subtype in the previous 24 hours.

tion is also a consistent feature during the course of a delirious episode, supporting its usefulness as a reliable marker of delirium (Fann et al. 2002; Leonard et al. 2007a). Temporal course is a key indicator—delirium is typically of acute onset and symptom severity fluctuates over the course of the day. In addition, the presence of a potential etiological cause of delirium is also diagnostically valuable.

The demonstration of generalized cognitive disturbance allows distinction from disorders with more discrete neuropsychological disruptions (e.g., amnesic syndromes, mood disorders, attention deficit disorder). Where patients are known or suspected of having prior cognitive impairment, it is essential that a deterioration from baseline is used to identify symptoms that reflect delirium.

In clinical practice, making a diagnosis of delirium usually requires gathering information from multiple sources. A patient's mental status can be assessed by observation, interview, and formal cognitive testing. Further information regarding the course of any deficits is gleaned from the observer's knowledge of the patient, clinical notes, nursing staff, family, and other caregivers. Accurate assessment of attention combines clinical observation with specific cognitive tests, such as digit span, serial sevens test, or recitation of the months of the year in reverse order.

For many centuries the concept of delirium has included altered consciousness with generalized disturbance of higher cortical function. Historically, clouding of consciousness has been emphasized, but this is a concept that lacks precision and encompasses a combination of diminished attention, poor awareness, comprehension and grasp, altered wakefulness levels, and other cognitive disruptions. It does, however, capture delirium as essentially a disorder of impaired consciousness.

Specific diagnostic criteria for delirium first appeared in DSM-III, prior to which delirium was encapsulated in DSM I and DSM II under the general category of acute brain syndrome, characterized by five key symptoms—impairments of orientation, memory, all intellectual functions, and judgment, as well as lability and shallowness of affect. Other disturbances, such as hallucinations and delusions, were considered secondary to the disturbance of the sensorium. Note that inattention was not cardinal. DSM-II (American Psychiatric Association 1968) described two acute organic brain syndromes, psychotic and nonpsychotic types.

DSM-III, DSM-III-R, and DSM-IV included efforts to further clarify the major criterion describing altered states of consciousness, considered as either a disturbance of consciousness or inattention. DSM-III-R is the most inclusive of the breadth of delirium symptoms and tends to be preferred by researchers. DSM-IV requires fewer symptoms and therefore tends to overdiagnose cases. All DSM ver-

sions required that symptoms not be better accounted for by a dementia.

DSM-IV (American Psychiatric Association 1994) and its text revision, DSM-IV-TR (American Psychiatric Association 2000), have five categories of delirium; the criteria are the same for each category except the one for etiology. The categories are 1) delirium due to a general medical condition, 2) substance intoxication delirium, 3) substance withdrawal delirium, 4) delirium due to multiple etiologies, and 5) delirium not otherwise specified. This notation of etiology in DSM-IV is reminiscent of that used in DSM-I (American Psychiatric Association 1952).

The ICD-10 (World Health Organization 1992) research diagnostic criteria for delirium are similar to the DSM-IV criteria. However, ICD-10 mandates that disturbances of *both* memory and orientation be evident. Specifically, a disproportionate disturbance of immediate recall and recent memory with relatively intact remote memory is required. Disturbances of memory are notoriously difficult to attribute to delirium in populations with comorbid dementia. In such cases it is helpful to demonstrate that disturbances in memory represent a clear deterioration from a recent baseline or focus inattention. The pattern mandated in ICD-10 is not always evident in delirium research, and orientation is prone to great fluctuation during the course of an episode (Leonard et al. 2007a). This impacts considerably upon detection especially where lucidity is equated with absence of disorientation. The ICD-10 criteria for delirium also require the presence of many features which are highly variable in their frequency (e.g., affective changes, perceptual disturbances). A number of studies have shown that the ICD-10 criteria lack sensitivity, excluding many patients who would be classified as delirious by DSM systems and whose clinical profiles and prognoses are very similar to delirium as diagnosed by these other systems (Cole et al. 2003a; Laurila et al. 2004).

Some studies have suggested that the presence of some features of delirium, although insufficient to meet DSM or ICD criteria, may indicate a subsyndromal condition that is not recognized in DSM. Although delirium is usually characterized by an acute onset replete with many symptoms, it may be preceded by a subclinical delirium with more insidious changes in sleep pattern or cognition (Harrell and Othmer 1987) and background slowing on the EEG (Matsushima et al. 1997). J.G. Franco et al. (2009) found that subsyndromal delirium was comparable to full delirium for sleep-wake cycle and perceptual disturbances, affective lability, short-term memory deficits, motor disturbances, and acute onset but was intermediate in severity between normal controls and full delirium for inattention, delusions, language and thought process abnormalities, disorientation, and long-term memory and visuospatial impairments.

Cognitive Assessment

Because delirium is primarily a cognitive disorder, bedside assessment of cognition is critical to proper diagnosis. All cognitive domains—orientation, attention, short- and long-term memory, visuoconstructional ability, and executive function—are affected in delirium. Use of bedside screening tests (see also Chapter 1, “Psychiatric Assessment and Consultation”) such as the MMSE (Folstein et al. 1975) is important clinically to document the presence of a cognitive disorder, but it lacks specificity for delirium (Trzepacz et al. 1988a). The MMSE is too easy for many people (ceiling effect) and has a limited breadth of items, particularly for prefrontal executive and right-hemisphere functions. Despite these shortcomings, some work (O’Keeffe et al. 2005) suggests that serial assessment with the MMSE can identify delirium in older medical patients, with a decrease of 2 or more points on the MMSE sensitive to delirium occurrence. There is evidence that some items are more indicative of delirium (e.g., orientation to current year and date, backwards spelling, copying of a pentagon) (Fayers et al. 2005), whereas others are more consistent with Alzheimer’s dementia (e.g., orientation to time, recall of three objects) (Solfrizzi et al. 2001). Lowery et al. (2008) found that a combination of the MMSE with tests of attention and reaction time allowed for a high discrimination of delirium in postoperative patients without dementia. Overall, the MMSE is a useful means of identifying cognitively impaired patients, but the differentiation of delirium and dementia requires additional assessment methods.

The Cognitive Test for Delirium (CTD; Hart et al. 1996) is a bedside test designed specifically for patients with delirium who are often unable to speak or write in a medical setting (e.g., on a ventilator). Unlike the MMSE, the CTD has many nonverbal (nondominant hemisphere) items and abstraction questions. The CTD correlates highly with the MMSE ($r=0.82$) in patients with delirium and was performable in 42% of the ICU patients in whom the MMSE was not. It has two equivalent forms that correlated highly ($r=0.90$) in patients with dementia, which makes it better suited for repeated measurements. Cognitive impairment on the CTD correlates highly with scores for the cognitive subscale of the DRS-R-98 (Meagher et al. 2007). However, it correlates less well with symptom rating scales for delirium that also include noncognitive symptoms—for example, the Medical College of Virginia (MCV) Nurses Rating Scale for Delirium ($r=-0.02$) (Hart et al. 1996) and the DRS-R-98 ($r=-0.62$) (Trzepacz et al. 2001c). An abbreviated version of the CTD with just two of its nine items (visual attention span and recognition memory for pictures) retained good reliability and discriminant validity (Hart et al. 1997). Kennedy et al. (2003) found that a CTD cutoff score of less

than 21 (rather than 19) was more suited to identification of delirium in recovering acute TBI patients. Greater severity on the inattention item of the CTD was found to be predictive of shorter survival time in delirious palliative care patients with cancer diagnoses (Leonard et al. 2008).

The Clock Drawing Test (CDT) assesses constructional praxis, visuospatial ability, executive function, and verbal and semantic memory. While it is a useful screen for cognitive impairment in medically ill patients, it lacks specificity for either presence or severity of delirium (Adamis et al. 2005) and does not discriminate between delirium and dementia (Manos 1997).

More discrete tests focusing on simple and complex attention (e.g., digit or spatial span, Trail Making Test B) can be useful in identifying and monitoring progress in delirious patients (Fann et al. 2002; Meagher and Leonard 2008; O’Keeffe and Gosney 1997; Trzepacz et al. 1988a). Overall, the use of systematic formal testing that focuses on delirium-relevant aspects of cognition (such as attention) can assist in more accurate detection of delirium.

Delirium Assessment Instruments

Delirium assessment tools can serve a variety of functions from clarifying diagnosis to studying the relationship between phenomenology and other clinical variables, including treatment response. A wide range of instruments have been described, but few have been subjected to robust investigation of psychometric properties or applicability across health care settings. Key considerations in choice of instrument include purpose of use (screening vs. diagnosis vs. severity measure vs. phenomenological profiling), ease of use (including time to administer, need for training, and knowledge of assessor—nurse vs. physician), characteristics of the population under study, and evidence to support validity and reliability in different settings and/or population. None are intended to substitute for adequate clinical experience. Furthermore, proper training on administration of these instruments increases their accuracy. There are a variety of delirium tools used but many are not described here due to infrequent use, inadequate validation, or exclusion of some key delirium symptoms (e.g., inattention, sleep–wake disturbance). Several are recommended (Kean and Ryan 2008; Timmers et al. 2005) that can be used together or separately, depending on the purpose. For example, a screening tool can be used for case detection, followed by application of DSM criteria, and then a more thorough rating for symptom severity.

The Confusion Assessment Method (CAM) is the most widely used screening tool for diagnosis of delirium across health care settings (Inouye et al. 1990) and has been translated into many languages. The CAM is based on DSM-III-

R criteria and has two forms: 1) a full scale with 11 items rated as present or absent and 2) the more commonly used algorithm that requires the presence of 3 of 4 key symptoms for a diagnosis of delirium. It has been adapted for use in intensive care settings (Ely et al. 2001a, 2001b), emergency departments (Monette et al. 2001), palliative care (Ryan et al. 2009), and even a telephone interview version (Fisher and Flowerdew 1995).

In general, the CAM has acceptable sensitivity and specificity when used by trained physicians, but it is much less useful when in nonexpert hands (Kean and Ryan 2008). Its sensitivity is much lower when used by nurses (Rolfson et al. 1999). Although the CAM can have utility as a screening tool, it is not adequate for diagnosis (Laurila et al. 2002) and has not been subjected to blind validation against patients with dementia or other psychiatric disorders, which limits its applicability.

Cole et al. (2003a) assessed the sensitivity and specificity of the full CAM in patients with DSM-III-R–diagnosed delirium, dementia, or comorbid delirium and dementia. With a cutoff of 6 of 11 items present, the authors found 95% sensitivity and 83% specificity in delirium-only patients and 98% sensitivity and 76% specificity in comorbid patients; however, use of fewer items (e.g., a minimum cutoff of 3 symptoms) greatly reduced the specificities to 60% for delirium and 47% for comorbid delirium and dementia.

An extension of the CAM is the CAM-ICU (Ely et al. 2001a, 2001b), aimed for use by nurses for severely medically ill patients in the ICU. The CAM-ICU uses specific adjunctive tests and standardized administration to enhance reliability and validity; 95% validity and 0.92–0.96 interrater reliability have been reported, compared with expert psychiatric diagnosis of delirium with DSM-IV criteria, in two different validation studies of 150 patients (Ely et al. 2001a, 2001b). Routine application of the CAM-ICU may permit earlier detection leading to haloperidol use for shorter time periods (Van den Boogaard et al. 2009).

The Delirium Rating Scale (DRS; Trzepacz et al. 1988a) is a 10-item scale assessing a breadth of delirium features and can function both for diagnosis and to assess symptom severity because of its hierarchical nature and anchored item choice descriptions (Trzepacz 1999a; van der Mast 1994). It has been translated into Italian, French, Spanish, Korean, Japanese, Mandarin Chinese, Dutch, Swedish, German, Portuguese, and a language of India. It is generally used by those who have some psychiatric training. The DRS has high interrater reliability and validity, even when compared with other psychiatric diagnoses, and distinguishes delirium from dementia. Factor analysis finds a two- or three-factor structure (Trzepacz 1999a; Trzepacz and Dew 1995). However, it does not function as well for frequent repeated measurements and has been modified by

some researchers to a seven- or eight-item subscale. It is useful in children and adolescents (Tukel et al. 2003) and in hypoactive patients who border on stupor.

The DRS-R-98 is a substantially revised version of the DRS that addresses its shortcomings (Trzepacz et al. 2001c). It allows for repeated measurements and includes separate or new items for language, thought process, motor agitation, motor retardation, and five cognitive domains. It is intended for administration by clinicians with appropriate training in psychiatry, delirium, and use of the scale. An administration guide is available (obtainable from Dr. Trzepacz). Factor analysis (J.G. Franco et al. 2009) described two factors—cognition and psychosis/agitation. Inattention, thought process abnormalities, and sleep–wake disturbance loaded onto both factors, consistent with their being core domains of delirium.

The DRS-R-98 Total scale has 16 items, with 3 diagnostic items separable from 13 severity items that form a severity scale that also was validated. Severity is rated for a broad range of symptoms. The total scale is used for initial evaluation of delirium to allow discrimination from other disorders. The DRS-R-98 total score distinguished ($P<0.001$) delirium from dementia, schizophrenia, depression, and other medical illnesses during blind ratings, with sensitivities ranging from 91% to 100% and specificities from 85% to 100%, depending on the cutoff score chosen. The DRS-R-98 has high internal consistency (Cronbach $\alpha=0.90$), correlates well with the DRS ($r=0.83$) and CTD ($r=-0.62$), and has high interrater reliability (intraclass correlation coefficient [ICC]=0.99). Japanese, Korean, Greek, Portuguese, Danish, Dutch, German, Spanish (Colombia and Spain), Lithuanian, Norwegian, Italian, Thai, Hebrew, Turkish, and Chinese (traditional and modern) versions are available. In addition, Japanese, Korean, Dutch, traditional Chinese, Portuguese, and Spanish (Spain and Colombia) versions have been validated (de Negreiros et al. 2008; de Rooij et al. 2006; Fonseca et al. 2005; J.G. Franco et al. 2007; Huang et al. 2009; Kato et al., in press; Lim et al. 2006; Trzepacz et al. 2001a), and Turkish, Thai, Hebrew, Italian, and Greek validations are under way. Revalidations confirm the high sensitivity, specificity, and reliability of the DRS-R-98.

The Memorial Delirium Assessment Scale (MDAS) is a 10-item severity rating scale intended for repeated ratings within a 24-hour period (Breitbart et al. 1997). It takes approximately 10 minutes to complete and is intended for physician use. It was originally developed to assess delirium severity in patients with cancer or AIDS, but subsequent work has included elderly patients in general hospital (Marcantonio et al. 2002) and ICU (Shyamsundar et al. 2009) settings. The MDAS does not include items for temporal onset or fluctuation of symptoms, which are needed to diagnose delirium and help distinguish it from demen-

tia. The MDAS correlated highly with the DRS ($r=0.88$) and MMSE ($r=-0.91$). Japanese and Italian versions have been validated (Grassi et al. 2001; Matsuoka et al. 2001). Sensitivity, specificity, and concordance with other delirium measures have varied from excellent to moderate (Kazmierski et al. 2008; Shyamsundar et al. 2009). Factor analyses have shown a two-factor structure for the MDAS (Lawlor et al. 2000b; Shyamsundar et al. 2009). The motor activity items of the MDAS as well as the DRS-R-98 have been used widely to define motor subtypes of delirium (Meagher 2009).

Electroencephalography

In the 1940s, Engel and Romano (1944, 1959; Romano and Engel 1944) wrote a series of classic papers that described the relation of delirium, as measured by cognitive impairment, to EEG generalized slowing. In their seminal work, they showed an association between abnormal electrical activity of the brain and symptoms of delirium, the reversibility of both of these conditions, the ubiquity of EEG changes across different underlying disease states, and the improvement in EEG background rhythm that paralleled clinical improvement. In most cases, EEGs are not needed to make a clinical diagnosis of delirium; instead, they are used when seizures are suspected or differential diagnosis is difficult, as in schizophrenic patients with medical illness. Most often, a careful assessment of behaviors, cognition, and history is sufficient to diagnose delirium. Nonetheless, EEG is the only technological method to assist in delirium diagnosis.

EEG characteristics in delirium include slowing or dropout of the dominant posterior rhythm, diffuse theta or delta waves (i.e., slowing), poor organization of the background rhythm, and loss of reactivity of EEG to eye opening and closing (Jacobson and Jerrier 2000). Similarly, quantitative EEG in delirium shows slowing of power bands' mean frequency, especially in posterior regions (see Figure 5-5).

In burn patients, Andreasen et al. (1977) showed that the time course of EEG slowing could precede or lag behind overt clinical symptoms of delirium, although sensitive delirium symptom ratings were not used. EEG dominant posterior rhythm, along with serum albumin and Trail Making Test B, distinguished delirious from nondelirious cirrhosis patients in another study (Trzepacz et al. 1988b). Although generalized slowing is the typical EEG pattern for both hypoactive and hyperactive presentations of delirium and for most etiologies, delirium tremens is characterized by low-voltage fast activity (Kennard et al. 1945) that is superimposed on slow waves. Intoxication with sedative-hypnotics is associated with fast beta waves. Although diffuse slowing is the most common presenta-

tion, false-negative results occur when a person's characteristic dominant posterior rhythm does not slow sufficiently to drop from the alpha to the theta range, thereby being read as normal despite the presence of abnormal slowing for that individual. (Generally, a change of more than 1 cycle per second [cps] from an individual's baseline is considered abnormal.) Jacobson and Jerrier (2000) warned that it can be difficult to distinguish delirium from drowsiness and light sleep unless the technologist includes standard alerting procedures during the EEG. Comparison with prior baseline EEGs is often helpful to document that slowing has in fact occurred. Less commonly, an EEG may detect focal causes of confusion, such as ictal and subictal states, including toxic ictal psychosis, nonconvulsive status, and complex partial status epilepticus (Drake and Coffey 1983; Trzepacz 1994) or a previously unsuspected focal lesion (Jacobson and Jerrier 2000) (see Table 5-6). A toxic ictal state may occur after tricyclic antidepressant (TCA) overdose, in which the seizure threshold is lowered and anticholinergic toxicity contributes to delirium. New-onset complex partial seizures, usually related to ischemic damage (Sundaram and Dostrow 1995), are an underrecognized cause of delirium in the elderly, especially when prolonged confusion occurs during status.

Quantitative EEG (qEEG) has shown promise in delirium assessment. Power spectra reveal decreased alpha and increased theta and delta bands that may help to distinguish delirium from dementia (Jacobson and Jerrier 2000; Jacobson et al. 1993a, 1993b). C. Thomas et al. (2008) found that a prolonged activation procedure combined with spectral analysis for alpha/delta density ratios during qEEG discriminated patients with delirium from patients with comorbid delirium-dementia and cognitively normal frail medically ill elderly subjects.

Evoked potentials also may be abnormal in delirium. Metabolic causes of delirium precipitate abnormalities in visual, auditory, and somatosensory evoked potentials (Kullmann et al. 1995; Trzepacz 1994), whereas somatosensory evoked potentials are abnormal in patients whose delirium is due to TBI. In general, normalization of evoked potentials parallels clinical improvement; however, evoked potentials are not clinically used for assessment of delirium.

EEGs and evoked potentials in children with delirium show patterns similar to those in adults, with diffuse slowing on EEG and increased latencies of evoked potentials (J.A. Katz et al. 1988; Prugh et al. 1980; Ruijs et al. 1993, 1994). The degree of slowing on EEGs and evoked potentials performed serially over time in children and adolescents correlates with the severity of delirium and with recovery from delirium (Foley et al. 1981; Montgomery et al. 1991; Onofrij et al. 1991).

FIGURE 5-5. Typical electroencephalogram (EEG) and quantitative EEG (qEEG) findings in delirium.

Examples of bipolar lead EEG and qEEG in delirium showing diffuse slowing, especially of the dominant posterior rhythm. On qEEG, higher power is shown in darker shading, according to each of the four frequency bands.

Etiology

Delirium has a wide variety of etiologies, which may occur alone or in combination (see Table 5-7). Single etiology delirium is the exception (Meagher et al. 2007), with most cases involving the contribution of multiple factors, often sequentially, making regular rigorous reassessment of causation essential in its management (Meagher and Leonard 2008). Etiological factors include primary cerebral disorders, systemic disturbances that affect cerebral function, drug and toxin exposure (including intoxication and withdrawal), and a range of factors that can contribute to delirium but have an uncertain etiological role by themselves (including psychological and environmental factors). To be considered causal, an etiology should be a recognized possible cause of delirium and be temporally related in onset and course to delirium presentation; also, the delirium should not be better accounted for by other factors.

Multiple etiologies are common, with between two and six possible causes typically identified, especially in the elderly and those with terminal illness (Breitbart et al. 1996; Francis et al. 1990; Meagher et al. 1996; O'Keeffe and Lavan 1996; Trzepacz et al. 1985). A single etiology is identified in fewer than 50% of cases (Camus et al. 2000; O'Keeffe and

Lavan 1999; Olofsson et al. 1996). In frail elderly, Laurila et al. (2008) identified a mean of 3 etiologies per delirious patient, in addition to a mean of 5.2 predisposing factors. The most common etiologies were infectious, metabolic abnormalities, adverse drug effects, and cardiovascular events. Drug classes most commonly associated with delirium in the elderly are benzodiazepines, opioids, and anticholinergics. Delirium in cancer patients can be due to the direct effect of the primary tumor or the indirect effects of metastases, metabolic problems (organ failure or electrolyte disturbance), chemotherapy, central nervous system (CNS) radiation and other treatments, infections, vascular complications, nutritional deficits, and paraneoplastic syndromes. Sagawa et al. (2009) found the most frequent causes of delirium in cancer inpatients were opioids (29%), inflammation (27%), and dehydration and/or sodium level abnormalities (15%), with two or more causes identified in more than 40% of cases. No association between etiology and either reversibility or motor subtype was found. This multifactorial nature has been underemphasized in research—etiological attribution typically is based on clinical impressions that are not standardized (e.g., the most likely cause identified by referring physician) or that are oversimplified by documenting a single etiology for each case. That

TABLE 5-6. Electroencephalographic patterns in patients with delirium

Electroencephalographic finding	Comment	Causes
Diffuse slowing	Most typical delirium pattern	Many causes, including anticholinergic, posttraumatic brain injury, hepatic encephalopathy, hypoxia
Low-voltage fast activity	Typical of delirium tremens	Alcohol withdrawal; benzodiazepine intoxication
Spikes/polyspikes, frontocentral	Toxic ictal pattern (nonconvulsive)	Hypnotic drug withdrawal; tricyclic and phenothiazine intoxication
Left/bilateral slowing or delta bursts; frontal intermittent rhythmic delta	Acute confusional migraine	Usually in adolescents
Epileptiform activity, frontotemporal or generalized	Status with prolonged confusional states	Nonconvulsive status and complex partial status epilepticus

delirium due to a single etiology is the exception rather than the rule highlights the importance of considering the possibility of further etiological inputs even when a cause has been identified.

Some causes are more frequently encountered in particular populations. Delirium in children and adolescents involves the same categories of etiologies as in adults, although frequencies of specific causes differ. Delirium related to illicit drugs is more common in younger populations, whereas delirium due to prescribed drugs and polypharmacy is more common in older populations. Cerebral hypoxia is common at age extremes—chronic obstructive airway disease, myocardial infarction, and stroke are common in older patients, whereas hypoxia due to foreign-body inhalation, drowning, and asthma are more frequent in younger patients. Poisonings are also more common in children than in adults, whereas young adults have the highest rates of head trauma.

There are probably a relatively small number of pathophysiological mechanisms utilized by many different etiologies and precipitants to cause the brain disturbance that results in delirium. Major pathophysiological perturbations hypothesized have been reviewed by Maldonado (2008) and include oxygen deprivation, inflammatory, neurotransmitter imbalance, neuronal aging, physiological stress, and cellular signaling. These are often complementary and concurrent; they are both systemic and CNS disturbances or both. For example, proinflammatory cytokines can be produced in the periphery and enter the brain through the ventricular system, and the brain can also produce its own cytokines by glia. Medication adverse effects or toxicities can perturb neurotransmitter systems, leading to imbalance in key brain regions responsible for maintaining consciousness and attention.

Once delirium is diagnosed, a careful and thorough, but prioritized, search for causes must be conducted. Ame-

liorations of specific underlying causes are important in resolving delirium; however, this should not preclude treatment of the delirium itself, which can reduce symptoms even before underlying medical causes are rectified (Breitbart et al. 1996).

Neuropathogenesis

Delirium is a syndrome which means its symptoms are stereotyped while resulting from numerous different causes. This suggests that different pathophysiological or pharmacological perturbations affecting the brain ultimately culminate into common dysfunction of certain neural circuits (as well as neurotransmitters) which leads to a common clinical expression. This is termed a “final common neural pathway” and refers to a neural network of certain regions and circuits that supports consciousness and higher level thinking and produces characteristic symptom profile when dysfunction occurs (Trzepacz 1999b, 2000). The involvement of certain specific regions and pathways is largely based on interpretation of structural and functional neuroimaging data (Fong et al. 2006; Trzepacz 2000; Trzepacz et al. 2002a). Prefrontal, posterior parietal, and fusiform cortices and basal ganglia are implicated, especially on the right side, plus thalamus especially anterior and medial nuclei. The thalamus is poised at the intersection of the reticular activating system and circuitry to the cerebral cortex. It is reciprocally connected to the cerebral cortex and supports the desynchronized fast-wave EEG of wakeful conscious states. Its intralaminar nucleus, which is highly cholinergic, is involved in sensorimotor gating and supports cerebral cortical activation along with the medial reticular activating system and is important in subserving consciousness (Perry et al. 1999). Dysfunction in both cortical and subcortical regions in delirium has been supported by studies of regional cerebral blood flow,

TABLE 5–7. Selected etiologies of delirium**Central nervous system (CNS)**

Meningitis, encephalitis
 CNS HIV infection
 Stroke
 Subarachnoid hemorrhage
 Cerebral edema
 Seizures
 Hypertensive encephalopathy
 Eclampsia
 CNS vasculitis
 CNS tumor
 CNS paraneoplastic syndrome

Drug intoxication

Alcohol and other drugs of abuse
 Sedative-hypnotics
 Opioids, especially meperidine
 Anticholinergics
 Antihistamines
 Corticosteroids

Drug withdrawal

Alcohol
 Sedative-hypnotics

Hyperthermia

Heatstroke, neuroleptic malignant syndrome,
 malignant hyperthermia, serotonin syndrome

Metabolic and endocrine disturbance

Hypo- or hyperglycemia
 Severe electrolyte disturbance
 Acidosis or alkalosis
 Hypoxia
 Hypercarbia
 Uremia
 Severe endocrinopathy
 Hepatic failure
 Refeeding syndrome (see Chapter 14, “Eating Disorders”)
 Other metabolic disorders (e.g., porphyria, carcinoid syndrome)

Systemic conditions

Sepsis, bacteremia
 Minor infection in dementia (e.g., urinary tract infection)
 Acute graft rejection
 Acute graft-versus-host disease
 Shock
 Postoperative state
 Disseminated intravascular coagulation and other hypercoagulable states

Trauma

Traumatic brain injury
 Subdural hematoma
 Fat emboli

single photon emission computed tomography, positron emission tomography, EEG, and evoked potentials (Trzepacz 1994; Yokota et al. 2003).

The best-established neurotransmitter alteration accounting for many cases of delirium is reduced cholinergic activity (Trzepacz 1996a, 2000). There are numerous lines of evidence to support this and a role for acetylcholine in the classic symptoms of delirium. Furthermore, desynchronized waking EEG patterns and consciousness require muscarinic activity. The cholinergic system has widespread efferents and is involved in cortical activation, induction of REM sleep, EEG fast-wave activity, motor components of behavior, attentional processes, learning and memory, mood, and sensory gating.

Many medications and/or their metabolites have anticholinergic activity and have been reported to cause delirium. Some act postsynaptically; others act presynaptically; and still others, such as normeperidine, have anticholinergic metabolites (Coffman and Dilsaver 1988). Tune et al. (1992) measured the anticholinergic activity of many medications in “atropine equivalents.” They identified medications usually not recognized as being anticholinergic (e.g., digoxin, nifedipine, cimetidine, codeine). Delirium induced by anticholinergic drugs is associated with generalized EEG slowing and is reversed by treatment with physostigmine or neuroleptics (Itil and Fink 1966; Stern 1983). Numerous studies find relationships between delirium and higher serum anticholinergic assay levels, and there is a

high correlation between cerebrospinal fluid (CSF) and serum anticholinergic activity (Plaschke et al. 2007). Serum levels of anticholinergic activity are elevated in patients with postoperative delirium and correlate with severity of cognitive impairment (Tune et al. 1981), improving with resolution of the delirium (Mach et al. 1995). Post-electroconvulsive therapy (ECT) delirium is also associated with higher serum anticholinergic activity (Mondimore et al. 1983).

Both metabolic and structural etiologies of delirium involve anticholinergic effects. Hypoxia and hypoglycemia reduce acetylcholine by affecting the oxidative metabolism of glucose and the production of acetyl coenzyme A, the rate-limiting step for acetylcholine synthesis and thiamine deficiency via being a necessary cofactor for synthesis (Gibson et al. 1975; Trzepacz 1994). Oxidative metabolic stress occurring acutely due to low glucose, hypoxia or reduced perfusion will result in lower choline and adenosine-5'-triphosphate (ATP), required for acetylcholine production. Furthermore, free-radical damage in mitochondria over the years may explain an increased risk of delirium with aging, in addition to alterations in the efficiency of cholinergic neurotransmission. High levels of intraoperative oxygen desaturation, as measured by frontal lobe cerebral oximetry, are associated with postoperative delirium (Zaubler et al. 2009). Clinical indices of oxidative stress (low hemoglobin, low hematocrit, and low oxygen saturation) were associated with ICU delirium, whereas Acute Physiology and Chronic Health Evaluation II (APACHE II) scores were not (Seaman et al. 2006). Parietal cortex levels of choline are reduced in chronic hepatic encephalopathy (Kreis et al. 1991).

Alzheimer's and vascular dementias impair cholinergic neurons and are associated with increased risk for delirium. Dementia with Lewy bodies is associated with significant loss of cholinergic nucleus basalis neurons, and with its fluctuating symptom severity, confusion, hallucinations (especially visual), delusions, and EEG slowing mimics delirium. Its delirium symptoms respond to donepezil (Kaufer et al. 1998). Age-associated changes in cholinergic function also increase delirium propensity. Stroke and TBI are associated with decreased cholinergic activity (Yamamoto et al. 1988) and have enhanced vulnerability to antimuscarinic drugs (Dixon et al. 1994). The low cholinergic state seems to correlate temporally with delirium following the acute event. Thus, there is broad support for an anticholinergic mechanism for many seemingly diverse causes of delirium.

Increased dopamine also may play a major role and its effects are often opposite of that of acetylcholine (Trzepacz 2000). Dopamine has the same effect on the EEG as do anticholinergic drugs. Dopamine release increases during hypoxia (Broderick and Gibson 1989) so this would be ex-

pected to exacerbate effects of low acetylcholine. Delirium due to dopamine excess includes intoxication with dopamine agonists (Ames et al. 1992), ECT, alcohol withdrawal (Sander et al. 1997), opiate intoxication, and cocaine toxicity (Wetli et al. 1996). The efficacy of antidopaminergic agents, particularly neuroleptics, in treating delirium, including that arising from anticholinergic causes (Itil and Fink 1966; Platt et al. 1994), also suggests a neuropathogenic role for dopamine. Blockade of D_2 receptors increases acetylcholine release, as does stimulation of D_1 receptors (Ikarashi et al. 1997). Drugs that antagonize D_2 receptors or that agonize/allosterically modulate M_1 and M_4 receptors reverse sensorimotor gating disturbances in rats (Jones et al. 2005), consistent with findings for therapeutics that improve delirium and affect these systems (see section "Treatment" later in this chapter).

The underlying pathophysiology for motor subtypes may be related to neurotransmitter activity. The distribution of dopamine D_3 and D_4 receptor subtypes in the nucleus accumbens can produce hyper- or hypoactivity in rodents, suggesting that an individual's response to excess dopamine in delirium may relate to these receptors. Van der Cammen et al. (2006) reported that hyperactive delirious patients had higher homovanillic acid (HVA) levels than hypoactive patients, consistent with more dopamine turnover.

Both increased and decreased gamma-aminobutyric acid (GABA) levels have been implicated in causing delirium. Increased GABAergic activity is one of several putative mechanisms implicated in hepatic encephalopathy (Mousseau and Butterworth 1994). GABA activity is reduced during delirium following withdrawal from ethanol and sedative-hypnotic drugs. Decreased GABA activity is also implicated in the delirium caused by penicillins, cephalosporins, and quinolones (Akaike et al. 1991; Mathers 1987). Both low and excessive levels of serotonin are also associated with delirium (van der Mast and Fekkes 2000). Serotonin syndrome (see Chapter 38, "Psychopharmacology") is the obvious example of the latter, but serotonergic activity may be increased in patients with hepatic encephalopathy (Mousseau and Butterworth 1994; van der Mast and Fekkes 2000) and sepsis (Mizock et al. 1990). Histamine may play a role in delirium through its effects on arousal and hypothalamic regulation of sleep-wake circadian rhythms. Both H_1 and H_2 antagonists can cause delirium, although both also have anticholinergic properties (Picotte-Prillmayer et al. 1995; Tejera et al. 1994). Glutamate release is increased during hypoxia, and glutamatergic receptors may be activated by quinolone antibiotics (P.D. Williams and Helton 1991). Glutamate surges accompany acute brain damage from stroke or trauma and may mediate neuronal damage that causes preferential basal fore-

brain and thalamic cholinergic neuron damage that can lead to delirium (Robbins et al. 1997; Weiss et al. 1994).

Whereas some etiologies of delirium alter neurotransmission directly or via general metabolism, others may antagonize or interfere with specific receptors and neurotransmitter precursors. Altered ratios of plasma amino acids during severe illness, surgery, and trauma may affect brain synthesis of neurotransmitters including tryptophan and tyrosine (Pandharipande et al. 2009; Trzepacz and van der Mast 2002; van der Mast and Fekkes 2000). In addition to changes in major neurotransmitter systems, neurotoxic metabolites, such as quinolinic acid from tryptophan metabolism (Basile et al. 1995), and false transmitters, such as octopamine in patients with liver failure, have been implicated in the pathogenesis of delirium. Because glia help to regulate neurotransmitter amounts in the synapse, glial dysfunction also may be involved and may implicate glutamate, which is regulated by astroglia. Increased blood-brain barrier permeability—as occurs in uremia, allowing a host of offending proteins to enter the brain—is another possible mechanism contributing to delirium. Cytokines are increased during stress, rapid growth, inflammation, tumor, trauma, and infection (Hopkins and Rothwell 1995; Rothwell and Hopkins 1995; Stefano et al. 1994). Raised levels of cytokines—whether occurring as part of the body's response to inflammation or infection or from treatment with interferons or interleukins—can cause delirium. The mechanism by which cytokines cause delirium may be through neurotoxicity (Lipton and Gendelman 1995), through effects on a variety of neurotransmitters (Rothwell and Hopkins 1995; Stefano et al. 1994), by altering blood-brain barrier permeability, or through effects on glial function. Proinflammatory cytokines interleukin-6 (IL-6) and interleukin-8 (IL-8) as well as C reactive protein (CRP) and BDNF have been associated with delirium (Adamis et al. 2007b; de Rooij et al. 2007; Pfister et al. 2008; Van Munster et al. 2008).

Differential Diagnosis

Delirium is frequently detected late or not at all in clinical practice. Between one-third and two-thirds of cases are misdiagnosed or completely missed across a range of care settings and by a variety of specialists, including psychiatrists and neurologists (Johnson et al. 1992; Kishi et al. 2007; Meagher and Leonard 2008). The failure to recognize the symptoms or diagnosis of delirium results in poorer outcomes (Kakuma et al. 2003; Rockwood et al. 1994). Poor detection rates are in part explained by delirium's fluctuating nature and complex phenomenology which confer considerable clinical variability and a broad differential diagnosis.

Delirium detection is also hampered by the prevailing stereotype (as in delirium tremens) of an agitated psychotic patient which in fact occurs in approximately one-third of presentations (Meagher 2009), since most patients with delirium have either mixed or hypoactive symptom profiles (Meagher and Trzepacz 2000). The hypoactive presentation is less appreciated because the quiet, untroublesome patient is often presumed to have intact cognition and is more easily overlooked in time-pressured modern health care environments. Nursing staff play a key role in delirium recognition because of their consistency of contact with patient and family but can easily overlook delirium due to limited skills in assessing cognition (Inouye et al. 2001) or a tendency to attribute delirium symptoms to fatigue, anxiety, depression, or patient eccentricities (Irving et al. 2006). Detection can be improved by maintaining a high level of suspicion for delirium, improving awareness of its varied presentations, and routinely assessing cognitive function using a systematic approach supplemented by one of the currently available screening instruments for delirium (Rockwood et al. 1994), such as the CAM or CAM-ICU (Ryan et al. 2009).

Delirium has a wide differential diagnosis. It can be mistaken for dementia, depression, psychosis, anxiety, somatoform disorders, and, particularly in children, behavioral disturbance (see Table 5–8). Accurate diagnosis requires close attention to symptom profile and temporal onset and is further supplemented by a variety of tests (e.g., cognitive, laboratory, EEG). Given that delirium can be the presenting feature of serious medical illness, any patient experiencing a sudden deterioration in cognitive function should be examined for possible delirium.

The most difficult differential diagnosis for delirium is dementia—the other cause of generalized cognitive impairment. Particularly challenging can be diagnosing dementia with Lewy bodies because it may mimic delirium with fluctuation of symptom severity, visual hallucinations, attentional impairment, alteration of consciousness, and delusions (Robinson 2002). Despite this substantial overlap, delirium and dementia can be reliably distinguished by a combination of careful history taking for symptom onset, examination of the patient, and selected clinical tests. Abrupt onset and fluctuating course are highly characteristic of delirium. In addition, level of consciousness and attention are markedly disturbed in delirium but remain relatively intact in uncomplicated dementia. Dementia patients often have nocturnal disturbances of sleep, whereas delirium is characterized by varying degrees of disruption of the sleep–wake circadian cycle, including fragmentation, napping, and sleeplessness. Overall, the presentation of delirium does not seem to be greatly altered by the presence of dementia, with delirium symptoms dominating

TABLE 5-8. Differential diagnosis of delirium

	Delirium	Dementia	Depression	Schizophrenia
Onset	Acute/subacute	Insidious ^a	Variable	Variable
Course	Fluctuating	Often progressive	Diurnal variation	Variable
Reversibility	High ^b	Low	Usually but can be recurrent	No, but has exacerbations
Identifiable medical etiology	Usually; often multifactorial	Neuropathological	Occasionally	Neuropathological
Level of consciousness	Impaired	Clear until late stages	Unimpaired	Unimpaired (perplexity in acute stage)
Attention/memory	Inattention, poor registration and immediate recall, impaired working memory and long-term retrieval	Poor short-term memory; intact attention until later stages (except Lewy body type); confabulation	Poor attention, forgetfulness, ("pseudodementia")	Poor attention; memory intact
Hallucinations	Visual most common; can be auditory, tactile, gustatory, olfactory	Can be visual or auditory	Auditory most common	Auditory most common
Delusions	Fleeting, fragmented, and usually persecutory	Paranoid, often fixed	Complex and mood congruent	Frequent, complex, systematized, and often paranoid
Sleep disturbances	Fragmentation of sleep-wake cycle	Nocturnal insomnia	Initial/middle insomnia, early-morning awakening, hypersomnia	No characteristic pattern
Language	Impaired semantic (fluent aphasia); dysnomia and dysfluencies	Depends on stage and frontal vs. posterior type	Unimpaired	Unimpaired except for neologisms
Thought process	Tangential, circumstantial, and loose associations	Impaired in later stages; distinguish from aphasia, agnosia, apraxia	Unimpaired	Loose associations

^aExcept for large strokes.^bCan be chronic (paraneoplastic syndrome, central nervous system adverse events of medications, severe brain damage).

the clinical picture when they co-occur (Cole et al. 2003a; Trzepacz et al. 1998; Voyer et al. 2006).

A range of tools can facilitate differentiation of delirium and dementia. The DRS (Trzepacz and Dew 1995), DRS-R-98, and CTD (Hart et al. 1996) have been shown to distinguish delirium from dementia during validation studies. Although abnormalities of the EEG are common to both delirium and dementia, diffuse slowing occurs more frequently in (81% vs. 33%)—and favors a diagnosis of—delirium. EEG slowing occurs later in the course of most degenerative dementias, although slowing occurs sooner with viral and prion dementias. Percentage theta activity on quantitative EEG may aid differentiation of delirium from dementia (Jacobson and Jerrier 2000). Visual attention and visual perception tasks may also distinguish delirium from dementia.

Several studies have addressed the issue of which symptoms may discriminate between patients with delirium and patients with dementia, or patients with both disorders, with varying results (Liptzin et al. 1993; O'Keeffe 1994; Trzepacz and Dew 1995; Trzepacz et al. 1998, 2002b). Overall, their results suggest that when delirium and dementia are comorbid, delirium phenomenology overshadows that of the dementia, but when the two are assessed as individual conditions, several discriminating symptoms are seen. Temporal onset, degree of inattention, and fluctuating course favor delirium. These research findings are consistent with the clinical rule of thumb that “it is delirium until proven otherwise.”

The early behavioral changes of delirium may be mistaken for adjustment reactions to adverse events, particularly in patients who have experienced major trauma or who have cancer. Hypoactive delirium is frequently mistaken for depression (Nicholas and Lindsey 1995; Spiller and Keen 2006). Some symptoms of major depression occur in delirium (e.g., psychomotor slowing, sleep disturbances, irritability). It has been estimated that 7% of patients with delirium attempt self-harm during an episode. However, in major depression, symptom onset tends to be less acute, and mood disturbances typically dominate the clinical picture, with any cognitive impairment more reflective of poor effort. Dehydration or malnutrition can precipitate delirium in severely depressed patients who are unable to maintain food or fluid intake. The distinction of delirium from depression is particularly important because, in addition to delayed treatment, some antidepressants have anticholinergic activity (paroxetine and TCAs) that can aggravate delirium. The overactive, disinhibited presentation of some patients with delirium can closely resemble agitated depression or mania, particularly delirious (Bell's) mania and agitated (“lethal”) catatonia, which typically include cognitive impairment.

Abnormalities of thought and perception can occur in both delirium and schizophrenia but are more fluctuant and fragmentary in delirium. Delusions in delirium are rarely as fixed or complex as in schizophrenia, and first-rank symptoms are uncommon (Cutting 1987). Unlike schizophrenia, hallucinations in delirium tend to be visual rather than auditory. Consciousness, attention, and memory are generally less impaired in schizophrenia, with the exception of the pseudodelirious picture that can occur as a result of marked perplexity in the acute stage of illness. Careful examination, coupled with EEG and/or an instrument such as the DRS-R-98, generally distinguishes delirium from these functional disorders.

Treatment

Delirium is an example par excellence of a disorder requiring a multifaceted biopsychosocial approach to assessment and treatment. After the diagnosis of delirium is made, the process of identifying and reversing suspected etiologies begins. Rapid treatment is important because of the high morbidity and mortality associated with delirium. Treatments include medication, environmental manipulation, and patient and family psychosocial support (American Psychiatric Association 1999). However, no drug has a U.S. Food and Drug Administration (FDA) indication for the treatment of delirium, and double-blind, placebo-controlled studies of efficacy and safety of drugs in treating delirium are very limited (American Psychiatric Association 1999).

Psychiatric consultation facilitates identification of predisposing and precipitating factors for delirium. Medication exposure, visual and hearing impairments, sleep deprivation, uncontrolled pain, dehydration, malnutrition, catheterization, and use of restraints are all factors that can be modified, but uncertainty remains as to the precise value of multicomponent interventions that attempt to reduce the incidence and severity of delirium through modification of recognized risk factors (Bogardus et al. 2003; Cole et al. 1998; Inouye et al. 1999) or systematic detection and multidisciplinary care of identified cases (Cole et al. 2002). The effect of such interventions depends on degree of implementation, with evidence that higher adherence leads to lower delirium rates (Inouye et al. 2003). A range of preoperative psychological interventions aimed at patient education and anxiety reduction may have preventive value, but these require more study before they warrant implementation into routine clinical practice.

The principles of management of delirium include ensuring the safety of the patient and his or her immediate surroundings (includes sitters), achieving optimal levels of environmental stimulation, and minimizing the effects of

any sensory impediments. The complications of delirium can be minimized by careful attention to the potential for falls and avoidance of prolonged hypostasis. Using orienting techniques (e.g., calendars, night-lights, reorientation by staff) and familiarizing the patient with the environment (e.g., with photographs of family members) are sometimes comforting, although it is important to remember that environmental manipulations alone do not reverse delirium (American Psychiatric Association 1999; Anderson 1995). It also has been suggested that diurnal cues from natural lighting reduce sensory deprivation and incidence of delirium (Wilson 1972), although sensory deprivation alone is insufficient to cause delirium (Francis 1993). Unfortunately, implementation of these environmental interventions occurs primarily in response to agitation rather than the core disturbances of delirium (Meagher et al. 1996).

Supportive interaction with relatives and caregivers is fundamental to good management of delirium. Relatives can play an integral role in efforts to support and reorient patients with delirium, but ill-informed, critical, or anxious caregivers can add to the burden of a delirious patient. A nontherapeutic triangle can emerge whereby health care providers respond to the distress of relatives by medicating patients, which complicates ongoing cognitive assessment. Clarification of the cause and meaning of symptoms combined with recognition of treatment goals can allow better management of what is a distressing experience for both patient and loved ones (Breitbart et al. 2002; Meagher 2001).

Prevention Strategies

Nonpharmacological and pharmacological interventions are available to prevent delirium. Preoperative patient education or preparation was helpful in reducing delirium symptom rates in early studies (Chatham 1978; Owens and Hutelmyer 1982; M.A. Williams et al. 1985), although caregiver education and environmental or risk factor interventions have had mixed results, with two not finding any significant effect on delirium rate (Nagley 1986; Wanich et al. 1992). In contrast, Inouye et al. (1999) studied the effect on delirium of preventive measures that minimized six of the risk factors identified in their previous work with hospitalized elderly patients. They used standardized protocols in a prospective study of 852 elderly inpatients to address cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration, which resulted in significant reductions in the number (62 vs. 90) and duration (105 vs. 161 days) of delirium episodes relative to control subjects. Effects of adherence on delirium risk were subsequently reported for 422 elderly patients during implementation of this standardized proto-

col (Inouye et al. 2003). Adherence ranged from 10% for the sleep protocol to 86% for orientation. Higher levels of adherence by staff resulted in lower delirium rates, up to a maximum of an 89% reduction, even after controlling for confounding variables. At 6-month follow-up of 705 survivors from this intervention study of six risk factors, no differences were found between groups for any of the 10 outcome measures, except for less frequent incontinence in the intervention group (Bogardus et al. 2003), suggesting that the intervention's effect was essentially during the index hospitalization without any longer-lasting benefits. However, in a subset of high-risk patients at baseline, the intervention group had significantly better self-rated health and functional status at follow-up. A recent pediatric surgery report found reduced delirium in a randomized controlled trial of family-centered preparation for surgery (Kain et al. 2007).

Milisen et al. (2001) compared delirium rates in two cohorts of elderly hip surgery patients ($N=60$ in each)—before and after implementing an intervention consisting of nurse education, cognitive screening, consultation by a nurse or physician geriatric/delirium specialist, and a scheduled pain protocol. They found no effect on delirium incidence but a shorter duration of delirium (median 1 vs. 4 days) and lower delirium severity in the intervention group. Marcantonio et al. (2001) used a different study design and randomly assigned 62 elderly hip fracture patients to either a perioperative geriatric consultation or usual care. On the basis of daily ratings, they found a lower delirium rate (32% vs. 50%) and fewer cases of severe delirium (12% vs. 29%) in the consultation group. Length of stay was not affected, and the effect of consultation was greatest in those patients without preexisting dementia or poor ADL performance.

The cholinergic deficiency hypothesis of delirium suggests that enhancing acetylcholine should reduce delirium incidence or severity. Perioperative piracetam use during anesthesia was reviewed across eight studies, mostly from the 1970s, and was believed to have a positive effect on reducing postoperative delirium symptoms (Gallinat et al. 1999). Citicholine 1.2 mg/day was assessed for delirium prevention in a randomized, placebo-controlled trial of 81 dementia-free hip surgery patients, given 1 day before and each of the 4 days after surgery, but there was no significant difference in delirium incidence between groups (Diaz et al. 2001). More recently, there have been randomized prophylaxis trials using cholinesterase inhibitors. A lack of significant effect on delirium incidence was reported in studies using donepezil (Liptzin et al. 2005; Sampson et al. 2006) and rivastigmine (Gamberini et al. 2009) for acute prophylaxis. In contrast, chronic prophylaxis with rivastigmine in older stroke patients significantly reduced the number of

delirium episodes over a 2-year follow-up period when compared with cardioaspirin (Moretti et al. 2004).

Kalisvaart et al. (2005) studied 408 elderly hip surgery patients in a double-blind, randomized comparison of one to two doses of 0.5-mg dose haloperidol or placebo given up to 3 days before and/or 3 days after hip surgery. They found significant differences for shorter delirium duration, lower DRS-R-98 scores, and shorter lengths of stay in the active treatment group, although the study was underpowered to detect an incidence difference. Delirium incidence was significantly reduced in a randomized, double-blind, placebo-controlled prophylaxis trial in elderly joint replacement surgery patients treated perioperatively with low-dose rapidly dissolving olanzapine 5 mg (14.3% vs. 40.2%) (Larsen et al. 2007). Similarly, risperidone 1 mg immediately after surgery significantly reduced delirium incidence in elective cardiac surgery patients as compared with placebo (11.1% vs. 31.7%) (Prakanrattana and Prapaitrakool 2007).

Maldonado et al. (2009) reported significantly reduced delirium incidence (3%) as measured by the DRS when a novel α_2 -adrenergic receptor agonist, dexmedetomidine, was used for postoperative sedation, as compared with propofol (50%) or fentanyl/midazolam (50%), in cardiac valve surgery patients in a randomized open-label trial. In contrast, Pandharipande et al. (2007) did not find a difference in delirium incidence as measured by the CAM-ICU in dexmedetomidine (79%) as compared with lorazepam (82%) in ventilated ICU patients in a randomized multisite trial, although there was a trend toward more delirium-free days. Improved pain control after hepatectomy surgery in elderly patients who used patient-controlled epidural anesthesia with bupivacaine and fentanyl ($n = 14$), compared with continuous epidural mepivacaine ($n = 16$), was associated with lower incidences of moderate and severe delirium (36% vs. 75% and 14% vs. 50%, respectively), and antipsychotic drug use also was lower in the former group (Tokita et al. 2001).

Pharmacological Treatment

Current delirium pharmacotherapies have evolved from their use in the treatment of mainstream psychiatric disorders; hence, psychiatrists are well acquainted with the practicalities of their use. Pharmacological treatment with a neuroleptic agent (D_2 antagonist) is the clinical standard for delirium treatment, usually either haloperidol or an atypical antipsychotic. Itil and Fink (1966) found that chlorpromazine reversed experimentally induced anticholinergic delirium and reversed EEG abnormalities. There are over 33 prospective trials studying more than 3,300 patients in neuroleptic treatment of delirium (Bourne et al. 2008), and although only a minority are blinded, random-

ized, and controlled, the evidence base finds neuroleptic agents to be useful and well tolerated. Nonetheless, there is a need for large randomized multisite trials (Seitz et al. 2007; Trzepacz et al. 2008).

Haloperidol is the conventional neuroleptic most often chosen for the treatment of delirium. It can be administered orally, intramuscularly, or intravenously (American Psychiatric Association 1999; Sanders and Stern 1993; Tessler et al. 1985), although the intravenous route has not been approved by the FDA. Intravenously administered haloperidol is twice as potent as that taken orally (Gelfand et al. 1992). Bolus intravenous doses usually range from 0.5 to 20 mg, although larger doses are sometimes given. In severe, refractory cases, continuous intravenous infusions of 15–25 mg/hour (up to 1,000 mg/day) can be given. Platt et al. (1994) reported that both hypoactive and hyperactive subtypes responded to treatment with haloperidol or chlorpromazine, and they noted improvement within hours of treatment, even before the underlying medical causes were addressed. In delirious patients receiving palliative care, haloperidol can be given subcutaneously (Fonzo-Christe et al. 2005).

Cases of prolonged QTc interval and torsade de pointes (multifocal ventricular tachycardia) have been increasingly recognized and attributed to intravenously administered haloperidol, even in young patients, and therefore patients need to be monitored (Hatta et al. 2001; Kriwisky et al. 1990; Metzger and Friedman 1993; O'Brien et al. 1999; Perrault et al. 2000; Wilt et al. 1993). Risk factors include female sex, heart disease, hypokalemia, higher doses of the offending agent, concomitant use of a QT-prolonging drug, and a history of long QT syndrome (Justo et al. 2005). The American Psychiatric Association (1999) "Practice Guideline for the Treatment of Patients With Delirium" advised that QTc prolongation greater than 450 msec or to greater than 25% over a previous electrocardiogram may warrant telemetry, cardiac consultation, dose reduction, or discontinuation. They also recommend monitoring use of other drugs that can prolong the QTc interval, as well as serum magnesium and potassium, in critically ill patients with delirium whose QTc is 450 msec or greater.

There have been five randomized controlled comparator efficacy trials, all of which found improvement for active agents and, when studied, superiority to placebo or lorazepam (Breitbart et al. 1996; Han et al. 2004; Hua et al. 2006; Kim et al. 2005; Lee et al. 2005). More than two-thirds of delirious patients in these studies experienced rapid clinical improvement, typically after 2–6 days of treatment (Bourne et al. 2008). One of the placebo-controlled studies, a randomized three-arm trial in elderly delirious patients assessed longitudinally with the DRS,

reported comparable response rates in the haloperidol (87.5%) and olanzapine (82%) groups that were significantly greater than those in the placebo group (31%) (Hua et al. 2006). In contrast, a three-arm double-blind, randomized, controlled multisite trial of ziprasidone versus haloperidol versus placebo in mechanically ventilated ICU patients found no difference between groups for delirium-free days or mortality, but unfortunately delirium severity was not measured. There may have been confounding, as all three groups also received concomitant open-label haloperidol as needed (Girard et al. 2010). In a double-blind randomized trial in delirious ICU patients, patients treated with quetiapine required less as-needed haloperidol to control agitation, had a shorter duration and faster resolution of delirium, and were discharged to home or rehabilitation at a higher rate compared with those receiving placebo (Devlin et al. 2010).

The atypical antipsychotics olanzapine (5–20 mg), risperidone (1.5–4 mg), and quetiapine (25–750 mg) have been studied in case series, open-label case-control convenience samples, open-label prospective trials using standardized measures, and blinded trials (Bourne et al. 2008; Meagher and Leonard 2008). An open-label trial of the atypical agent perospirone suggested its efficacy (Takeuchi et al. 2007).

Clinical experience with neuroleptics in pediatric delirium supports their beneficial effects, but no controlled studies have been done. A retrospective report of 30 children (ages 8 months–18 years; mean age = 7 years) with burn injuries supported the use of haloperidol for agitation, disorientation, hallucinations, delusions, and insomnia (R.L. Brown et al. 1996). The mean haloperidol dose was 0.47 mg/kg, administered intravenously, orally, and intramuscularly. Haloperidol was not efficacious in 17% of the patients (4 of 5 of these failures were via the oral route). Extrapyramidal symptoms (EPS) were not observed, and one episode of hypotension occurred with the intravenous route. In ICU pediatric delirium, 37 were treated with either haloperidol or risperidone (Schieveld et al. 2007) and two of the haloperidol children had acute torticollis as an EPS adverse event. Intravenous haloperidol single doses of 0.15–0.25 mg resulted in prompt resolution of delirium in two young children (28 and 42 months old) (Schieveld and Leentjens 2005).

Antipsychotic agents carry black-box FDA warnings for increased mortality when used in agitated elderly patients with dementia. Whether the risks are applicable to short-term use in delirium is not known. However, a retrospective analysis of haloperidol and risperidone use in 111 of 326 delirium cases found no statistical increased risk of mortality between the exposed (20.7%) and unexposed (17.2%) groups; instead, increased mortality was asso-

ciated with medical comorbidity and acute physiology scores (Elie et al. 2009).

Other classes of drugs are indicated in particular situations. Benzodiazepines are generally reserved for delirium due to ethanol or sedative-hypnotic withdrawal; lorazepam or clonazepam (the latter for alprazolam withdrawal) is often used. Intravenous lorazepam is sometimes combined with intravenous haloperidol in critically ill patients to lessen EPS and increase sedation. However, benzodiazepine use should be limited because they can be deliriogenic. With the use of standardized assessment methods and a double-blind, randomized, controlled design, Breitbart et al. (1996) found that delirium in patients with AIDS significantly improved with haloperidol or chlorpromazine but worsened with lorazepam. Even at low doses, lorazepam has been reported to be an independent risk factor for causing delirium in ICU patients (Pandharipande et al. 2006). Anticholinergic poisoning-induced delirium and/or agitation was controlled and reversed with physostigmine (87% and 96%, respectively), whereas benzodiazepines controlled agitation in only 24% and were ineffective in treating delirium (Burns et al. 2000). Patients who received physostigmine had a lower incidence of complications (7% vs. 46%) and a shorter time to recovery (median = 12 vs. 24 hours). Lorazepam has a significant aggravating effect on delirium in medical ICU patients, but this effect was not found for propofol, morphine, and fentanyl (Ely et al. 2004a; Pandharipande et al. 2006) (see Figure 5–6).

The cholinergic deficiency hypothesis of delirium suggests that treatment with a cholinergic enhancer drug could be therapeutic. Physostigmine reverses anticholinergic delirium (Stern 1983), but its side effects (seizures) and short half-life make it unsuitable for routine clinical treatment of delirium. Three case reports found that donepezil improved delirium postoperatively, in dementia with Lewy bodies, and in alcohol dementia (Burke et al. 1999; Kaufer et al. 1998; Wengel et al. 1998, 1999). Physostigmine administered in the emergency department to patients suspected of having muscarinic toxicity resulted in reversal of delirium in 22 of 39, including several patients in whom the cause could not be determined (Schneir et al. 2003); only 1 patient in 39 had an adverse event (brief seizure). Rivastigmine added to antipsychotics in delirium nonresponders resulted in recovery in 71%, suggesting that a combination of acetylcholine enhancement and D₂ receptor blockade may be beneficial (Dautzenberg et al. 2004).

A single 8-mg intravenous dose of ondansetron, a serotonin₃ receptor antagonist, was reported to reduce agitation in 35 postcardiotomy delirium patients (Bayindir et al. 2000). Supplementary oxygen reduced delirium in a

FIGURE 5–6. Probability of transitioning to delirium as a function of sedative lorazepam dosage, patient age, and severity of illness (left).

(A) *Lorazepam dosage*—The probability of transitioning to delirium increased with increases in lorazepam dosage administered within the previous 24 hours. This incremental risk was large at low doses and plateaued at around 20 mg/day. (B) *Age (years)*—The probability of transitioning to delirium increased dramatically for each year of life after age 65 years. (C) *Severity of illness*—The probability of transitioning to delirium increased dramatically for each additional point in the Acute Physiology and Chronic Health Evaluation II (APACHE II) severity-of-illness score until reaching a plateau at an APACHE II score of 18.

suppository. Several open-label studies found reductions in the DRS scores similar to those seen with haloperidol (Nakamura et al. 1995, 1997a, 1997b; Uchiyama et al. 1996), attributed to enabling improved sleep–wake cycle.

Conclusion

Clearly, further delirium treatment research is needed—especially randomized, placebo-controlled, adequately powered clinical trials addressing both efficacy and safety. However, mounting evidence from prospective trials is supportive of current clinical practice and in a consistent fashion with neurotransmitter hypotheses for delirium.

Dementia

Antonio Lobo, M.D., Ph.D.

Pedro Saz, M.D., Ph.D.

Miguel Ángel Quintanilla, M.D., Ph.D.

CONCERN IS INCREASING about the worldwide epidemic (Ferri et al. 2005) and consequences of dementia. The high prevalence of dementing conditions in medical settings, often undiagnosed, and the association of dementia with longer hospital stays and greater use of health resources have direct implications for psychosomatic medicine and consultation-liaison psychiatry (Table 6-1). The psychiatric consultant is an invaluable collaborator with other health care professionals in the identification, evaluation, treatment, management, discharge planning, placement, and rehabilitation of the patient with dementia. In this chapter, we focus on the general clinical approach to dementia and its common causes. Some of these and other causes of dementia are also discussed elsewhere in this book: those disorders that are particularly likely to present with other neurological symptoms in Chapter 32, "Neurology and Neurosurgery"; HIV infection in Chapter 28, "HIV/AIDS"; other infections in Chapter 27, "Infectious Diseases"; alcohol and other substance use in Chapter 17, "Substance-Related Disorders"; toxic/metabolic conditions in Chapter 22, "Endocrine and Metabolic Disorders," and Chapter 37, "Medical Toxicology"; rheumatological/inflammatory conditions in Chapter 25, "Rheumatology"; traumatic brain injury in Chapter 35, "Physical Medicine and Rehabilitation"; and paraneoplastic syndromes in Chapter 23, "Oncology."

Concept of Dementia and Clinical Approach

Dementia is defined as a syndrome of global deterioration of intellectual function occurring in clear consciousness and caused by brain disease. It is a paradigm of the disease model in psychiatry (McHugh and Slavney 1998). The notion of deterioration emphasizes the acquired nature of the impairment in dementia, to distinguish it from mental retardation, and the requirement of clear consciousness underlines the difference from delirium, if dementia is the only diagnosis. The impairment of memory is the most frequent and important sign or symptom, but deterioration in at least two other cognitive domains is required in our operational definition (Table 6-2). Also, the deterioration must be severe enough to adversely affect activities of daily living (ADLs). Social or occupational activities are also impaired.

Deterioration in personality and noncognitive psychopathological symptoms are almost universal in dementia (Lyketsos et al. 2002; Steinberg et al. 2008) and are most important for psychiatrists. Although there is general agreement that only the cognitive psychopathology should be included in the diagnostic criteria, we have argued for the inclusion of noncognitive, psychopathological symptoms, particularly negative symptoms in view of their frequency

We gratefully acknowledge research grants from the Fondo de Investigación Sanitaria, Ministry of Health, Spain (PI 042722); Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Ministry of Science and Innovation, Spain. We also wish to thank Olga Ibáñez for her administrative help.

TABLE 6-1. Relevance of dementia in psychosomatic medicine and consultation-liaison psychiatry**General relevance**

- ◆ Worldwide epidemic (Ferri et al. 2005)
- ◆ High prevalence: 9.6% in the U.S. elderly community (Breitner et al. 1999); 74% in nursing homes (Macdonald et al. 2002)
- ◆ High incidence: 2.8 per 1,000 person-years in 65- to 69- year age group; increases to 56.1 per 1,000 person-years in the older-than-90- year age group (Kukull et al. 2002)
- ◆ Dramatic increase in the projected dementia rates is expected in the next decades (Organization for Economic Cooperation and Development 2002)
- ◆ Burden of the disease:
 - Patient-related
 - Caregiver-related (Colvez et al. 2002)
 - DAT leads to earlier institutionalization (Patterson et al. 1999)
 - DAT patients occupy two-thirds of nursing home beds (Macdonald et al. 2002)
 - Gross annual cost of caring for people with dementia living in the United States (National Institute on Aging 2003): \$100 billion
- ◆ Mortality rate at least twice that of individuals without dementia (Dewey and Saz 2001)

Specific relevance to psychosomatic medicine and consultation-liaison psychiatry

- ◆ High prevalence in general hospital patients (Erkinjuntti et al. 1986)
- ◆ High prevalence in specific medical conditions
- ◆ One-third of elderly referrals to consultation-liaison psychiatrists go undiagnosed (Huyse et al. 1996)
- ◆ Almost all patients have noncognitive neuropsychiatric symptoms (Lyketsos et al. 2002; Saz et al. 2009)
- ◆ Most patients with early dementia go undiagnosed, both in the general population (Lobo et al. 1997) and in primary care (Boise et al. 2004)
- ◆ Patients with dementia have longer hospital stays, which are associated with higher costs and greater use of health resources after discharge (Lyketsos et al. 2000)

Note. DAT = dementia of the Alzheimer's type.

and relative specificity (Saz et al. 2009). Persistence of the syndrome is important for the diagnosis, and some international committees require that symptoms be present for at least 6 months (World Health Organization 1992). However, exceptions to this norm occur and are important in settings such as the general hospital. Progression of the syndrome is the norm in most cases of dementia but is not included in the concept because some cases of dementia are stable and potentially reversible.

Recent research has identified a construct known as *mild cognitive impairment*, a possible transitional state between the cognitive changes of normal aging and dementia (Petersen 2004). Mild cognitive impairment is defined as an entity of subjective memory difficulties, accompanied by cognitive difficulties documented by neuropsychological tests in individuals who are otherwise functioning well and do not meet the clinical criteria for dementia. Several studies have shown that persons without dementia who have cognitive impairment have a higher chance of progressing to dementia, the annual conversion rate being

10%–15%. However, mild cognitive impairment is a heterogeneous concept (Wahlund et al. 2003), and most cases do not progress to dementia, even after a follow-up period of 10 years (Mitchell 2009).

TABLE 6-2. The dementia syndrome

- A. Global deterioration of intellectual function
 - Memory
 - At least two other cognitive functions
- B. Clear consciousness
- C. Impairment of personal activities of daily living and social or occupational activities due to the decline in intellectual function
- D. Deterioration in emotional control, motivation, or personality frequent but not necessary for diagnosis
- E. Duration of at least 6 months (important exceptions, such as in the general hospital)

Epidemiology, Etiology, and Risk Factors

Dementia has been etiologically associated with numerous heterogeneous conditions, as listed in Table 6-3. The adjusted prevalence estimate was 9.6% for all dementias in the U.S. population after age 65 and 6.5% for dementia of the Alzheimer's type (DAT) (Breitner et al. 1999). Similar rates have been reported in Europe (A. Lobo et al. 2000). It has been estimated that the number of patients with DAT will continue to increase in the United States (L.E. Hebert et al. 2001), but most of the dementia epidemic will occur in the developing world (Ferri et al. 2005).

Incidence estimates of dementia show that DAT rates rise from 2.8 per 1,000 person-years (age group: 65-69 years) to 56.1 per 1,000 person-years (age group: older than 90 years) (Kukull et al. 2002). These data are consistent with those in comparable studies in countries outside the United States (Fratiglioni et al. 2000). In all these population studies, both the prevalence and the incidence rates of elderly patients with dementia, and DAT in particular, increase dramatically with age, approximately doubling every 5 years.

DAT and vascular dementia have been reported to be the most frequent types of dementia in population studies (Fratiglioni et al. 2000; Van der Flier and Scheltens 2005). However, research suggests that a clinical diagnosis of dementia made during life may fail to reflect the pathogenic complexity of this condition in very elderly persons because most cases at autopsy have significant mixtures of dementia-related lesions, including DAT and vascular-type lesions (Neuropathology Group, Medical Research Council Cognitive Function and Aging Study 2001; White et al. 2005). Both dementia with Lewy bodies (DLB) and frontotemporal dementia (FTD) in cases of earlier onset may prove to be considerably more common than previously recognized (Campbell et al. 2001).

Dementia is also commonly found in general hospitals. A large-scale study documented that 9.1% of the patients age 55 years and older admitted to a teaching hospital medical service had dementia, but the prevalence was 31.2% in patients age 85 years and older (Erkinjuntti et al. 1986). Dementia is also common in elderly patients with alcoholism (60%-70%) (Kasahara et al. 1996), Parkinson's disease (Aarsland et al. 2001), HIV disease (American Academy of Neurology AIDS Task Force 1991), and traumatic brain injury (TBI; Kraus and Sorenson 1994).

The prevalence of mild cognitive impairment ranges between 3% and 19% in population studies in individuals age 65 years or older (Gauthier et al. 2006). It may account for more than one-third of the patients referred to memory clinics (Wahlund et al. 2003).

Epidemiological studies also have suggested that non-cognitive, psychopathological symptoms, sometimes called behavioral and psychological symptoms of dementia, predict a poorer outcome (Shin et al. 2005). They also may be early markers of the disease (E. Teng et al. 2007). Lyketsos et al. (2002) found in their population-based study that the most frequent disturbances among individuals with dementia were apathy (36%), depression (32%), and agitation or aggression (30%). The reported prevalence of depressive syndromes in dementia has ranged widely, from 10% to 54%, across recruitment sites (A. Lobo et al. 1995; Zubenko et al. 2003). The prevalence of depression varies according to diagnostic criteria used and was 44% when National Institute of Mental Health criteria were used (R. Teng et al. 2008). Depression in elderly patients with dementia may have different symptoms from depression in elderly patients without dementia and frequently has negative consequences for both patients and caregivers (Lyketsos and Lee 2004). Psychotic symptoms are also frequent in DAT and are associated with rapid cognitive deterioration (Ropacki and Jeste 2005).

In the first population-based estimate among those with mild cognitive impairment, 29% of the individuals were considered to have clinically significant neuropsychiatric symptoms during the previous month (Lyketsos et al. 2002). The behavior changes observed in mild cognitive impairment are similar to those of DAT and may help identify the subgroup of mild cognitive impairment patients with prodromal dementia (Apostolova and Cummings 2008).

Table 6-4 summarizes the results of recent, sophisticated analytic epidemiological research, including case-control studies in incident cases. Confirmed risk factors for DAT are scarce and limited to age, unalterable genetic factors (the apolipoprotein E epsilon4 [*APOE* ϵ 4] genotype), and mild cognitive impairment. Mild cognitive impairment may have important clinical but also preventive implications (Modrego et al. 2005).

Other probable risk factors and protective factors in DAT are also listed in Table 6-4 (Ravaglia et al. 2005; Van der Flier and Scheltens 2005; Verghese et al. 2003). Recent meta-analytic studies have found evidence to support an association between depression and dementia from both case-control studies and prospective studies (Jorm 2001). Depression has to be seriously considered as a probable risk factor for dementia. The attributable risk of DAT related to cardiovascular risk factors is still debated (Posner et al. 2002), but research has suggested that cerebrovascular disease plays an important role in determining the presence of dementia and specifically DAT (Ivan et al. 2004; Launer 2002). Hypertension may be particularly relevant in this respect because it is very common in the commu-

nity and may be preventable. However, hypotension also has been suggested as a risk factor (Qui et al. 2003). Until now, insufficient evidence has been found to support some factors hypothesized as increasing the risk for DAT, such as high aluminum levels and hyperhomocysteinemia,

or others thought to be protective, such as low cholesterol levels, estrogen therapy, or antioxidants in the diet (Larrieu et al. 2004; Podewils et al. 2005). However, recent studies have suggested social isolation and loneliness as risk factors for DAT (R.S. Wilson et al. 2007) and the potential

protective effects of physical activity (Buchman et al. 2008; Taaffe et al. 2008) or the Mediterranean diet (Scarmeas et al. 2009). Although the preventive potential of moderate alcohol consumption has stirred considerable interest (Peters et al. 2008), it remains a controversial issue (E. Lobo, C. Dufouil, G. Marcos, B. Quetglas, P. Saz, E. Guallar, and A. Lobo, "Evidence Against and Association Between Alcohol Intake and Cognition in the Elderly: The ZARADEMP Project" [manuscript in review], May 2010).

Risk and protective factors for vascular dementia are also listed in Table 6–4. The risk factors include hyperhomocysteinemia and low serum folate levels, which are potentially reversible and can be identified early.

Genetics

Genetic knowledge about dementing conditions, most relevant if related to pathophysiology, may be summarized as follows. Huntington's disease is inherited as an autosomal dominant trait with complete penetrance, the mutation responsible being in an elongated and unstable trinucleotide (CAG) repeat on the short arm of chromosome 4 (Haskins and Harrison 2000). In DAT, particularly with early onset, several well-documented cases suggest that the disorder is transmitted in families through an autosomal dominant gene, although such transmission is rare. Possible genetic loci for familial DAT have been documented in chromosomes 21 (the amyloid precursor protein [APP] gene), 14 (the presenilin-1 gene), and 1 (the presenilin-2 gene). Furthermore, the APOE ε4 gene coded in chromosome 19 has been associated with an increased risk of developing DAT and might advance its age at onset by several years. A gene carried on chromosome 17 is thought to be related to familial multiple system tauopathy, an early-onset dementia similar to DAT.

Wilson's disease is an autosomal recessively inherited defect in the copper-carrying serum protein ceruloplasmin, resulting in the destructive deposition of copper in the basal nuclei, the defective gene being localized on chromosome 13 (Loudianos and Gitlin 2000). Recent advances in the genetics of other dementias include the identification of *tau* gene mutations on chromosome 17 in some familial cases of FTD (H.J. Rosen et al. 2000) and the identification of genetic loci in other disorders that produce dementia, such as Pick's disease; Gerstmann-Straussler-Scheinker syndrome, an autosomal dominant, familial type of prion dementia; cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; some forms of cerebral amyloid angiopathy; alcoholism; major depression; and some forms of Parkinson's disease (Lev and Melamed 2001).

Important changes in the classification of dementia might soon occur following dramatic advances in the genetics of dementia. Tau aggregates and alpha-synucleinopathy aggregates observed in neurodegenerative disorders have generated the concepts of tauopathies and alpha-synucleinopathies, respectively, to differentiate them from the amyloidopathies such as DAT. Most cases of FTD now tend to be classified as tauopathies, related to mutations in the *tau* gene (Buee et al. 2000), with a large clinical spectrum including Pick's disease, progressive supranuclear palsy (PSP), corticobasal degeneration, and multisystem atrophy (Lebert et al. 2002). Alpha-synucleinopathies include DLB and Parkinson's disease (Ferrer et al. 2002; Litvan 1999), but the findings of both types of pathological aggregates in several diseases have led to some disagreement in classifications (Iseki et al. 2003; Litvan 1999).

General Clinical Features

The Dementia Syndrome

The clinical picture may differ widely according to the type and severity of dementia, and the characteristics are important in the differential diagnosis. In most cases of degenerative processes—in particular, DAT, some types of vascular dementia, and dementias due to endocrinopathies, brain tumors, metabolic disorders, and abuse of medications—the onset of symptoms is gradual, and the signs of the dementia syndrome are subtle and may at first be ignored by both the patient and his or her relatives. In contrast, the onset may be abrupt after severe cerebral infarcts, head trauma, cardiac arrest with cerebral hypoxia, and encephalitis.

The full dementia syndrome progresses through severity levels in degenerative processes and is very characteristic in DAT (Table 6–5). The earliest manifestations, such as impairment of memory, may be very subtle. Individuals with dementia also show impairment in thinking and their capacity for reasoning, but the earliest difficulties can be mistakenly disregarded or explained away as the expression of fatigue, distraction, or discouragement. The deficits may become apparent in the face of more complex problems or when specifically tested, but patients often attempt to compensate for defects by using strategies to avoid showing failures in intellectual performance. Similarly, language is impoverished if carefully observed, and praxic difficulties for complex tasks may be documented, but special examinations may be necessary. A general loss of efficiency in all aspects of thinking as well as disturbances in the executive functions necessary to maintain goal-directed behavior, including planning, organizing, and sequencing, may be apparent, and the patient has dif-

ficulties in his or her usual occupation and with ADLs, such as using the telephone, managing small amounts of money, cooking, or taking responsibility for medications.

The dementia syndrome in degenerative disorders such as DAT relentlessly progresses to severe deterioration (see Table 6–5). Eventually, the patient may retain only the earliest learned information; he or she is totally disoriented, with extreme impoverishment of thought, and communication with the patient is impossible. Apraxia and agnosia are severe. The patient is incontinent of urine and feces and is entirely dependent on caregivers. He or she may be totally disconnected from his or her environment, with respect to both input and output. The most severe neurological signs, including primitive reflexes, motor system rigidity, and flexion contractures, are then present, and the patient is confined to bed. The patient may experience a final stage of decortication, but death, from pneumonia or some other infection, commonly occurs before this stage.

Changes in personality and behavior are frequent, and the patient may seem to be less concerned than he or she had been about issues of daily life or about the effects of his or her behavior on others. Catastrophic reactions, with agitation or extreme emotion, also may be observed as a reaction to the subjective awareness of the patient's inability to cope with a problem.

Noncognitive, psychopathological symptoms are often quite disturbing for patients and caregivers (Shin et al. 2005) and may be quite persistent unless treated. The modern classification of these symptoms distinguishes delirium, affective syndrome, psychotic syndrome, drive disturbances (sleep and eating), and specific problem behaviors (usually in late stages). Major depressive episodes are frequent in DAT and other types of dementia (Zubenko et al. 2003) and often have serious adverse consequences for patients and their caregivers. Paranoid ideas are frequent, often representing "logical" conclusions based on misinterpretations, misperceptions, or memory deficits. They may not be persistent, but complex and well-systematized delusions, as well as hallucinations, are also reported (for all modalities). Late-evening agitation (the sundowning phenomenon) may be quite disturbing and has been associated with circadian rhythms in DAT (Volicer et al. 2001).

The course of the syndrome is also variable according to type of dementia and has implications for the differential diagnosis. An incrementally worsening or stepwise course is common in vascular dementia, whereas the deficits may be stable in some types of dementia, such as in dementia related to head trauma. Furthermore, the regression of symptoms is a possibility, once treatment is initiated, in dementias caused by potentially reversible disorders, such as normal-pressure hydrocephalus (NPH); metabolic and toxic conditions; or dementias related to

TABLE 6–5. Clinical findings in patients with dementia of the Alzheimer's type, by severity level**Mild (MMSE score = 18–23; duration of disease = 1–3 years)**

Impaired registration and recent memory (early sign); remote recall mildly impaired
 Defective temporal orientation
 Mild impairment of thinking; bewilderment in the face of complexity
 Impoverishment of language; naming problems
 Mild apraxia for complex tasks
 Agnosia not evident unless tested
 Difficulties in planning, sequencing, and executing instrumental activities of daily living
 Frequent personality changes: irritability, less apparent concern about issues of daily life and effects of their behavior on others
 Depression in approximately 20% of patients; mild apathy; loss of initiative; lack of energy
 Frequent misinterpretations; psychotic phenomena rare
 Urinary incontinence in fewer than 10%
 Other neurological signs and primitive reflexes rare

Moderate (MMSE score = 12–17; duration of disease = 2–8 years)

Recent memory and remote recall more severely impaired
 Severe temporal disorientation, moderate spatial disorientation
 Obvious impairment of thinking; catastrophic reactions if pressured
 Fluent aphasia, anomia, paraphasic errors, empty quality of language, perseveration
 Praxic difficulties to manage dressing, feeding, manipulations
 Agnosia evident: failure to identify objects, including familiar faces
 Difficulties in planning, sequencing, and executing extend to basic activities of daily living
 Evident personality changes: marked irritability; marked lack of concern about issues of daily life and effects of their behavior on others
 Dysphoric mood, depression less frequent; apathy; loss of initiative
 Frequent psychotic phenomena (delusions, illusions, hallucinations)
 Restlessness, pacing, wandering occasionally, agitation, sporadic aggressiveness
 Urinary incontinence frequent; fecal incontinence rare
 Gait disorder and frequent primitive reflexes

Severe (MMSE score <12; duration of disease = 7–12 years)

Memory: only earliest learned information retained
 Total disorientation
 Severe impairment of thinking; indifference in the face of failures
 Extreme impoverishment of language; communication impossible
 Complete incapacity to manage dressing, feeding, simple manipulations
 Severe agnosia: does not identify close relatives
 Total dependence for even basic activities of daily living
 Total disconnection from environment
 Affective indifference; severe apathy; loss of initiative
 Double incontinence (urinary and fecal)
 Motor system rigidity and flexion contractures of all limbs; final stage of decortication

Note. MMSE = Mini-Mental State Examination.

the use of medications, to subdural hematoma, or to brain tumors. In fact, studies have found that only 4%–23% of the patients referred to memory clinics had potentially reversible conditions (Hejl et al. 2002), and actual reversal of dementia through treatment is rare (Ovsiew 2003).

Clinicopathological Correlations

Some clinical characteristics suggest the involvement of specific brain areas and should help in clinical recognition of entities with different implications, as well as in understanding the underlying pathology of cognitive and non-cognitive phenomena (McHugh and Folstein 1979). *Cortical dementia* is the conceptual term for those dementias in which the predominance of dysfunction is in the cortex, even if coexisting pathology exists in subcortical regions (Cummings and Benson 1984). Together with amnesia, not helped by cues to remember, the most characteristic signs are aphasia, apraxia, and agnosia, which are often designated the four A's (Table 6–6).

Subcortical dementia describes the predominant involvement of the white and deep gray matter structures, such as basal ganglia, thalamus, and their frontal lobe projections. McHugh and Folstein (1975) were among the first to emphasize that parts of the brain other than the cortex have a role in cognitive activity and described the distinctive combination of three features in what they called the “subcortical dementia syndrome”: a slowly progressive dilapidation of all cognitive powers; prominent psychic apathy and inertia that may worsen to akinetic mutism; and the absence of aphasia, alexia, or agnosia (see Table 6–6). The

same authors also emphasized the early appearance in subcortical dementia of prominent noncognitive symptoms, particularly depression and other affective disturbances considered to be a direct consequence of the cerebral pathology. Rabins et al. (1999) have designated some specific features of subcortical dementia as the four D's:

- ♦ **Dysmnnesia**—memory impairment; patients may benefit from cues to remember
- ♦ **Dysexecutive**—related to troubles with decision making
- ♦ **Delay**—related to slowed thinking and moving
- ♦ **Depletion**—reduced complexity of thought

When both cortical and subcortical regions are involved, the clinical characteristics include aspects of cortical dementia, such as aphasia and apraxia, and the apathetic state characteristic of lesions in the subcortical areas.

Clinical Types and Pathophysiology of Dementia

Cortical Dementias

Alzheimer's Disease

Most cases of Alzheimer's disease start after age 65, but an earlier onset is not infrequent. The characteristic general dementia syndrome has been described and includes the cortical signs (see Tables 6–5 and 6–6). The insidious onset and slowly worsening, relentless course are most characteristic and crucial in the diagnostic process. Other char-

TABLE 6–6. Clinical characteristics of cortical and subcortical dementia syndromes

	Cortical	Subcortical
Aphasia	Early	No
Agnosia	Late	No
Apraxia	Rather early	Rare
Alexia	Rather late	No
Apathy, inertia	Rare or late	Very marked, early
Loss of initiative	Frequent, late	Marked
Psychomotor retardation	Rare or late	Very marked, early
Amnesia	Recall and recognition not aided by cues to remember	Recognition better preserved, may be aided by cues to remember
Gait	Normal until late	Abnormal, early
Extrapyramidal signs	Rare or late	Very marked, early
Pathological reflexes (grasp, snout, suck, etc.)	Late	Rare
Affective syndromes	Less frequent	Frequent, severe

acteristic clinical signs and symptoms include 1) a “hippocampal type” of memory difficulty, which is not reliably aided by cues on memory testing and has a high number of intrusions and false recognitions; 2) language difficulties, including a fluent aphasia with anomia, paraphasic errors, and a tendency of the patient to perseverate; 3) the capability of the patient in many cases to continue to recognize objects and to use them appropriately when he or she can no longer name them accurately; and 4) agnosia for faces, including family faces in late stages of the disease. Gait disorder in the middle stages is also common, as well as frontal signs such as grasping and sucking reflexes, along with a change in muscular tone.

The neuropathology of this condition is its defining characteristic (Folstein and McHugh 1983); its extent and severity correlate with the type and severity of the cognitive signs and symptoms. Cortical atrophy occurs, with widened sulci and ventricular enlargement. The most severe changes occur in the medial temporal lobe, including the hippocampus. Areas of association cortex in the parietotemporal lobes, and to a lesser degree the frontal lobes, are also involved. Characteristic microscopic findings are neuronal loss; synaptic loss, particularly in the cortex; senile plaques, with a core of amyloid peptide; neurofibrillary tangles, containing abnormally phosphorylated tau proteins; granulovacuolar degeneration of the neurons; and amyloid angiopathy. The location and abundance of microscopic findings determine the postmortem histological diagnosis of Alzheimer's disease (Cummings et al. 1998). The cause of DAT is not well known. Heredity is important in its causation, and genes implicated have been discussed earlier in this chapter. However, it is likely that DAT is heterogeneous. It is suspected that the primary process may occur many years before clinical symptoms are apparent. This process would initiate a cascade of events leading to neuronal cell death, and this would eventually result in characteristic signs and symptoms.

The amyloid hypothesis gives an important pathogenic role to the APP. The abnormal breakdown of this protein present in neuronal membranes would lead to deposition of the amyloid peptide to form the senile plaques. This is considered to be a central phenomenon in the pathogenesis of DAT. Hope is now placed in studies to disentangle the way in which APP is converted to beta-amyloid because this may lead to specific preventive treatments.

Several studies have supported the cholinergic deficit hypothesis in DAT, including specific degeneration of cholinergic neurons in the nucleus basalis of Meynert; decreases in acetylcholine and choline acetyltransferase concentrations in the brain; and observations about the role of cholinergic agonists and antagonists. Other hypotheses are suggested by the decrease in norepinephrine activity

and, more recently, by reports of decreased levels of many neurotransmitters, including serotonin and the neuroactive peptides somatostatin and corticotropin. Evidence also indicates that the excitatory activity of L-glutamate plays a role in the pathogenesis of DAT. However, some research suggests that vascular factors may play an important role in determining the presence and severity of the clinical symptoms of DAT (Launer 2002).

Dementia With Lewy Bodies

DLB is a condition of uncertain nosological status, with cortical signs suggesting DAT alongside the classic, extrapyramidal features of Parkinson's disease (McKeith et al. 1996). However, the typical neuropathological findings of DAT are much less common in this condition. The distinctive feature is the presence of Lewy bodies, intracellular inclusion bodies in the cortex, particularly in limbic areas, whereas in Parkinson's disease they are typically found in subcortical regions. Most authors now include both DLB and Parkinson's disease among the alpha-synucleinopathies on the basis of recent pathological findings (Boeve 2006). Mean age at disease onset varies between 60 and 80 years. Psychotic syndromes and confusional states are common and may be the presenting symptomatology. Other characteristics include relative preponderance of visuospatial and frontal lobe signs and clear day-to-day fluctuations in symptoms and cognitive performance. Parkinsonian features, together with fluctuation in cognitive performance, hallucinations, and delusions, are core features of the diagnosis (McKeith et al. 2005). Patients who have DLB have frequent falls and/or transient, unexplained episodes of loss of consciousness. They have a characteristic vulnerability to neuroleptics, which frequently exacerbate extrapyramidal dysfunction. Such reactions may be severe and may include acute episodes of rigidity, instability, and falls. DLB patients may have a dramatic decline in the late stage of the disease, death coming after a few months of very severe neurological and psychiatric symptoms.

Frontotemporal Dementia

FTD syndromes, often accompanied by cortical signs, are also the result of neurodegenerative diseases. The most characteristic features that distinguish FTD from DAT are personality changes and neuropsychiatric symptoms, which may be quite marked and precede the cognitive decline by several years. The psychiatric symptoms in FTD include marked irritability; poor judgment; defective control of impulses, including violent impulses in some cases; disinhibition; and a general disregard for the conventional rules of social conduct. Restlessness and hyperorality also have been reported. Social withdrawal or overt depression

may be the first symptom in some patients. Executive dysfunction is a frequent early sign of the disease. Language disorder may be the initial manifestation when the temporal lobes are the main site of pathology. Onset of FTD is usually earlier than in DAT, in the fifth decade of life, and the average duration is 10 years. In clinical samples, it may be the second most common type of dementia, after DAT.

Neuronal loss and gliosis in the frontotemporal areas define this type of neurodegenerative dementia. Several types of FTD have been described, the differences being related to predominant location of lesions and the corresponding signs and symptoms. They include the frontal lobe subtype, the thalamostriatal subtype, the motor neuron subtype, and the amnesic subtype. Pick's disease, characterized by the presence of distinctive intraneuronal Pick bodies and ballooned Pick cells on microscopic examination, may be diagnosed in up to 25% of cases. This disease and the remaining types of FTDs tend now to be classified as tauopathies, with a large clinical spectrum including Pick's disease, PSP, corticobasal degeneration, and multi-system atrophy (Lebert et al. 2002). PSP is often classified among the subcortical dementias because of the predominance of subcortical signs. Primary progressive aphasia is an atypical dementia typified by insidious and progressive impairments in language, with relative preservation of memory and other cortical functions. Although the disorder was once thought to be rare, it is now recognized as being not uncommon (Mesulam 2003).

Subcortical Dementias

Huntington's Disease

Huntington's disease has the three main characteristics of the subcortical dementia syndrome (Folstein and McHugh 1983), together with the classic choreoathetoid movement disorder and a positive family history. Huntington's disease usually has its onset in the third or fourth decade, although juvenile forms occasionally occur. The psychopathology, both cognitive and noncognitive, may appear before the movement abnormalities. The initial pattern of subcortical dementia evolves into the global impairment seen in mixed dementias. Very severe cognitive loss and profound self-neglect, resembling an akinetic mute state, may be seen in the last stage of the disease. Several authors also have reported prominent symptoms that may be difficult to differentiate from primary mood disorder, particularly depression. However, demoralization and depressive reactions are also frequent, and the risk of suicide is increased (Huntington 1872). Suspiciousness and misinterpretations are quite common, but delusions and hallucinations with paranoid and catatonic features also have been described.

The neuropathology in Huntington's disease includes atrophy of the caudate nucleus and loss of gamma-aminobutyric acid (GABA) interneurons (Lishman 1998).

Parkinson's Disease

A typical subcortical, progressive dementia syndrome may occur in patients with Parkinson's disease, and recent studies suggest that it may eventually affect most patients (Aarsland et al. 2003). However, contrary to Huntington's disease, it tends to occur late in the course of the illness, after the motor symptoms have advanced significantly. Classic parkinsonian signs in a patient with dementia point to the diagnosis. Apathy is particularly prominent and may advance to an akinetic mute state. Individual parkinsonian patients endure a wide variety of psychopathological symptoms, including frequent emotional reactions to the disease, but a depressive disorder identical to that seen in affective illness and responsive to the usual treatments is found in approximately one-third of patients (Miyasaki et al. 2006).

Nigral pathology alone is probably not sufficient for the development of dementia in Parkinson's disease and requires the spread of pathology to other subcortical nuclei, the limbic system, and the cerebral cortex. The main degenerative pathology seems to be Lewy body type, principally made of alpha-synuclein (Duyckaerts et al. 2003). Losses of cholinergic, dopaminergic, and noradrenergic innervation have been suggested to be the underlying neurochemical deficits.

Wilson's Disease

Subcortical dementia with characteristic extrapyramidal signs also may be seen in Wilson's disease. This combination of symptoms, together with onset during adolescence or early adulthood, should suggest the diagnosis. Cognitive deficits are usually mild, and psychosis is infrequent. However, depressive syndromes, irritability, disinhibition, personality changes, and poor impulse control are common, with the severity paralleling the severity of the neurological signs (Shanmugiah et al. 2008). The psychopathological features result from destructive deposition of copper in the basal nuclei (Starosta-Rubinstein 1995) because of an inherited defect in the copper-carrying serum protein ceruloplasmin.

Normal-Pressure Hydrocephalus

NPH can present as a very characteristic neuropsychiatric syndrome, a triad of clinical symptoms combining motoric and psychopathological features (Folstein and McHugh 1983; McHugh 1966): 1) an early gait disturbance, resembling the stiff steps of spastic paraparesis; 2) subcortical dementia with particularly severe apathetic features; and

3) urinary incontinence that may not appear until late in the course. An insidious onset with cognitive difficulties is common, but the illness may eventually progress to a state resembling akinetic mutism if untreated. Studies monitoring cerebrospinal fluid pressure have shown waves of increased pressure that are exaggerated in NPH patients. The resulting mechanical pressure on the subcortex tissue surrounding lateral and third ventricles may lead in chronic hydrocephalus to exhaustion of the normal elasticity of brain tissue and eventually to tissue destruction.

Mixed Dementia and Dementia in Disseminated Brain Diseases

Vascular Dementia

Vascular dementia is defined as the dementia resulting from ischemic, ischemic-hypoxic, or hemorrhagic brain lesions due to cerebrovascular or cardiovascular pathology. Clinical findings in vascular dementia are heterogeneous and depend to a great extent on the speed, total volume, and localization of the lesions (Knopman 2006). Typically, the onset is in the 70s, and the dementia syndrome is the result of small or large brain infarcts, which lead to cognitive deterioration when they have enough cumulative effects on critical areas of the brain. However, cognitive impairment and dementia also can be seen in chronic ischemia without frank infarction. Acute onset usually develops after stroke, either from thrombosis, from an embolism, or rarely from a single massive hemorrhage. Onset and course of dementia are often more gradual in so-called multi-infarct dementia, as a consequence of many minor ischemic episodes, which produce an accumulation of lacunae in the cerebral parenchyma.

Cortical dementia occurs when the infarcts affect primarily the cortex, with focal neurological signs being the norm. Subcortical dementia is typically seen in patients with a history of hypertension and foci of ischemic destruction in the deep white matter of the cerebral hemispheres. A variant of vascular dementia results from extensive subcortical degeneration and white matter loss, known as *leuko-araiosis*, as a result of chronic vascular insufficiency. In such cases, extensive, diffuse demyelination of white matter can be seen in periventricular regions, and recent neuroimaging techniques have shown that the condition is more frequent than previously suspected. Mixed cortical and subcortical syndromes are also common in vascular dementia, with neuroimaging findings or autopsy findings suggesting the presence of lesions in both cerebral areas. Mild cognitive impairment of the vascular type also has been described, with an outcome worse than in nonvascular mild cognitive impairment (Frisoni et al. 2002).

The course of vascular dementia has classically been described as stepwise and patchy, but advances in brain imaging techniques have shown that patients with vascular dementia may have clinical courses as gradual and smooth as in patients with DAT. Noncognitive symptoms are common. Poststroke depression, independent of the disability caused by the disease, is frequent. Emotional lability, with transient depressive mood, weeping, or explosive laughter, is also a classic finding in these patients. Personality is usually relatively preserved, but in a proportion of patients, personality changes may be evident, with apathy or disinhibition or the accentuation of previous traits such as egocentricity, paranoid attitude, or irritability.

In more than two-thirds of vascular dementia patients, the pathological correlate is the lacunar state, characterized by multiple lacunar infarctions in subcortical structures such as the basal ganglia and thalamus. The term *vascular cognitive impairment* has been proposed to broaden the current definitions of vascular dementia to recognize the important part cerebrovascular disease plays in several cognitive disorders, including DAT and other degenerative dementias (O'Brien et al. 2003). It is now estimated that the prevalence of mixed cases of vascular dementia and DAT has been underestimated (Langa et al. 2004); that pure vascular dementia is rare; and that, in addition to simple coexistence, vascular dementia and DAT may share common pathogenetic mechanisms (Jellinger 2002).

Prion Dementias

Prion dementias are uncommon diseases that are now considered to be caused by an abnormal form of a normal cerebral protein named *prion protein*. This protein is encoded by a gene on chromosome 20. Because the diseases are transmissible by transferring the altered prion proteins, they act like infectious agents. Nevertheless, neither immunological response nor viruses have been detected in the process.

Creutzfeldt-Jakob disease is one such dementia and is considered to be a sporadic nonfamilial form. It has an extremely rapid course. Cognitive deterioration is progressive, widespread, very severe, and accompanied by pyramidal and extrapyramidal signs, early characteristic myoclonic jerks, muscle rigidity, and ataxia. The average onset is in the 50s, and death usually occurs in 6–12 months (Will et al. 1996). Pathological findings are widespread in both the cortex and the subcortical structures. Spongiform change in neurons is characteristic, and neuronal loss and astrocytic proliferation occur. The clinical diagnosis is based on the rapid progression of dementia, with myoclonic jerks and a characteristic electroencephalogram (EEG) pattern with bursts of generalized, triphasic complexes in most cases (Bourgeois

et al. 2008). Brain imaging may be normal. A specific protein, the "14-3-3 protein" has been reported in the cerebrospinal fluid in a proportion of patients (Waldemar et al. 2007).

A new form of Creutzfeldt-Jakob disease has been detected in Europe. It may begin earlier, before age 40 years, and signs, symptoms, and progression of the disease are similar to those in the original form. It is believed to be the human form of bovine spongiform encephalopathy. An autosomal-dominant familial type, known as Gerstmann-Straussler-Scheinker syndrome, also has been described. This genetic form has similar clinical and pathological features but is less malignant, and death usually occurs after several years.

Infection-Associated Dementias

HIV-associated dementia, formerly called *AIDS dementia complex*, is now the most common dementia caused by an infectious disease (see also Chapter 27, "Infectious Diseases," and Chapter 28, "HIV/AIDS"). Cognitive deterioration is frequently observed in infection with HIV-1 and may be severe enough to fulfill criteria for dementia (World Health Organization 1990). Cognitive dysfunction may be the earliest or the only clinical manifestation of AIDS. At least two types of AIDS-associated dementia have been described. In one of them, the heterogeneity of psychopathological manifestations and the occurrence of both cortical and subcortical features suggest disseminated brain pathology. This is most likely the result of opportunistic infections common in advanced stages of HIV. The other type is a subcortical dementia, with prominent psychomotor retardation. It is considered to be caused directly by HIV, through activation of neurotoxic elements in the immune system.

Noncognitive psychopathology—in particular, depressive syndromes associated with cognitive dysfunction—is also common in patients infected with HIV-1. The incidence of dementia in patients with HIV has declined after the development of antiretroviral therapy, with early treatment. Furthermore, the prior prognosis with typical survival of a few months has now been improved considerably (Bourgeois et al. 2008).

Neurosyphilis may evolve into different types of dementia if left untreated. The most severe form is general paresis, which becomes evident 15–20 years after the original infection. The dementia may be easily recognized in the advanced state and is accompanied by characteristic signs, such as pupillary abnormalities, dysarthria, tremor of the tongue, and hypotonia. However, the onset is commonly insidious, and the diagnosis may be suggested when the initial memory difficulties are accompanied by indifference, facial quivering, tremor, and, sometimes, myoclo-

nus. Intellectual deterioration is progressive and severe, with cortical deficits and often signs suggesting frontal lobe involvement, including disinhibited behavior. Psychotic phenomena, such as grandiose or hypochondriacal delusions, are common.

Chronic meningitis, caused by chronic bacterial, parasitic, or fungal infections, can eventually cause progressive dementia, with fluctuations in arousal and cognitive performance, apathy and lethargy, disorientation, and cranial nerve abnormalities.

Immunosuppressed or debilitated chronically ill patients are at special risk. Herpes simplex encephalitis may cause major neurological and cognitive sequelae. Because herpes encephalitis has a predilection for the temporal lobes, amnesic and aphasic syndromes are common, but dementia also can be seen. Other cortical signs reflect damage to other cortical areas.

Progressive multifocal leukoencephalopathy (PML) is a rare complication of a common subacute viral disorder, most commonly seen in immunosuppressed patients. Clinical signs and symptoms are quite heterogeneous, and the dementia may include both cortical and subcortical signs and symptoms, reflecting widespread lesions in the central nervous system. PML is usually progressive, with motor dysfunction and blindness sometimes developing; death commonly follows in a few months.

Metabolic and Toxic Dementias

Metabolic and toxic dementias (see also Chapter 22, "Endocrine and Metabolic Disorders," and Chapter 37, "Medical Toxicology") form a heterogeneous group of diseases (see Table 6-3) of special interest to the consultant psychiatrist because they are relatively frequent in medical settings and are potentially reversible. Dementia in these conditions has predominantly subcortical features but may have mixed characteristics. Psychomotor slowing may be severe in cases of hypothyroidism. Memory deficits are often accompanied by problems in executive function, with impaired attention and concentration also common. Whether the metabolic and toxic encephalopathies are best conceptualized as reversible dementias or as chronic deliria is unclear, and perhaps the distinction is primarily semantic, particularly in cases of hepatic, renal, and cardiopulmonary failure. Progression of the dementia is usually quite insidious, in relation to the chronicity of the metabolic or toxic condition, and the course tends to be disease specific.

The neuropathology in these conditions is not well known. Hippocampal neurons are probably most vulnerable to anoxic injury but are also vulnerable to severe hypercholesterolemia and to repeated or severe episodes of hypoglycemia, such as may occur in type 1 diabetes mellitus.

Hypothyroidism can produce subcortical damage through a mechanism of relative cerebral hypoxia. Vitamin B₁₂ deficiency, as seen in pernicious anemia, has been associated with disseminated degeneration in areas of cortical white matter, the optic tracts, and the cerebellar peduncles. In pellagra, lack of nicotinic acid and probably other vitamin B deficiencies may lead to neuronal destruction.

Alcoholic dementia, one possible complication of chronic alcoholism, is more frequent after age 50 years and is likely multifactorial in etiology. The pathophysiology of this condition is not well known, but thiamine and other vitamin B deficiencies and multiple TBIs have been found in these patients. Pathological findings at autopsy suggest that this condition is probably underdiagnosed. The cognitive deficits are more global here than in pure amnesic syndrome (e.g., Korsakoff's psychosis), and unlike those patients, alcoholic patients with dementia may complain of decreased efficiency of memory and intellectual functioning. Neuropathological changes include cortical atrophy and nerve fiber disintegration with dissolution of myelin sheaths. Dementing syndromes are also seen in distinct brain diseases related to chronic alcoholism, such as Marchiafava-Bignami disease, with degeneration of the corpus callosum and anterior commissure, or in acquired hepatocerebral degeneration.

Dementing syndromes also may occur in chronic intoxication with medications, which can be either prescribed or abused by patients. The onset is insidious, and the course is progressive; physicians should be alert to the possibility of this reversible dementia. Benzodiazepines, including those with high potency and a short half-life, are known to cause anterograde amnesia and impairment of memory consolidation and subsequent memory retrieval. Elderly patients are more vulnerable to developing the dementia syndrome. Syndromes of cognitive deterioration have been reported in cocaine users and also in heavy users of cannabis.

Neoplastic-Associated Dementias

Neoplastic disease may affect any part of the brain and produce essentially any kind of neuropsychiatric symptoms, depending on tumor location and extent, as well as rapidity of tumor growth and propensity to cause increased intracranial pressure (see also Chapter 23, "Oncology," and Chapter 32, "Neurology and Neurosurgery"). Dementia is one such syndrome, and certain symptom clusters that occur with regularity may suggest the general location of lesions.

Initial symptoms of depression and some cognitive loss, with apathy, negativism, and akinesia, suggest the possibility of frontal lobe tumors such as meningioma or some forms of glioblastoma; a low performance on execu-

tive function tests further supports a frontal lobe site. Temporal lobe tumors are prone to produce seizures, and the psychiatric symptomatology may be complex and include features such as sexual disturbances, irritability, aggressiveness, and hallucinations. Tumors in the parietal region often cause characteristic language disorders when the location is in the dominant hemisphere. In the non-dominant hemisphere, they tend to produce signs such as unilateral neglect or apraxia. Tumors around the third ventricle, such as craniopharyngiomas and colloid cysts, may obstruct the flow of spinal fluid and cause hydrocephalic, subcortical dementia.

Paraneoplastic limbic encephalitis is a nonmetastatic complication of small cell lung carcinoma (and less commonly several other cancers) and may manifest with dramatic, sudden onset of memory loss. A full dementia syndrome may eventually develop (Foster and Caplan 2009). Mood disturbance, behavior change, and sometimes psychotic symptoms are also common. Pathological findings include neuronal loss, astrogliosis, lymphocytic perivascular infiltration, and glial nodules. The psychiatric symptoms may antedate the diagnosis of malignancy by several years. Early medical intervention might considerably improve the outcome of treatment in some cases (Dalmau et al. 2008).

Dementia Following Traumatic Brain Injury

A variety of cognitive difficulties are very frequent after TBI (see also Chapter 35, "Physical Medicine and Rehabilitation"). Symptoms vary depending on the site of the lesion. Cognitive deficits become permanent in more than half of the patients if they do not recover memory and orientation within 2 weeks after injury. Common difficulties include dysmnnesia, organic personality disorder, dysphasia, attentional disturbances, and impairments suggestive of frontal lobe damage, particularly executive dysfunction. Dementia also occurs in a minority of cases and may be accompanied by seizures and neurological deficits, as well as secondary psychiatric syndromes, including depression, mania, and psychosis. Dementia in boxers (dementia pugilistica) commonly starts with signs of ataxia, dysarthria, and parkinsonian-like extrapyramidal signs before the global cognitive deficits are appreciated. Dementia due to subdural hematoma is notable because it is potentially reversible. Focal neurological signs, personality changes, and lethargy or agitation may be the presenting symptoms. The history of brain trauma may not be confirmed in a considerable proportion of cases (Bourgeois et al. 2008). In cases of dementia following TBI, diffuse axonal injury, with anatomical disruption and axonal tearing, has been described, and contusional foci in cortical areas and intracerebral hemorrhage also have been reported.

Depression

The relation between dementia and depression is complex. *Pseudodementia*, a term no longer used, referred in the past to depressed patients who perform poorly on cognitive tasks because of lack of interest and motivation. However, it is clear that the dementia syndrome of depression (DSD) is not “pseudo” because it is debilitating and often the harbinger of degenerative diseases (Sáez-Fonseca et al. 2007). DSD may occur during episodes of severe mood disorder (Folstein and McHugh 1978). DSD is probably associated with potentially reversible neurotransmitter dysfunction. It is more frequent in elderly patients with a history of depression, and the presenting depressive syndrome often includes severe psychomotor retardation and other melancholic symptoms, as well as psychotic features such as delusions. Cortical signs such as language disturbances are uncommon, and in DSD, in contrast to DAT, prompting and organization of material tend to improve memory performance (O’Brien et al. 2001). DSD may be potentially reversible and tends to disappear with successful treatment of depression. However, cognitive monitoring and follow-up are recommended because a persistent dementia syndrome may develop in a significant proportion of cases (Chen et al. 2008). Depressive symptoms in the elderly and a history of late-onset depression have been associated with the severity of subcortical white matter lesions, suggesting an etiological role for vascular disease (de Groot et al. 2000). The dissection of apathy and depression in cognitively impaired patients is often difficult, but it is relevant for treatment. Furthermore, apathy and depression may have a differential role in the development of dementia (Vicini Chilovi et al. 2009).

Diagnosis and Differential Diagnosis

Early detection of dementia can play an important role in both the social and the health care dimensions of the disease (Organization for Economic Cooperation and Development 2002). A brief interview can detect the dementia syndrome with reasonable accuracy (Boustani et al. 2003) and can be taught to nonpsychiatrists. However, a systematic search for dementia should follow general screening principles and should be linked ideally to a system prepared to care for all identified patients (J.M.G. Wilson and Junger 1968). Dementia should be suspected in patients at risk referred to psychiatrists, particularly elderly medical patients with delirium or unexpected behavioral disturbances and patients referred by primary care physicians because of subjective complaints or observations by relatives about memory problems or loss of intellectual efficiency. In both cases, the clinical approach to diagnosis follows a

classic sequence: first, to identify characteristic signs and symptoms of cognitive impairment; second, to document whether the signs and symptoms cluster in the defined syndrome and to complete a differential diagnosis by discarding false-positive cases; and finally, to search for the etiological type of dementia. A search for associated medical conditions, neuropsychiatric symptoms, and special social needs completes the evaluation process.

Clinical History

A clinical history corroborated through reliable caregivers and a systematic mental status examination are the foundation of the diagnostic process (Rabins et al. 2007). In taking the history, it is important to search for specific evidence of deterioration in memory and other cognitive functions summarized in the general dementia syndrome (see Table 6-5). Specific, convincing examples should be required as support for the diagnosis of dementia. Furthermore, the consultant must assess the presence, extent, and consequences of the cognitive problems in occupational activities and ADLs (see Figure 6-1). An outside informant is crucial for obtaining data about decline in cognitive function measured against premorbid abilities. The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE; Jorm and Jacomb 1989)—and in particular the short form (Jorm 1994)—is suggested as a useful, simple questionnaire that has good reliability and validity. The onset and pattern of progression of the cognitive difficulties also should be carefully documented. Insidious diseases such as DAT can easily go undetected for years before becoming apparent. Finally, it is also important to determine whether changes in personality and behavior have accompanied the cognitive difficulties and whether psychopathological signs and symptoms, including apathy and loss of initiative, are present.

Mental Status Examination

A systematic, basic bedside or office mental status examination is a minimum requirement in each case of suspected dementia. The cognitive assessment is relatively easy to complete and should include all relevant domains. Table 1-4 (“Detailed assessment of cognitive domains”) in Chapter 1, “Psychiatric Assessment and Consultation,” summarizes the cognitive areas to cover in the assessment. In-depth examination of recent memory should be emphasized. Other important areas to explore are remote memory and fund of knowledge; attention; language and verbal fluency; visuospatial skills; and abstraction. Figure 6-2 shows the performance on some construction tasks by patients with dementia. It is strongly recommended that the clinician be familiar with a standard assessment method,

FIGURE 6–1. Impairment in instrumental^a and basic^b activities of daily living (ADLs) in patients with dementia of the Alzheimer's type of mild severity (Mini-Mental State Examination score > 18) at time of diagnosis.

ideally one supported by efficiency data. Although no standardized instrument is a substitute for sound clinical assessment, some are quite helpful, provided their limitations are kept in mind.

The Mini-Mental State Examination (MMSE) is one such instrument for screening purposes (sensitivity $\geq 87\%$; positive predictive value $\geq 79\%$ in clinical populations) (Folstein et al. 1975, 2001) and is widely considered to be the standard measure in most clinical and research studies

(Gray and Cummings 2002). It fares very well in different cultures, if the standardization has been adequate (A. Lobo et al. 1999). Data on the efficiency of individual items in the MMSE, remarkable in items such as temporal orientation, may help the consultant in interpreting the results of the test (Table 6–7). A recent meta-analysis supports the accuracy of this brief scale in the detection of dementia (Mitchell 2009). The limits of the MMSE relate to both floor and ceiling effects, and population norms have to be considered

FIGURE 6-2. Performance in construction tasks (commands to draw interlocked pentagons and a clock) by patients with increasing levels of dementia severity.

Impairment in performance appears earlier in clock drawing than in pentagon construction and increases with severity level of dementia. Clock A (Mini-Mental State Examination [MMSE] score=18) shows executive deficits in planning and organization; construction deficits to place the numbers; probable perseveration (24 hours); and deficits in judgment to correct errors and to place the hands indicating the time (11:10). Pentagon A shows nominal construction deficit. Clock B (MMSE score=15) shows subtle construction deficits (mild deviation of numbers, but spacing is correct); executive deficits in planning and judgment to indicate the time; and unsuccessful executive attempts to correct errors (in placing number 6; in placing the hands). Pentagon B shows mild construction deficit. Clock C (MMSE score=14) shows deficits both in remembering and in understanding the command and probable "stimulus dependence syndrome" (the pen in the patient's hand acts as a stimulus and writes inappropriately inside the circle). Pentagon C shows construction and visuomotor coordination deficits.

in adjusting the usual cutoff point (23 of 24) (Crum et al. 1993; A. Lobo et al. 1999) to avoid false-positive cases in individuals with limited educational background or, conversely, false-negative cases in highly educated, intelligent patients. The Modified Mini-Mental State (3MS; E. L. Teng and Chui 1987), with minor changes introduced to circumvent these difficulties, works well in clinical practice (McDowell et al. 1997). Executive functions, which are not well covered in the MMSE, may be easily assessed at bedside with the Frontal Assessment Battery (FAB; Dubois et al. 2000). Standardized assessment scales also may be recommended for cases of severe dementia (Rabins and Steele 1996), for noncognitive symptoms in individuals with dementia (Cummings et al. 1994), and specifically for depression (Alexopoulos et al. 1988).

Neurological Examination

The neurological examination is also an integral part of, and informs, the diagnosis and differential diagnosis. The examination should be standard but may be focused on the assessment of neurological signs described in the clinical section, including specific gait difficulties, praxias, and pathological reflexes. Other testing should be included if warranted by clinical information.

Differential Diagnosis

Differential diagnosis starts by ruling out false-positive cases of dementia—namely, previous mental retardation; amnesic syndromes (such as in Korsakoff's psychosis), without the global deficits required for the diagnosis of de-

mentia; cognitive difficulties due to general physical frailty, particularly in elderly patients; and age-related memory impairment (or benign senescent forgetfulness), characterized by a minor degree of memory problems observed as a normal part of aging and not significantly interfering with a person's social or occupational behavior. Pseudodementia syndromes may be the result of motivational or emotional factors interfering with performance. They include acute psychotic episodes, conversion disorder, factitious disorder, and malingering, suggested by reports of relatives, examination, or evidence of primary and/or secondary gains. Schizophrenia may present special diagnostic difficulties, both because of the emotional and psychotic features and because of the cognitive deficits (Zakzanis et al. 2003a). The cardinal symptoms of schizophrenia and longitudinal history should help clarify the diagnosis. The central cognitive functions and ADLs that deteriorate in dementia usually are preserved in schizophrenia.

Ganser's syndrome, or the syndrome of "approximate answers," requires special consideration. This syndrome is characterized by the voluntary production of severe cognitive symptoms (Dwyer and Reid 2004; Lishman 1998). Key features include approximate answers to simple questions (i.e., incorrect answers that imply the person knows the correct answers—e.g., "How many legs does a table have?" "Three." "How much is 2 + 2?" "Five.""). The cause of this rare syndrome remains uncertain. It was previously classified as a factitious disorder, but current classification systems categorize it as a dissociative disorder, the symptoms of which are judged as psychogenic in origin (Wirtz et al. 2008).

Ganser's syndrome is frequently associated with brain injury but may occur in patients with a variety of psychiatric disorders. The differential diagnosis may be very difficult. Objective psychological tests may be useful to document the factitious nature of the cognitive symptoms. The fact that the symptoms are often worse when the patients believe they are being watched also helps in the recognition of this syndrome. A major predisposing factor is the existence of a previous severe personality disorder.

Depressive disorders in elderly patients also should be considered because these patients may have memory difficulties, slowed thinking, and lack of spontaneity, which suggest dementia (see discussion of DSD earlier in this chapter in the "Depression" subsection).

Delirium makes it very difficult to determine whether concurrent dementia is present, and delirium without fluctuating level of consciousness may be very difficult to distinguish from dementia. The diagnosis of delirium is suggested when global cognitive disturbance (including immediate and recent memory) is accompanied by rapid onset, fluctuating level of consciousness, impairment of attention, incoherence of thought, visual illusions or hallucinations or other perceptual disturbances, and disturbances of the sleep-wake cycle, all in the presence of a severe medical condition. Definitive diagnosis often must be postponed until the follow-up after recovery from acute medical illness. A "double" diagnosis of delirium superimposed on dementia is very common in general hospital patients; A. Lobo and Saz (2004) found that a postdischarge diagnosis of dementia is confirmed in approximately half the cases of uncertain diagnosis.

Mild cognitive impairment, as described in the "Concept of Dementia and Clinical Approach" section, merits special consideration because of its high prevalence and the high rate of progression to dementia. Clinical judgment is required for the diagnosis, but neuropsychological assessment is helpful. The screening instruments and rating scales presented in this chapter may be used for this purpose. Scores of 2 or 3 on the Global Deterioration Scale (GDS; Reisberg et al. 1982) or a score of 0.5 on the Clinical Dementia Rating Scale (CDR; Hughes et al. 1982) has been considered to correspond to mild cognitive impairment. Neuroimaging findings helpful in the diagnosis are described in the following sections.

Once false-positive cases are ruled out and a dementia syndrome is confirmed, the consultant determines whether the syndrome has characteristics of cortical, subcortical, or mixed type (see Table 6-6), as described in the previous sections. The onset and progression of the cognitive difficulties, the other psychopathological features, and whether another medical condition is present will give further clues as to the type of dementia. For diagnostic purposes, clinical

differences between types of dementia have been emphasized in the "Clinical Types and Pathophysiology of Dementia" section. The search for potentially reversible types of dementia due to medical conditions or toxic effects (see Table 6-3) has long been emphasized and remains an important step in the diagnostic process. Such conditions are more frequent in general hospital patients, although the identification of truly reversible causes has become less common than in the past, and true reversibility has been questioned (Weytingh et al. 1995).

Workup recommendations for the diagnosis of dementia are available (Knopman et al. 2001; Small et al. 1997), although standard workup is applicable to every patient. Table 6-8 lists a screening battery of tests that are

TABLE 6-8. Laboratory tests and other diagnostic procedures in the assessment of dementia

Screening battery^a

- Complete blood cell count with differential cell type count
- Erythrocyte sedimentation rate
- Blood glucose
- Blood urea nitrogen
- Electrolytes, calcium, magnesium
- Thyrotropin
- Vitamin B₁₂ and folate levels
- Urinalysis
- Fluorescent treponemal antibody absorption^b
- Liver and renal function tests

Neuroimaging

Other tests and procedures^a

- Blood tests
 - Arterial blood gases
 - Blood and urine screens for alcohol, drugs, and heavy metals
 - Serum HIV test^{b,c}
 - Homocysteine level
 - Antinuclear antibody, C3, C4, anti-double-stranded DNA, anticardiolipin antibody
- Other
 - Chest X ray
 - Electrocardiogram
 - Disease-specific tests (e.g., serum copper and ceruloplasmin for Wilson's disease)
 - Lumbar puncture^c (usually after CT or MRI)

^aTests may be selected on the basis of patient age.

^bMay require special consent and counseling.

^cTests selected on the basis of specific symptoms (history and physical examination) or patient populations.

commonly used to identify conditions associated with dementia, such as infectious, metabolic, and neoplastic diseases and substance-induced dementia. The specific tests used should be determined by various factors, including the patient's age, medical comorbidities, history, and physical examination. Neuroimaging is often obtained, and neuropsychological testing may be very useful in some

cases (Table 6-9). Lumbar puncture should be considered for patients with early onset or atypical clinical features, as well as for patients with positive syphilis serology or suspected hydrocephalus, central nervous system infection, vasculitis, immunosuppression, or metastatic cancer.

The DSM-IV-TR (American Psychiatric Association 2000) diagnostic criteria for dementia overlap with the

TABLE 6-9. Neuroimaging findings in dementia syndromes

Syndrome and findings	Neuroimaging modalities
Dementias treatable by surgical procedures	
Normal-pressure hydrocephalus, brain tumors, subdural hematoma	CT, MRI
Dementia of the Alzheimer's type	
Enlarged ventricles	CT, MRI
General atrophy	CT, MRI
Medial temporal lobe or hippocampus atrophy (early markers)	CT, MRI (combined with SPECT)
Temporoparietal (and sometimes frontal) hypoperfusion	SPECT
Temporoparietal (and sometimes frontal) hypometabolism; relative sparing of visual and sensorimotor cortex	PET
Absence of signs of vascular dementia	CT, MRI
Vascular dementia	
Leukoaraiosis in white matter (very frequent)	CT
Areas of infarct (very characteristic, only half the cases)	CT
Hyperintensities in white matter (more sensitive)	MRI
Frontotemporal dementia	
Frontal (and temporal) atrophy	CT, MRI
Frontal (and temporal) hypoperfusion	SPECT
Normal-pressure hydrocephalus	
Very enlarged ventricles	CT, MRI
Huntington's disease	
Atrophy of caudate nucleus	CT, MRI
Alcoholic dementia	
Enlarged ventricles and atrophy	CT, MRI
HIV dementia	
Atrophy	CT, MRI
Demyelination of subcortical white matter	MRI
Hypermetabolism of thalamus and basal ganglia	PET
Depression	
Frontal hypometabolism, asymmetric (reversible)	PET
Mild cognitive impairment	
Hippocampal and entorhinal volume reduction	MRI, CT
Hypoperfusion or hypometabolism	SPECT, PET

Note. Structural imaging: CT = computed tomography; MRI = magnetic resonance imaging. Functional imaging: PET = positron emission tomography; SPECT = single photon emission computed tomography.

ICD-10 criteria (World Health Organization 1992), and the latter also have been adapted for use in general hospital patients (Malt et al. 1996). It is accepted that a definitive diagnosis of Alzheimer's disease requires histological evidence in the brain at autopsy (McKhann et al. 1984). However, a careful clinical diagnosis coincides with the pathological diagnosis in most cases (Rabins et al. 2007). This diagnosis must be based on the presence of a cortical type of dementia syndrome, an insidious onset with slow deterioration (although plateaus may occur in the progression), and characteristic psychopathological and neurological signs and symptoms (see Table 6-5). The diagnosis is further supported by neuroimaging findings (see Table 6-9); the absence of clinical evidence; or findings from special investigations, which suggest that the mental state may be due to vascular dementia (Table 6-10) or another systemic disease that can induce a dementia syndrome.

Genetic testing for DAT is promising and relies on the fact that two general groups of genes are associated with this disease. Presenilin-1 is a fairly accurate predictor of early-onset Alzheimer's disease, but genetic testing for mutations in presenilin has proven to be ineffective as a screening tool because of its low sensitivity (Kurz et al. 2002). The *APOE* genotype is statistically associated with late-onset Alzheimer's disease, but current genetic testing for the *APOE* $\epsilon 4$ allele cannot be recommended for screening because of its low efficiency (Patterson et al. 2008).

The clinical characteristics supporting a diagnosis of vascular dementia are summarized in Table 6-10, and Table 6-9 includes the characteristic and differential neuroimaging findings. More stringent diagnostic criteria are also available (Roman et al. 1993) and are widely considered important for research purposes. A diagnosis of a mixed DAT and vascular type of dementia or a double diagnosis is usually made when clinical and imaging characteristics of both coexist. This may happen, for example, when cerebrovascular episodes are superimposed on a clinical picture and history suggesting Alzheimer's disease. The presence of cerebrovascular lesions in patients with DAT has been confirmed by recent evidence, including postmortem findings (Kalaria 2000).

Neuroimaging and Electroencephalography

Neuroimaging has revolutionized the ability of clinicians to diagnose dementia. It is a useful adjunct to clinical diagnosis and is considered to be mandatory in some stringent diagnostic systems (McKhann et al. 1984; Roman et al. 1993). However, it may be unnecessary in cases of advanced symptoms and long history of the disease. Computed tomography (CT) and magnetic resonance imaging (MRI) are very useful in ruling out reversible conditions such as NPH, subdural hematoma, and brain tumors. Therefore,

TABLE 6-10. Clinical characteristics suggesting vascular dementia

Mixed type of dementia syndrome
Uneven cognitive deterioration
Relative preservation of insight and judgment
Abrupt onset, stepwise course
Emotional incontinence and lability
History of strokes
History of cardiovascular risk factors
Focal neurological signs and symptoms

these imaging modalities should be routinely considered in patients with history or findings suggesting those conditions, specifically when such patients have cognitive impairment with rapid onset or recent head trauma; focal neurological signs or abnormalities in gait; severe headache, papilledema, or visual field defect; early appearance of incontinence; or history of stroke or seizures without known risk factors.

In DAT, both CT and MRI are helpful diagnostic tools (see Table 6-9). However, the findings are not totally specific (in particular, for general atrophy), which may be found in elderly patients without dementia. Images of enlarged ventricles are considered to be better discriminators. Early markers of the disease may be the CT—and particularly the MRI—views of the medial temporal lobe and hippocampus (Chetelat and Baron 2003). Single photon emission computed tomography (SPECT) may be particularly useful in early cases of FTD to detect changes in blood flow. Positron emission tomography (PET) is also a promising technique (see Table 6-9), although not all hospitals have adequate facilities. The utility of both functional techniques has been supported by meta-analytic reviews (Zakzanis et al. 2003b). However, the costs of tests, and whether the results will make a difference in management of the patient, should be considered before routine recommendation in clinical practice. In vascular dementia, neuroimaging can provide strong support for the diagnosis, especially the MRI finding of hyperintensities in the white matter, and some authors suggest that the diagnosis is excluded in the absence of vascular lesions (Roman 2002). However, some hyperintensities are also found in DAT and other degenerative dementias, as well as in control subjects (Pantoni and Garcia 1995).

The EEG has limited utility in the differential diagnosis of dementia because abnormalities are frequent but relatively nonspecific. Slow-wave activity characteristic of delirium does not appear until late in the course of DAT. The EEG is very useful in diagnosing Creutzfeldt-Jakob disease

(triphasic, periodic burst patterns) (Waldemar et al. 2007) and in patients with some metabolic dementias, such as hepatic encephalopathy (triphasic waves), although in neither case is the finding pathognomonic.

Neuropsychological Testing

Neuropsychological testing is valuable as an adjunct to the clinical examination but is no substitute for sound clinical judgment. Any battery of tests for the evaluation of dementia should assess a wide range of cognitive abilities, with special emphasis on memory. The age, education, and culture of the population must be considered in standardizing the instruments and interpreting the results. Neuropsychological testing may be particularly useful to differentiate dementia from age-related cognitive impairment and to provide both quantitative and qualitative information that helps differentiate subtypes of dementia (Chertkow et al. 2008). Batteries commonly used include measures of memory, intellect, language, and visuospatial function. Some are exhaustive, with the administration taking several hours—a feature that limits their utility. A rather short battery has been standardized by the Consortium to Establish a Registry for Alzheimer's Disease (Welsh et al. 1992) and has been used in different countries.

Dementia Rating Scales

Aside from the MMSE, screening and assessment instruments for dementia include classic scales, such as the Blessed Mental Status Examination (Blessed et al. 1968). Instruments for specific purposes have been designed; one such instrument, the Alzheimer's Disease Assessment Scale (ADAS; W.G. Rosen et al. 1984), is considered to have improved sensitivity for DAT. The use of these instruments does not replace a careful mental status examination. Educational and cultural factors must be taken into account in interpreting the results of cognitive assessment with any of these instruments. Primary care physicians and nurse practitioners can be trained in their use. Global staging instruments, such as the CDR (Hughes et al. 1982), have come into wide use. A variety of assessments are also available for documenting functional deficits, such as the classic instruments of Lawton and Brody (1969), the Katz Index (Katz et al. 1970), or the Functional Assessment Staging (FAST) procedure, which can be used in conjunction with the GDS staging system (Reisberg et al. 1993).

Clinical Course, Prognosis, and Outcome

The course and prognosis of dementia are generally disease specific but may be influenced by a variety of factors.

Timely surgical treatment, before irreversible brain damage occurs, may have spectacular results in subdural hematoma or brain tumors, depending on type and location. Classical studies suggested the improvement of severe apathy in NPH by surgical shunting, although cognitive improvement was not as evident. However, a systematic review concluded that no evidence indicates whether placement of a shunt is effective (Esmonde and Cooke 2002). One would expect that dementia associated with medications or metabolic conditions should be reversible, but this is not always the case in practice (Weytingh et al. 1995).

Medical comorbidity may be present in two-thirds of DAT patients and is strongly associated with greater impairment in cognition and in self-care (Doraiswamy et al. 2002). Optimal management of medical illnesses may offer potential to improve cognition in Alzheimer's disease. Dementias associated with infections have disease-specific prognoses. Untreated HIV dementia generally progresses quickly (over months) to severe global dementia, mutism, and death. However, with careful antiretroviral treatment, patients may survive for years. Adequate treatment with dopamine agonists and other standard treatments significantly improves the prognosis of dementia in Parkinson's disease. Early treatment with thiamine is vital in alcoholic patients with cognitive dysfunction (Blansjaar and van Dijk 1992).

Important events or changes in a patient's routine may precipitate episodes of behavioral disturbance. Medical illness (most often urinary tract infection or pneumonia) or the use of benzodiazepines or alcohol also may precipitate episodes of delirium. Patients with good premorbid adjustment and greater intelligence and education are in general more able to compensate for intellectual deficits and disability. Support from family and caregivers may determine to an important extent the presence or absence of affective and other psychological symptoms, as well as the course of dementia.

Studies suggest that median survival after the onset of DAT is much shorter than has previously been estimated and is strongly associated with age. In the study by Brookmeyer et al. (2002), median survival ranged from 8.3 years for persons who received the diagnosis at age 65 years to 3.4 years for persons who received the diagnosis at age 90 years. No important differences in mean survival have been found between DAT and vascular dementia (Wolfson et al. 2001).

The relative risk of death for DAT is two to three times higher than in persons without DAT, particularly in older women (Dewey and Saz 2001; Dodge et al. 2003). The mean annual rate of progression of cognitive impairment is approximately 2–4 points when degree of impairment is assessed with the MMSE (Ballard et al. 2001). Most re-

searchers have found faster rates of decline in early-onset DAT (Stern et al. 1997). A more recent review (Sarazin et al. 2002) suggested that an increased rate of deterioration was associated with the following factors: low baseline cognitive status, presence of Lewy bodies, language deficits, lower scores on nonverbal neuropsychological tests, extrapyramidal signs, and myoclonus. The relation between APOE $\epsilon 4$ and the course of DAT is still debated (Galasko et al. 2000), but the presence of psychotic symptoms at baseline is strongly and independently predictive of a more rapid decline (Paulsen et al. 2000). However, some reports consider that cognitive decline in such cases might be related to neuroleptic treatment (McShane et al. 1997). Neuropsychiatric symptoms tend to fluctuate in the course of dementia in most patients, but depression, agitation, and aggression may show greater persistence as compared with delusions and hallucinations (Devanand et al. 1997).

Functional impairment in DAT is highly correlated with the severity of cognitive impairment (Mohs et al. 2000). Instrumental ADLs demand higher cognitive functions than do the basic ADLs, and, as expected, the former are impaired earlier. Nursing home placement has consistently been related not only to severity of dementia but also to severity of both functional impairment and neuropsychiatric symptoms (Luppa et al. 2008). Strong evidence suggests that caring for patients with dementia has a negative effect on caregivers, often more negative than when caring for a person with physical disabilities (Morris et al. 1988); the ability of caregivers to tolerate neuropsychiatric symptoms reduces the probability of nursing home placement (Luppa et al. 2008).

Considerably less evidence is available regarding the course of other degenerative diseases, but clinical experience and some reports suggest that disease progression is similar to that in DAT. Duration of DLB ranges from 1.8 to 9.5 years (Walker et al. 2000), and early-onset cases might have a more rapid decline. Visual hallucinations tend to be persistent in DLB (Ballard et al. 2001), but psychosis does not appear to predict accelerated decline (Mohs et al. 2000). The increased survival reported in studies might be related to a decrease in the prescription of neuroleptics in patients with DLB (McShane et al. 1997), in view of the greater awareness of their negative side effects, which include rapid cognitive decline.

A faster rate of deterioration in executive functions, but not of other cognitive functions, has been reported in patients with FTD when compared with DAT (Galasko et al. 2000). Loss of autonomy appears early in the course of FTD and is frequently accompanied by behavior changes. In the late stages of subcortical dementias, such as Huntington's disease, apathy may be quite severe and cause profound self-neglect; the patient's condition may resem-

ble the akinetic mute state. Duration of disease varies from 5–10 years in PSP to 10–15 years in Huntington's disease. Survival in Parkinson's disease might be 12–14 years, provided the treatment is adequate, and patients with Wilson's disease may have a normal survival time if their symptoms are adequately treated with penicillamine before irreversible liver and brain damage occurs. The course of vascular dementia is typically stepwise but varies significantly depending on the type of vascular problem. Prognosis is poor, and patients usually die as a result of new cardiovascular events or strokes, but considerable individual variation is seen.

Treatment

General Principles

The general principles for treatment of dementia are summarized in Table 6–11. Extensive clinical guides on how to provide care for patients with dementia are available (Rabins et al. 2006, 2007). Patients with dementia very often have a broad range of medical problems, neuropsychiatric symptoms, and social needs accompanying their cognitive deterioration. Therefore, they usually need a multimodal plan, which should be adapted to the individual and to the specific stage of the disease. Specific recommendations are discussed in the following sections.

Adequate medical care is crucial in all dementias because both cognitive function and behavior may be adversely influenced by medical problems. Specific and frequent problems that must be addressed include the management of pain, urinary tract infections, and decubitus ulcers. Tube feeding to improve survival in hospitalized patients with advanced dementia is controversial, if not contraindicated, because it lacks demonstrated benefits (Meier et al. 2001). Treatment in nonreversible dementia aims at controlling the underlying condition as much as possible and slowing the progression of symptoms. The treatment of cognitive loss with new pharmacological agents has become a major focus, and the identification and treatment of neuropsychiatric symptoms are especially relevant for psychiatrists. General measures include mandatory restrictions on driving. Both patients and families should be informed that dementia increases the risk for accidents, even in the early stages, and patients certainly should not be driving when dementia reaches a moderately severe stage. Psychological and social support and treatment always should be considered for patients. Psychiatrists also should be alert to the potential needs of caregivers. Long-term treatment must be considered in most dementias, and psychiatrists should participate in public health, including public awareness campaigns that

TABLE 6–11. General principles for treatment of dementia and bases for consultation-liaison programs**Use a multimodal treatment plan and individualize it for each patient.**

Adjust treatment to stage of disease.

Provide adequate care of emergencies.

Evaluate for suicidal potential, self-harm (e.g., falling or wandering), or accidents (e.g., fires).

Treat agitation and potential for violence.

Initiate early treatment of potentially reversible medical or surgical conditions etiologically related to dementia (e.g., hypothyroidism, subdural hematoma).**See patient on regular basis.**

Schedule frequent visits when starting therapy; see for routine follow-up every 4–6 months thereafter (more frequent visits may be required in special circumstances).

Ensure adequate medical care.

Maintain the patient's physical health: nutritious diet, proper exercise.

Identify and treat comorbid medical conditions: cardiopulmonary dysfunction, pain, urinary tract infections, decubitus ulcers, visual and auditory problems, etc.

Care for iatrogenic events, pressure sores, aspiration pneumonia, fecal impaction.

Exert stringent control of unnecessary drugs taken for other medical disorders.

Try to control underlying disease and slow progression in nonreversible dementias.

Prevent and treat vascular problems (in both vascular dementia and dementia of the Alzheimer's type): hypertension, hyperlipidemia, obesity, cardiac disease, diabetes, alcohol dependence, smoking cessation, etc.

Treat cognitive loss: pharmacological, other measures.

Use other general measures.

Use general health measures: recreational and activity therapies, etc.

Restrict driving and use of other dangerous equipment.

Identify neuropsychiatric symptoms; provide vigorous treatment if needed.**Provide psychological support and treatment for patient.**

Provide orientation aids (calendars, clocks, television).

Assess activities of daily living and provide assistance as needed.

Use special techniques: stimulation-oriented, reminiscence therapy, cognitive or reality therapy.

Provide social treatment.

Educate family caregivers.

Give advice with arrangements for wills, power of attorney, and general estate matters.

Suggest support groups, community organizations.

Provide support for caregivers and treatment if needed (e.g., for depression).**Arrange long-term treatment and coordinate with care organizations.**

Memory clinics

Community resources, geriatric day hospitals

Multidisciplinary rehabilitation in an outpatient setting

Support groups, Alzheimer's Association

Respite care

Long-term facility (including nursing homes, hospice) necessary if caregivers not available

Vigilance regarding neglect or abuse

Incorporate health care strategies.

Public awareness campaigns; campaigns for early detection and treatment of dementia

stress the importance of early detection and treatment of dementia (Organization for Economic Cooperation and Development 2002).

Pharmacological Treatment

General guidelines for psychotropic medication use in frail elderly patients are applicable (Spar and La Rue 2002). Specific suggestions for dementia patients are summarized in Table 6–12. Systematic evidence to support the effectiveness of particular psychotropic drugs in dementia patients is limited. Therefore, choice of drug class may be based on clinical evidence, and choice of agent is often based on the side-effect profile and on the characteristics of a given patient. Noncognitive, psychopathological, and behavioral manifestations in patients with dementia may be early targets for psychiatric intervention.

Treatment of Psychosis and Agitation

Some evidence indicates that antipsychotics are effective in controlling agitation, aggressiveness, wandering, and psychotic symptoms in individuals with dementia (Olin and Schneider 2002), mostly in studies of no longer than 12 weeks. The data suggest that improvement is greater for psychosis than for other symptoms. Antipsychotics are often administered in the evening so that maximum levels oc-

cur at sleep time. Most antipsychotics have long half-lives, so once-a-day doses may be sufficient. Oral administration is preferred, except in cases of emergency or when the patient is unable to take the medication by mouth. Initial treatment with low doses of a high-potency agent, such as haloperidol (0.5–2.0 mg/day; maximum dosage 5 mg/day), may be recommended, and evidence indicates that it is effective in reducing aggressiveness in agitated dementia (Lonergan et al. 2002). However, the atypical antipsychotics cause fewer extrapyramidal effects, and their use in dementia has been supported by randomized controlled trials (Ballard and Waite 2006; Daiello 2007; L.S. Schneider et al. 2006). Specific antipsychotics and doses recommended are risperidone (0.25–1 mg/day), olanzapine (1.25–5.0 mg/day), quetiapine (12.5–50 mg/day), or aripiprazole (5 mg/day). An increase in mortality associated with the use of atypical antipsychotics has been reported (Ballard and Waite 2006), and a black-box warning has been issued (U.S. Food and Drug Administration 2005). However, similar risks have been suggested for typical antipsychotics (Wang et al. 2005) (see Chapter 38, “Psychopharmacology”). In patients with Parkinson’s disease or DLB, atypical antipsychotics with limited extrapyramidal effects may be recommended (Rabins et al. 2007). Another option is clozapine (initial dose 12.5 mg/day; maximum dose 75–100 mg/day).

TABLE 6–12. Suggested guidelines for psychotropic medication use

Consider that agitation and/or behavioral disturbances may be due to

A medical condition, pain, other psychiatric condition, or sleep loss, which would resolve with treatment of the primary condition.
Hunger, constipation, stressful atmosphere, change in living conditions, or interpersonal difficulties.

Use strategies to minimize the total amount of medication required.

Instruct caregivers to appropriately administer sedatives when warranted.
Mild symptoms or limited risk often may resolve with support, reassurance, and distraction.

Remember that dementia patients are often physically frail and have decreased renal clearance and slowed hepatic metabolism.

Be specific in selecting target symptoms.

Use low initial doses, one-quarter to one-third of the usual initial dose; dose increments should be smaller and between-dose intervals longer. Seek lowest effective dose.

Avoid polypharmacy.

Keep especially alert to

Medical conditions and drug interactions.
Frequent and worrying side effects: orthostatic hypotension and central nervous system sedation (may worsen cognition and cause falls); susceptibility to extrapyramidal side effects.
Idiosyncratic drug effects: mental confusion; restlessness; increased sedation; and vulnerability to anticholinergic effects of psychotropic medication.

In cases of extrapyramidal effects, reduce the dose or change to another drug rather than use anticholinergic drugs.

Reassess risks and benefits of psychotropic treatment on an ongoing basis.

The use of cholinesterase inhibitors—namely, donepezil, rivastigmine, and galantamine—is considered to be an appropriate pharmacological strategy for the management of psychotic symptoms and agitation in patients with dementia. Substantial clinical experience is available (Cummings et al. 2006), although the evidence of their efficacy is still limited, in part because of methodological considerations (Rodda et al. 2009). Similarly, some evidence supports the use of memantine in such cases (Wilcock et al. 2008).

There is less empirical support for, but considerable clinical experience with, the use of other medications in cases of agitated behavior, particularly in milder cases or cases unresponsive to neuroleptics. These medications include trazodone (50–400 mg/day; higher doses have been reported by some clinicians) (Rojas-Fernández et al. 2003), buspirone (15–50 mg/day) (Salzman 2001), carbamazepine (400–1,200 mg/day; maximum blood levels: 8–12 ng/mL) (Olin et al. 2001a), and gabapentin (400–1,200 mg/day) (L.J. Miller 2001). These medications may be particularly useful in cases of DLB because the likelihood of severe adverse side effects with the use of neuroleptics is quite high (McKeith et al. 1992). Anticonvulsants require close monitoring because of potential toxic effects. Several other agents have been proposed for the treatment of agitation in patients with dementia, including benzodiazepines and beta-blockers, but evidence of efficacy is very limited, and potential side effects preclude routine recommendation.

Treatment of Depression

Both well-designed studies (Lyketsos et al. 2003) and reviews of randomized controlled trials (Olin and Schneider 2002) suggest that antidepressants may be effective for treating depressive syndromes in patients with dementia. However, because antidepressants do have side effects, clinicians should prescribe with due caution (Bains et al. 2002). The newer antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs), are widely considered to be first-line treatment and should be preferred because of their favorable side-effect profile (Giron et al. 2001). SSRIs used in dementia include fluoxetine (initial dosage 5–10 mg/day, increase at several-week intervals to 40–60 mg/day); paroxetine (same dosages, increase every 1–2 weeks because of shorter half-life); sertraline (initial dosage 25 mg/day, increase at 1- to 2-week intervals to 150–200 mg/day); and citalopram (initial dosage 10 mg/day, increase at weekly intervals to a maximum dosage of 40 mg/day). Escitalopram (10–20 mg/day) is promising (Lepola et al. 2003). Aside from well-known gastrointestinal symptoms, some potential SSRI side effects, such as agitation, akathisia and other extrapyramidal symptoms, dizziness, and weight loss, require monitoring in dementia patients. Venlafaxine (initial

dosage 18.75–37.50 mg twice a day, increase at weekly intervals to 350–375 mg/day) is also recommended, particularly in apathetic patients because of stimulating effects, but it may elevate blood pressure at higher doses. Bupropion (initial dosage 37.5 mg/day, increase slowly to a maximum of 300 mg/day) and mirtazapine (initial dosage 7.5 mg at bedtime, increase slowly to a maximum of 45–60 mg at bedtime) have similarly been recommended. Trazodone (initial dosage 25–50 mg/day, increase at weekly intervals to 300–400 mg/day) is often recommended when sedation and improved sleep are desired. Trazodone's main risks in elderly patients with dementia are orthostatic hypotension and excessive sedation. In depressed patients with FTD, both SSRIs (Swartz et al. 1997) and trazodone (Lebert et al. 1999) have shown some benefit.

Classic cyclic antidepressants usually are not considered first-line treatment because they have more adverse effects such as orthostatic hypotension, delays in cardiac conduction, anticholinergic effects, impaired cognition, and delirium. However, some clinicians prefer these drugs, particularly in treating severe depressive syndromes. In such cases, because of a more favorable side-effect profile, the recommended drugs are nortriptyline, particularly when sedation is needed (initial dosage 10–25 mg/day, increase at weekly intervals to 100–150 mg/day; blood levels should not exceed 100–150 ng/mL), and desipramine (initial dosage 25–50 mg/day, increase at weekly intervals to 200 mg/day; blood levels should not exceed 150–200 ng/mL).

Evidence is limited on the beneficial effects of other drugs recommended in the treatment of depression-associated symptoms in dementia patients, such as buspirone for the treatment of agitation and anxiety associated with depression.

Psychostimulants, such as D-amphetamine and methylphenidate, are sometimes useful in patients with medical illness and depression, but few data are available regarding their use in DSD. Potential side effects of restlessness, agitation, sleep disturbances, and appetite suppression are uncommon at low doses. Apathy in depressed dementia patients also has been treated with bromocriptine and amantadine, but potential side effects include psychosis, confusion, dyskinesias, and anticholinergic effects, including delirium. Bupropion and psychostimulants also have been used to treat apathy (Herrmann et al. 2008). Clinical experience suggests that electroconvulsive therapy (ECT) may be useful in treating severe depression associated with dementia that does not respond to drugs, but the data are limited. In such cases, ECT should be given twice rather than thrice weekly, and less memory loss has been documented with unilateral than with bilateral placement of electrodes (American Psychiatric Association 2001; Rabins et al. 2007) (see also Chapter 40, "Electroconvulsive Therapy").

Treatment of Insomnia and Anxiety

Sleep disturbances, which are frequent in patients with dementia, should be primarily managed by careful attention to sleep hygiene. When the disturbances occur in patients with other neuropsychiatric symptoms requiring psychotropic treatment, a drug with sedating properties, given at bedtime, probably should be selected. Otherwise, trazodone (50–100 mg, once at bedtime) is often prescribed. Clinical experience suggests that low-dose antipsychotics (haloperidol 0.5–1.0 mg or the atypical antipsychotics) can be helpful. Zolpidem (5–10 mg at bedtime) and zopiclone (5–10 mg at bedtime) are good alternatives for short-term use. Clonazepam (0.5 mg/day, with increases in dosage up to 2 mg/day) is recommended by some clinicians in patients with frequent awakening or nocturnal wandering. However, all hypnotics have the potential risk of causing nocturnal confusion, daytime sedation, tolerance, rebound insomnia, worsening cognition, disinhibition, and delirium. Triazolam is not recommended because of its association with amnesia. Many patients use diphenhydramine because it is available in a variety of nonprescription preparations and therefore is erroneously believed to be safe. It is not a good choice because of its anticholinergic properties, which may exacerbate confusion and also counteract the effects of cholinesterase inhibitors.

The use of benzodiazepines for anxiety in patients with dementia is controversial because of the side-effect profile described, which also includes ataxia and falls, respiratory depression, and agitation among the most disturbing effects in dementia patients. Low dosages of relatively short-acting drugs, such as lorazepam (0.5–1.0 mg every 4–6 hours) or oxazepam (7.5–15.0 mg four times per day), are preferred when using benzodiazepines and may be beneficial for brief periods. Antidepressants should be considered for long-term treatment, but empirical evidence is very limited regarding their use for anxiety in dementia patients.

Treatment of Cognitive Deficits

Pharmacological treatment of DAT also should aim at restoring cognitive function and associated functional losses (Farlow and Boustani 2009). Currently, the main drugs approved act by inhibiting acetylcholinesterase and thus providing cholinergic augmentation. They may improve cognitive and behavioral symptoms, as well as functional ADLs, although the degree of benefit achieved is limited or symptomatic (see Cochrane reviews in Table 6–13; Birks and Harvey 2006) with little proven effect on the ultimate outcome. Tacrine, which was approved for treating DAT in 1993, has since been replaced by a group of drugs with fewer adverse effects, which include donepezil, rivastigmine, and galantamine (Mayeux and Sano 1999).

Donepezil used to be the most widely prescribed cholinesterase inhibitor, probably because it was the first one to appear (Organization for Economic Cooperation and Development 2002). More adverse effects with rivastigmine and galantamine had been encountered by clinicians, but they were minimized by careful dose titration. Furthermore, the new transdermal patch for rivastigmine (dosage 4.6–9.5 mg released per 24 hours once a day) and extended-release capsules of galantamine (8–24 mg) now available make all three drugs equally easy to use. Cost-effectiveness analysis of cholinesterase inhibitors supports their use (Loveman et al. 2006), but medical guidelines in many countries recommend that cholinergic augmentation therapy be used only in patients with mild to moderate forms of DAT (MMSE score >10 or 12 points or an equivalent score on the ADAS—cognitive subscale; Gillen et al. 2001). However, the U.S. Food and Drug Administration (FDA) has recently approved donepezil for treatment of severe cases of DAT (Rabins et al. 2007). Positive results also have been documented in moderate to severe cases of DAT with memantine (Reisberg et al. 2003) (see Table 6–13). It blocks the effects of glutamate in stimulating the *N*-methyl-D-aspartate receptor. A Cochrane review concluded that the evidence to date shows that in moderate to severe DAT, memantine improves measures of cognition and functional decline but does not effect clinically discernible change or improve global measures of dementia (Areosa Sastre et al. 2004). Some evidence indicates that the combined administration of cholinesterase inhibitors and memantine may be more effective than either one of the drugs alone (Fillit et al. 2006; Grossberg et al. 2006).

Cholinesterase inhibitors show some promise in the treatment of other dementias, such as DLB (McKeith et al. 2000) and Parkinson's disease (Maidment et al. 2006). Rivastigmine has been approved by the FDA for Parkinson's disease (Rabins et al. 2007).

An antioxidant, vitamin E (200–2,000 IU/day), was in the past recommended for DAT patients to prevent further decline. However, a systematic review found limited evidence to support its use (Isaac et al. 2008), and doubts have been raised about the safety of such doses (E. R. Miller et al. 2005) for treatment of DAT.

Positive results with a wide variety of agents to treat DAT have been reported, and systematic reviews support the benefits of nimodipine (90 mg/day), a calcium channel blocker (López-Arrieta and Birks 2000); nicergoline, an ergot derivative (Fioravanti and Flicker 2001); and selegiline, a monoamine oxidase-B inhibitor (Birks and Flicker 2003). Selegiline (5–10 mg/day) may delay cognitive deterioration and may be worth considering in patients who are intolerant of, or unresponsive to, cholinesterase inhibitors. At this dosage, it requires no dietary limitations as with other

TABLE 6-13. Drug treatments for cognitive and functional losses in dementia of the Alzheimer's type (DAT): Cochrane System Reviews

Drug	Effectiveness ^a	Cognitive ^a	Behavioral ^a	ADL ^a	Indications in DAT	Dosage	Mechanism of action	Side effects
Donepezil ^b	++	++	++	++	Mild or moderate	5-10 mg once daily	AChE inhibitor	Nausea, vomiting, diarrhea
Rivastigmine ^c	++	++	++	++	Mild or moderate	1.5-6 mg twice a day	AChE, BChE inhibitor	Nausea, vomiting, diarrhea
Galantamine ^d	++	++	++	++	Mild or moderate	4-12 mg twice a day	AChE inhibitor	Nausea, vomiting, diarrhea
Memantine ^e	+	++	+	+	Moderate or severe	10-20 mg twice a day	NMDA antagonist	Agitation, urinary incontinence

Note. AChE = acetylcholinesterase; ADL = activity of daily living; BChE = butyrylcholinesterase; NMDA = N-methyl-D-aspartate.

^a++ = evidence considerable; + = some evidence, limited number of controlled trials.

^eAroosa Sastre and Sherriff 2004; McShane et al. 2006.

monoamine oxidase inhibitors, but a major side effect is orthostatic hypotension.

Beneficial effects have been claimed, but not proven, with several agents, including statin therapy to lower serum cholesterol (Scott and Laake 2001); dehydroepiandrosterone (Huppert and Van Niekerk 2001); estrogen replacement therapy in postmenopausal women (Hogervorst et al. 2002); and ginkgo biloba, an extract of the leaves of the maidenhair tree (Birks et al. 2002; DeKosky et al. 2008). No evidence has been found for the use of Hydergine, an ergoloid mesylate, in DAT (Olin et al. 2001b). Preventive treatment with antihypertensive drugs is also controversial (Feigin et al. 2005; McGuinness et al. 2006), although the results of a large international trial with candesartan in mild hypertension are promising (Lithell et al. 2003). In view of recent findings related to vascular factors influencing the cognitive symptoms of DAT, multicomponent vascular care programs combining pharmacological and non-pharmacological interventions have been designed, but results to date have been negative (Richard et al. 2009).

Finally, systematic reviews do not support the use of indomethacin, a nonsteroidal anti-inflammatory drug (Tabet and Feldman 2002); piracetam, a nootropic agent with effects on increasing oxygen and glucose utilization and probable platelet antiaggregation properties (Flicker and Grimley Evans 2001); lecithin, a major dietary source of choline (Higgins and Flicker 2003); omega-3 polyunsaturated fatty acid (Lim et al. 2006); D-cycloserine, an antibiotic that enhances glutamate function (Laake and Oeksen-gaard 2002); nicotine (López-Arrieta et al. 2001); and folic acid (Malouf and Grimley Evans 2008) or vitamin B₁₂ (Malouf and Areosa Sastre 2003).

Future drugs may strategically aim to retard or prevent amyloid deposition and neuronal degeneration and to stimulate neuroprotection (Cutler and Sramek 2001). The development of experimental vaccines directed against the formation and accumulation of amyloid plaques has shown promise. Strategies include the development of drugs focused on reduction of amyloid beta (A β) production; promotion of the A β degrading catabolic pathway; immunotherapy for A β ; and inhibition of A β aggregation (Hamaguchi et al. 2006).

Drug treatment of mild cognitive impairment is controversial because evidence supporting pharmacological strategies remains limited. Efficacy of nicergoline (Fioravanti and Flicker 2001) and the dopamine receptor agonist piribedil (Nagaraja and Jayashree 2001) has been reported, and results of a meta-analysis support the use of acetyl-L-carnitine (Montgomery et al. 2003). Several long-term clinical trials are still ongoing (antioxidants, nootropics, anticholinesterases). Prevention and disease-modifying strategies raise ethical questions because interventions are fo-

cused on nondiseased elderly at risk, which means that long-term safety should be given disproportionate emphasis compared with efficacy. At present, treatment strategies for DAT could be extrapolated to mild cognitive impairment (Jelic and Winblad 2003). We recommend follow-up and monitoring of individuals with mild cognitive impairment, especially when neuroimaging suggests a high probability of conversion to DAT (see subsection "Neuroimaging and Electroencephalography" earlier in this chapter).

Vascular dementia has no standard treatment (Erkin-juntti 2002), but recently, symptomatic cholinergic treatment has shown promise in both DAT with vascular dementia and vascular dementia alone. However, evidence on the efficacy and safety of the drugs is limited (Craig and Birks 2006; Kavirajan and Schneider 2007). Individual patients might be helped with these drugs, but no general recommendations can be issued. Similarly, limited evidence supports the use of memantine (Kavirajan and Schneider 2007; McShane et al. 2006; Rabjns et al. 2007), nicergoline (Fioravanti and Flicker 2001), and nimodipine (López-Arrieta and Birks 2000). Evidence is also limited on the primary prevention and secondary prevention of vascular dementia (Roman 2002), but treating associated medical conditions and reducing known cardiovascular and cerebrovascular risk factors seem logical steps. Daily aspirin therapy to inhibit platelet aggregation has been recommended but remains controversial (R. Hebert et al. 2000) and is not supported by the results of a systematic review (Williams et al. 2000). The preventive effects of early treatment of even mild hypertension are also promising for vascular dementia (Lithell et al. 2003), but no convincing evidence has been found so far relating diabetic treatment to the prevention or management of cognitive impairment in type 2 diabetes (Areosa Sastre and Grimley Evans 2002). More studies are needed of the effectiveness and efficacy of prevention and treatment of mild cognitive impairment of vascular origin. In the meantime, good clinical sense recommends symptomatic treatment and control of other treatable risk factors—namely, cardiac disease, hyperlipidemia, obesity, hyperhomocysteinemia, hyperfibrinogenemia, and other conditions that can cause brain hypoperfusion, such as obstructive sleep apnea and orthostatic hypotension (Frisoni et al. 2002). Psychiatrists can play a prominent role in treating and preventing smoking and alcohol dependence. Genetic counseling may be considered in diseases of genetic basis, such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy.

Psychological Treatment

Two main goals may be identified in the psychological treatment of dementia: providing support and modifying

behavior. Few psychological treatments have been subjected to systematic evaluation, but some research, including single-case studies, along with clinical experience, supports their effectiveness. The supportive techniques are based on the recognition that deterioration of cognitive function and sense of identity has significant psychological meaning for patients with dementia and may be associated with high levels of distress. There is some overlap with cognitive-behavioral techniques because the support is often accompanied by educational measures in which the nature and course of their illness are clearly explained. Psychiatrists also can assist patients and teach other staff to find ways to maximize functioning in preserved areas and to compensate for the defective functions. This includes simple maneuvers, such as taking notes for memory problems or making schedules to help structure activities into a daily routine. In this way, patients with dementia may have a predictable schedule and avoid undue distress, including catastrophic reactions when confronted with unfamiliar activities or environments.

Behavioral treatments are often focused on specific cognitive deficits, and different strategies have been devised. Reality orientation operates through the presentation of orientation-related information (e.g., time-, place-, and person-related), which is thought to provide the person with a greater understanding of his or her surroundings. A systematic review found evidence that reality orientation has benefits for both cognition and behavior in dementia (Spector et al. 2000a). Cognitive stimulation therapy has been reported to have benefits for cognition and may be more cost-effective than treatment as usual (Knapp et al. 2006). Observational studies give some support to other strategies, such as recreational activity, art therapy, dance therapy, and pet therapy. Reminiscence therapy tries to stimulate the patient to talk about the past. Beneficial effects on the patient's mood and/or behavior have been reported with this technique, but the evidence in systematic reviews is limited (Chung et al. 2002; Spector et al. 2000b). Similarly, evidence is insufficient on the effectiveness of other techniques, such as validation therapy (Neal and Briggs 2000).

Family Support and Social Care

The fate of dementia patients is determined to a large extent by their social framework (Organization for Economic Cooperation and Development 2002). Psychiatrists and other providers should pay attention to the family and social structures, community supports, and the potential need for residential treatment. Strong evidence suggests that informal (i.e., family) caregivers very frequently have psychiatric morbidity and possibly also medical morbidity related to the burden of caring for patients with dementia

(J. Schneider et al. 1999). Empathic interventions may help them understand the complex mixture of feelings associated with caring for a loved one with a dementing illness. The effectiveness of techniques aimed at improving management of patients with dementia and coping strategies has been reported (Selwood et al. 2007). Referral to support groups is often indicated, and associations of families of patients with dementia exist in many countries and often provide critical support. Education, counseling, and support for family caregivers of DAT patients have been shown to improve the outcomes for both caregivers and patients (Olin and Schneider 2002) and to decrease the likelihood of placing a spouse in a nursing home (Cohen and Pushkar 1999). A book that has been very helpful for family and other caregivers is *The 36-Hour Day* (Mace and Rabins 2006).

Care Provision

Mental health facilities that specialize in treating dementia are varied. Psychiatrists should participate in supporting access to quality care, but no consensus currently exists about what constitutes quality care and how to assess care provision (Innes 2002). Social service referrals are very helpful to inform the family about available resources. Special care units for patients with dementia may offer models of optimal care, but no empirical evidence indicates that this type of unit achieves better outcomes than do traditional facilities.

The most common facility to care for patients with dementia is the memory clinic (Colvez et al. 2002). Such clinics gain value when attached to a psychosomatic medicine/consultation-liaison service, particularly when liaison is developed with primary care (A. Lobo and Saz 2004). Community resources include home health services, day care, or nursing homes. Shortage of nursing home beds is reported in most countries, so residential care remains important and in demand (Organization for Economic Cooperation and Development 2002). Geriatric day hospitals provide multidisciplinary rehabilitation in an outpatient setting. A review of studies documented a significant difference in favor of day hospital attendance when compared with no comprehensive elderly care (Forster et al. 2000). However, the general move toward an increased emphasis on community care is also dependent on the availability of informal caregivers. Respite services are considered very important for informal caregivers, although their effectiveness remains inconclusive.

Long-term care of patients with dementia presents special problems. Delirium, a frequent complication in institutionalized elderly patients with dementia, is discussed in Chapter 5, "Delirium." Another common complication is wandering. DAT patients may, at times, put themselves at risk, creating difficult challenges for caregivers and institu-

tional staff. Traditional interventions to prevent wandering include restraint, drugs, and locked doors. Because cognitively impaired patients may respond to environmental stimuli in different ways, new techniques that might reduce wandering include the design of visual and other selective barriers, such as mirrors and grids or stripes of tape. However, a systematic review has found no evidence that these techniques are effective (Price et al. 2000).

Overuse of medication in long-term institutionalized patients can lead to worsening of the dementia and to harmful side effects. Available alternatives, such as the search for medical, psychiatric, or environmental factors that may be causing agitation or behavior problems, are discussed in a previous section of this chapter ("Epidemiology, Etiology, and Risk Factors") and should be pursued. However, if a patient's behavior is dangerous, psychotropic medications should be used, and additional measures may be needed if no response occurs. Use of physical restraints should be limited to patients with imminent risk of physical harm to themselves or others and only until more definitive treatment is provided or after other measures have been exhausted (or pose greater risk to the patient). Good clinical practice and legal regulations in some countries require careful consideration and documentation of the indications and available alternatives, monitoring of the response, and reassessment of the need for treatment. Structured educational programs for staff may decrease both the abuse of tranquilizers and the use of physical restraints in the institutionalized elderly.

Aggression and Violence

Chiadi U. Onyike, M.D., M.H.S.

Constantine G. Lyketsos, M.D., M.H.S.

AGGRESSION IS UBIQUITOUS in human societies. As an adaptive behavior, it serves the expression of drives and feelings that are intimately connected with survival needs. Aggression is a complex socialized behavior associated with motivations such as self-preservation (which includes protection of offspring), retaliation, material advantage, and power. Thus, in some circumstances, aggression represents the expression of appetitive drives, and in others, it represents defensive behaviors. In an “everyday” perspective, aggressive behaviors range from assertiveness to coercion (including the use of force) and from hostile attitudes and verbal abuse to threats, belligerence, and violence.

Generally psychiatry is concerned with forms of aggression that can be attributed to medical or psychological disorders. Within this narrower context, aggression still encompasses a broad range of behaviors. In this chapter, we cover those aggressive behaviors that are associated with psychiatric, neurological, and general medical conditions. The focus is on fear-inducing and violent behavior: hostility, verbal abuse, and physically aggressive behaviors that threaten or inflict harm on an individual or an object. Definitions of aggression, violence, and related terms used in this chapter are presented in Table 7-1. Although most aggression involves intent to harm, the definition used in this chapter does not require such intent because clinically important aggressive behavior can occur in the absence of demonstrable intent, especially in patients with cognitive impairments, delirium, dementia, or mental retardation. Not included here are behaviors that may be characterized as *agitation*, such as yelling, screaming, and other non-threatening verbal outbursts; oppositional and resistive behaviors; intrusiveness; and restlessness, pacing, and

other hyperkinetic behaviors. We also do not address community violence (e.g., riots, war, terrorism) or criminality.

Psychiatrists primarily encounter aggression and violence when patients present for treatment in acute states. Aggression may manifest as a complication of delusional psychoses, dementia, agitated delirium, intoxication, conduct disorder in children or personality disorders (particularly antisocial, borderline, paranoid, and narcissistic types) in adults, and even adjustment disorder. Aggression also may complicate nonpsychiatric illnesses because it can develop when patients feel disregarded, dissatisfied, frustrated, confused, frightened, thwarted, disenfranchised, and angered by perceived unfairness or mistreatment, or as a “primary” symptom of the illness. Aggression can manifest in both males and females and in individuals of any age (except early infancy) and is seen in all patient care settings—outpatient clinics, inpatient units, rehabilitation programs, residential and custodial care facilities, nursing homes, and emergency departments. Aggressive behavior can result in involuntary confinement (in hospitals and jails), disruption of clinical and custodial care environments, longer hospital stays, and physical injury to patients, their caregivers (family and aides), and their health care providers. Family members, home health aides, and health professionals who are repeatedly exposed to aggression often experience demoralization, which leads to diminished quality of care for patients.

In this chapter, we focus on aggression and violence in the medically ill, beginning with the epidemiology of aggressive and violent behaviors in diverse clinical settings, including risk factors and the causes and precipitants of aggression; we use the epidemiological causal model of

TABLE 7-1. Terms used in this chapter

Aggression	Hostile, threatening, and violent behaviors directed at another person or objects, often with no (or trivial) provocation
Violence	Overt physical aggression directed at another person or object
Domestic violence	A continuum of behaviors directed against an intimate partner, ranging from verbal abuse, to threats and intimidation, to sexual assault and violence
Agitation	A state of pathologically intense emotional arousal and motor restlessness
Disinhibition	A behavioral state in which the individual's capacity for preemptive evaluation and restraint of behavioral responses is decreased or lost
Impulsivity	A behavioral state characterized by a proneness to act without thought or self-restraint; a habitual tendency toward "hair trigger" actions
Irritability	A state of abnormally low tolerance in which the individual is easily provoked to anger and hostility

host, agent, and environment. We also discuss elder abuse and intimate partner violence, which are not necessarily manifestations of illness but are important causes and correlates of psychiatric and medical morbidity. (Because our focus is on adults, we do not address child abuse in this chapter.) We then review evaluation, case formulation, and differential diagnosis of aggression. We conclude with a review of the management of aggressive behavior in the general hospital setting, including the emergency department. The content of this chapter is based on empirical evidence, existing care standards, and clinical experience.

Epidemiology

Violence is common among individuals with psychiatric disorders. A 1990 community-based study found that 55.5% of the respondents who reported violent behavior in the previous year had a psychiatric diagnosis, compared with 19.6% of the nonviolent respondents (Swanson et al. 1990). In that study, 8.9%–21.1% of the men and 3.3%–21.7% of the women who had a psychiatric diagnosis reported violent behavior, in contrast to 2.7% of the men and 1.1% of the women who did not have such diagnosis. The association was lowest for anxiety disorders and highest for substance use disorders, major affective disorders, and schizophrenia. More recent data indicate that violence is not the inevitable outcome of mental illness. For example, analyses of longitudinal data on mental disorders and violence collected during the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) indicated that mental illness alone did not predict future violent behavior (Elbogen and Johnson 2009). Future violence (measured by self-report) was instead associated with various clinical factors (substance abuse and perceived threats), demographic factors (age, sex, and income), historical factors

(past violence, juvenile detention, physical abuse, and parental arrests), and social factors (recent divorce, unemployment, history of victimization). These findings indicate that violence among individuals with mental illness is not merely a phenomenon of the illness; rather, the causal relationships are "complex, indirect and embedded in a web" of pertinent personal and contextual factors (Elbogen and Johnson 2009). Other research has found that individuals with severe mental illness attending crisis and inpatient services, and sometimes clinics, are more frequently the *victims* of violence rather than the perpetrators (Choe et al. 2008; Mericle and Havassy 2008).

Whereas most mental illness does not result in violent behavior, subgroups with high potential for aggressive and violent behavior have been described. Violent behavior has been observed in specific clinical conditions, particularly schizophrenia (and other primary psychoses), substance abuse, and personality disorders (antisocial, borderline, paranoid, and narcissistic) (Biancosino et al. 2009; de Barros and de Pádua Serafim 2008; Elbogen and Johnson 2009; Eronen et al. 1998; Fazel et al. 2009; Pulay et al. 2009). Violent behavior has also been observed in primary dementia (Kalunian et al. 1990; Lyketsos 2000) and cognitive disorder resulting from head trauma (Hesdorffer et al. 2009; Rao et al. 2009). Violence is also associated with specific states, such as confusion, intoxication (with alcohol or other substances), akathisia, fearfulness, agitation, paranoid delusions, and command hallucinations (McNiel et al. 2000; Swanson et al. 2006). While the presence of delusions does not necessarily indicate a higher risk for violent behavior (Appelbaum et al. 2000; Colasanti et al. 2008), psychotic illness concurrent with substance use appears to increase synergistically the risk of violent behavior (Elbogen and Johnson 2009).

Although men are generally more aggressive than women, the gender gap in the frequency and severity of ag-

gressive behavior narrows among individuals with major mental illness and may disappear among psychiatric inpatients and patients recently evaluated in the emergency department (Lam et al. 2000; Newhill et al. 1995), although this is not a consistent observation. There is evidence that a gender gap may exist for serious violence, such as assault, but not for lesser forms of aggression, such as threats (Hiday et al. 1998). Other psychosocial correlates of aggression include childhood conduct disorders (Hodgins et al. 2008; Swanson et al. 2008), onset of psychiatric illness at a younger age, previous violence, longer duration of hospitalization (Amore et al. 2008; Bobes et al. 2009; Elbogen and Johnson 2009), and treatment nonadherence and resistance, particularly among patients with psychotic illness (Ehmann et al. 2001; Swartz et al. 1998). Social and functional maladjustment can accentuate background risk for aggression and violence, particularly in patients with psychotic illness (Swanson et al. 1998). Ecological factors such as overcrowding, sensory overload, provocation by other patients, high staff anxiety, poor training, rigid rules, and insensitive staff attitudes and communication styles can predispose psychiatric inpatients to anger and violence (Flannery 2005; Hamrin et al. 2009).

All health care professionals, regardless of training and specialty, may encounter aggressive or violent patients. Aggression has been observed in all ambulatory, hospital, and custodial (or residential) settings, with the frequency generally varying according to the specific population (e.g., diagnostic mix, acuity levels) and the characteristics of the setting (e.g., crowding, staffing levels). Within settings, the frequency of violence may vary by the illness, its acuity and severity, or the mode of presentation of the patient. Aggression is especially common in emergency care settings, where there is typically a confluence of risk factors (e.g., high acuity, high emotions, crowding, overextended staff) to promote its development. Emergency medical services (EMS) personnel, the first responders for community emergencies, must stabilize and transport patients to the emergency department and are therefore at high risk for exposure to violence. It has been estimated that 8.5% of EMS encounters involve aggression (Grange and Corbett 2002); about half of these encounters involve violence. Patients were responsible for 90% of the incidents, and relatives and other bystanders for the remainder. Encounters that involved males, police presence, street gangs, suspected psychiatric disorder, and abuse of alcohol or other substances carried high risk for aggression incidents. Up to 95% of EMS personnel have had to restrain a patient, and more than 60% have been assaulted (with 25% reporting injury from the assault) (Corbett et al. 1998). Other studies have reported similar or higher prevalence estimates of assault and injury (Mock et al. 1998; Pozzi

1998). In the past, the risk to EMS workers exposed to aggression was compounded by limited formal training on how to manage aggressive patients and lack of counseling in the aftermath of an assault. Since 1998, these training needs have been met with comprehensive training curricula developed by the U.S. Department of Transportation.

Aggression in the emergency department (ED) may manifest as threats, belligerent confrontations, assault, and stalking and is especially common in large EDs (i.e., those with volumes of 60,000 or more cases annually) (Behnam et al. 2010). Surveys of such large EDs have shown that staff are threatened by patients every day, that use of restraints is frequently necessary, and that nearly 50% of these facilities have one or more staff members assaulted each month (resulting in injury in 25% of cases) (Blanchard and Curtis 1999). For many patients, the agitation, aggressiveness, or violent behavior may be the reason that they have been brought to the ED, whereas for other patients who were not agitated or aggressive on arrival, threatening and violent behavior may develop as a result of their acute condition or other factors. Furthermore, some patients have guns, knives, or other weapons in their possession when they arrive (Kansagra et al. 2008), which signals a general predisposition to violence. Although health professionals (especially nurses) are the typical victims of patient aggression, sometimes a visitor or another patient is assaulted. In still other cases, a family member or other visitor, not the patient, is the perpetrator of an aggressive act. More recent information, based on retrospective data, indicates that assailants are more likely to be male patients, repeat offenders, residents of deprived communities, and intoxicated (James et al. 2006). Other contributing factors include involuntary transport to the ED; negative perceptions of hospital staff; inadequately trained and/or overextended staff; crowding, noise, discomfort, and long waits; and inadequate security.

Aggression is common beyond the ED, in a variety of inpatient settings. Of the estimated 20% of general hospital staff assaulted by patients, up to 90% of incidents may occur in inpatient units (Whittington et al. 1996). In hospitalized patients, aggressive acts may occur as features or complications of confusion associated with the patients' primary conditions (e.g., thyroid storm, head injuries, hypoxia, encephalitis) or administered treatments (e.g., benzodiazepines or corticosteroids) or may result from co-occurring mental illness. On surgical units, aggression may result from confusion during the immediate postoperative period, undiagnosed alcohol withdrawal, or inadequately controlled postoperative pain. Aggression in the general hospital may also evolve from patients' dissatisfaction with care or frustration from unfulfilled wants and expectations or during patient and staff conflicts.

In a recently reported survey of intensive care units (ICUs) in England and Wales, nurses were subjected to verbal hostility by patients in 87% of the ICUs and by patients' relatives in 74% (Lynch et al. 2003). Nurses were assaulted by patients in 77% of the ICUs, and by patients' relatives in 17%; rates of hostility and assault directed at physicians were lower. Illness severity was associated with aggression committed by patients, whereas emotional distress, alcohol abuse, and sociopathic traits were associated with aggression committed by relatives. A similar pattern of aggressive behaviors may be seen on general medical and surgical wards, although the frequency of aggressive behaviors (particularly those committed by relatives) is likely to be lower.

Substance abuse and sociopathic traits among inpatients may contribute more to aggressive behaviors in hospital wards (as compared with aggression in ICUs). Individuals are more likely to show negative affects and personality traits during times of high stress, including serious medical illness; thus, patients with personality styles high in impulsivity, distrust, and aggressiveness (particularly antisocial or borderline personality disorders) may be more likely to commit violent acts during hospitalization. Substance abusers experiencing withdrawal symptoms or intense cravings are frequent perpetrators of in-hospital aggression. Nicotine dependence can also be a factor; smoking is no longer allowed in hospitals, and although nicotine withdrawal and craving are unlikely to directly cause violence, they can provoke or inflame conflict between patients and staff.

Aggression has serious consequences for patients and for those who care for them. These include disruption of the care environment, longer duration of hospitalization, higher treatment costs (Greenfield et al. 1989), and stigmatization of the mentally ill and their caregivers. Patients may sustain injuries, for example, from punching walls or glass, handling dangerous objects, falling, fighting with another patient, or resisting restraint. In addition, inpatients who are prone to impulsive aggressive acts tend to be at higher risk for flight (Bowers et al. 2000) and impulsive suicidal acts (Giegling et al. 2009).

Although all health care personnel are at risk for injury, nurses and clinical assistants are by far the most likely to be injured by violent patients (Hillbrand et al. 1996; Salerno et al. 2009; Whittington et al. 1996). Patient aggression results in demoralization, physical and psychological disability, absenteeism (as a result of sick days and disability), and job departures among nurses (Gerberich et al. 2004; Nachreiner et al. 2007), as well as higher administrative costs and litigation exposure for the care facility. Violence from patients can cause staff to adopt negative attitudes toward their work and their patients, resulting in

impaired job performance, poor patient-staff relationships, and patient dissatisfaction with care; the myriad negative effects on the treatment environment and the overall quality of patient care can lead to a vicious cycle in which a deteriorating environment promotes yet more violence (Arnetz and Arnetz 2001).

Mechanisms of Aggression

Aggression and violence can be categorized as impulsive or premeditated. *Impulsive* aggression is spontaneous behavior that is typically reactive, emotion laden, and sometimes explosive, whereas *instrumental* (or *premeditated*) aggression is purposeful, controlled behavior that may be predatory (committed for material or strategic advantage) or pathological (a deliberate response to misperceptions, hallucinations, or delusions). Generally, patients manifest predominantly impulsive or predominantly instrumental aggressive behaviors. Instrumental aggression is typically pathological, but patients with antisocial or borderline personality disorders frequently manifest predatory behavior. Impulsive aggression may be associated with cognitive deficits, psychotic states, and high emotional sensitivity and is usually accompanied by autonomic arousal (Nelson and Trainor 2007; Siever 2008). Instrumental aggression, on the other hand, may be associated with low sensitivity and low autonomic arousal, such as in conduct disorder and antisocial personality disorder (Nelson and Trainor 2007). Impulsive aggression is not necessarily unintentional; rather, it occurs on a *continuum of intention*, depending on the coalescence of individual susceptibility and context, ranging from entirely unintentional reflexive behaviors (e.g., ill-directed shoving and swinging in a patient with postictal confusion) to resistive behaviors (e.g., thrashing, spitting, and biting during placement of lines or tubes in an agitated patient with delirium) to spur-of-the-moment intentional behaviors (e.g., a patient with borderline personality disorder throwing a telephone at the nurse who is scolding her).

From a pathogenetic perspective, aggression is a heterogeneous behavior associated with background genetic, familial, and social determinants. These include unfavorable prenatal, perinatal, and rearing experiences (such as childhood experience of neglect or abuse); genetic determinants; poor education; and negative cultural and peer influences (Volavka 1999). These factors, and others acquired, such as Axis I conditions, brain injury syndromes, and personality disorders, can be viewed as coalescing in the individual to yield a *host* with a baseline propensity for aggression that interacts with specific provocations (*agents*) and occurs in environments or *circumstances* to produce aggressive behaviors. Examples of *agents* include threats by others, misper-

ceptions, conflicts, or physical discomfort. *Circumstances* are contexts, such as intense (or distant) interpersonal relationships, personal losses, or hospitalization for serious illness, that are captured in a narrative that reveals a vulnerable patient's maladaptive interactions with his or her environment. This framework describes the setting and sequence of events leading to an episode of aggressive behavior, while simultaneously placing these events in the context of the specific circumstances and the individual's psychological assets and liabilities.

The *host-agent-context* framework allows for enhanced understanding of any patient and his or her observed aggressive behavior. In some cases, an aggressive episode is the latest in a pattern of recurring impulsive, predatory, or pathological acts, which may (or may not) be associated with identifiable triggers, in an individual with cognitive or emotional vulnerabilities. In other cases, the act may be an easily discerned complication of the patient's primary condition or a not-so-surprising reaction to distressing circumstances.

Consider the following illustrations:

- ◆ Aggression and violence in inpatient settings appear to be relatively frequent in the first 48 hours after admission in acutely psychotic patients and in substance users (Barlow et al. 2000; Sheridan et al. 1990). In contrast, a rapid reduction in the risk of aggression in patients with schizophrenia within a few days after admission also has been reported (Binder and McNiel 1990). Both of these observations are reconciled by realizing that agitation and acute psychosis often lead to more intensive treatment efforts.
- ◆ Substance users may become aggressive soon after admission as a result of the irritability that accompanies a withdrawal syndrome. When treatment for the withdrawal syndrome is prescribed preemptively, the risk for aggression is minimized.
- ◆ Three types of aggressive behavior have been described in schizophrenia (Hodgins 2008): 1) in the first type, antisocial behaviors that develop in childhood or early adolescence, well before the onset of schizophrenia, persist as psychopathic traits; 2) the largest group develop impulsive aggression at the onset of schizophrenia, and this remains a persistent feature of their illness; 3) in a small group, aggression is not observed for years after illness onset, until serious violence manifests as a complication of acute psychosis. Studies suggest that these types show differences in their neuropsychological profiles and brain morphology (Naudts and Hodgins 2006).
- ◆ Patient and staff conflicts—especially those that involve enforcement of rules, denying of requests (e.g., discharge, change in medications, off-unit smoking breaks), and in-

voluntary admission or transfer—can precipitate aggressive acts and violence (Sheridan et al. 1990).

Psychosomatic medicine specialists often encounter recurrent impulsive aggression, which occurs as an inexplicable event or a “hair trigger” response to relatively unimportant stimuli. This form of aggression is usually related to dysfunction of the brain areas involved in the modulation (or suppression) of primitive impulses and drives. It often arises as a consequence of physical illness or injury that directly or indirectly affects these brain areas. It is also true that in the general hospital setting, many episodes of impulsive aggression are not related to physical illness or injury per se but rather arise in an individual in whom impulsivity is a dominant (or prominent) behavioral *trait*—for example, individuals with personality disorders.

The role of the prefrontal cortex in maintaining self-control and prosocial behavior has been recognized for more than a century and a half, ever since the classic case of Phineas Gage (Harlow 1848, 1868), who underwent a dramatic personality change (manifesting as a coarse manner, jocularity, impulsivity, and aggressive outbursts) after sustaining orbitofrontal cortical injury from a projectile. Patients who suffer frontotemporal dementia, a neurodegenerative condition characterized by focal degeneration of the frontal and temporal cortices, frequently manifest a similar phenotype. Acquired antisocial behavior and aggressive behavior has also been observed in adults who suffered injuries of the prefrontal cortex in childhood (Siever 2008). Abnormalities in working memory, abstract thinking, moral reasoning, affective regulation, and behavioral inhibition have been noted in impulsively aggressive patients with antisocial personality disorder or frontal lobe injuries, and in children and adolescents with attention-deficit/hyperactivity disorder (ADHD) or conduct disorder (Brower and Price 2001; Coccaro and Siever 2002; Davidson et al. 2000). Brain imaging studies of impulsively aggressive patients and violent offenders have shown reduced activation in the frontal cortex (Nelson and Trainor 2007). These imaging studies have also shown hyperactivity in the limbic system (particularly the amygdala and cingulate cortex), suggesting that hypervigilance and heightened emotional responsiveness may underlie vulnerability to impulsive aggression, along with low thresholds for activation of fear, anger, and aggressive responses (Siever 2008). In other words, impulsive aggression may arise from a low threshold in the amygdala for activation of negative affects (fear, anger, and aggressive responses) or a failure of the orbitofrontal cortex to suppress negative affects prompted by cues in the environment.

There is considerable interest in the molecular underpinnings of aggressive behavior. Like other complex social

behaviors, aggression involves neural circuits that are modulated by a variety of neurotransmitter signals. The principal neurotransmitters identified with the modulation of aggressive behavior are dopamine, norepinephrine, 5-hydroxytryptamine (5-HT; serotonin), acetylcholine, gamma-aminobutyric acid (GABA), and neuropeptides such as opioid peptides, substance P, cholecystokinin, and vasopressin. It is now well established that low levels of 5-HT are correlated with impulsiveness and aggressiveness (Nelson and Trainor 2007; Siever 2008). Lower cerebrospinal fluid (CSF) levels of the 5-HT metabolite 5-hydroxyindoleacetic acid (5-HIAA) have been found in aggressive psychiatric patients, impulsive violent men (including violent offenders), disruptive and aggressive male children and adolescents and victims of violent suicides (Coccaro and Siever 2002). In animal studies, interventions that increase 5-HT activity by any of a variety of mechanisms (e.g., administration of 5-HT precursors and agonists, inhibition of 5-HT reuptake inhibition) reduce impulsive and aggressive behavior, whereas the opposite behavioral effects can be achieved by lowering 5-HT transmission. Furthermore, pharmacological challenge studies show blunted prolactin response to 5-HT agonist challenge (with buspirone or fenfluramine) in aggressive, antisocial, and suicidal individuals, suggesting deficient 5-HT transmission in these individuals (Siever 2008). Thus, it has been proposed that modulatory control of aggressive behavior by the prefrontal cortex is facilitated by 5-HT, and that disruption of 5-HT neurotransmission may lead to loss of inhibitory control of aggressive behavior.

Dopaminergic neurons, which contribute to a variety of motivated behaviors, may be required for the expression of aggressive behavior, although their precise role in modulating aggression remains unclear (Nelson and Trainor 2007). This requirement is reflected in the effectiveness of D₂-receptor antagonism in ameliorating aggressive behaviors (particularly in patients who are experiencing psychosis), although changes in alertness, autonomic arousal, and locomotor activity may partly explain the effects of these antagonists.

Another catecholamine, norepinephrine, has been linked to irritable aggression, although this is not a consistent observation. High levels of norepinephrine, which characterize states of hyperarousal, appear to facilitate aggression, although antagonists do not reliably reduce aggressive behavior in humans. It has been suggested that patients with blunted noradrenergic responsiveness manifest instrumental aggression, whereas impulsive aggression is associated with low 5-HT activity in association with normal or increased noradrenergic activity (Siever 2008).

Roles for other neurotransmitters are more speculative. Glutamatergic-GABAergic balance may play a role in

the modulation of aggression. It is noted that benzodiazepines, barbiturates, and other modulators of the GABA_A receptor reduce aggression at high doses, although lower doses may produce a disinhibited state and facilitate aggression. Provocation of violent reactions by benzodiazepines is rare. Abnormalities in acetylcholine transmission have been associated with irritability and aggression. Opioid signaling appears to inhibit aggression, as do high levels of vasopressin and oxytocin, neurotransmitters that appear to be biological facilitators of affiliation behaviors (Miczek et al. 2007; Siever 2008). The notion is that affiliation-promoting effects of vasopressin and oxytocin may reduce proneness to mistrust and hostility, thereby minimizing negative attribution bias and threat perceptions in ambiguous or stressful environments.

Evaluation of Aggression

An episode of belligerence and violence in the general hospital setting typically progresses from a specific clinical state—the *setting*—to a *sequence* of events that culminates in the *outcome*—aggressive behavior (see Figure 7-1). Several factors influence the expression of aggression in the clinic or hospital: aggression may occur if the patient has specific symptoms, mental states, adverse effects of medicines, dissatisfaction with care, or conflicts with staff. However, aggression can be prevented, its intensity reduced, or its consequences avoided or minimized by prompt intervention. The clinical progression of aggressive behavior in the general hospital is depicted in Figure 7-1. The choice of intervention depends on the specific situation as well as the case formulation and the specific diagnosis the patient has received.

Elucidation of the *setting–sequence–outcome* progression involves describing the specific aggressive behavior, the sequence of events preceding it, and the symptoms and factors that may be influencing its expression. This approach has been referred to as a “define and decode” strategy (Lyketsos 2000). The effects of the patient’s behavior also should be noted by inquiring about injury to the patient or others, damage to property, disruption of the milieu, and so on. Precipitants such as staff–patient conflicts, end of visiting hours, or recent administration of a medication should be carefully sought, and the history also should clarify the setting in which the behavior has occurred and the temporal relation of the aggressive behavior to any co-occurring symptoms. It is also helpful to know whether the patient is febrile, confused, in pain, craving cigarettes, cognitively impaired or disabled, anxious or fearful, hallucinating or delusional, or if he or she has epilepsy (especially a recent seizure). All prescribed medicines (e.g., insulin, benzodiazepines, anticholinergics, antipsychotics) should

FIGURE 7-1. Clinical progression of aggressive behavior in the general hospital.

be noted. The psychiatrist should systematically search for symptoms such as acute confusion, restlessness, akathisia, or agitation, which require urgent intervention.

In addition to collecting a careful history of the aggressive episode, the evaluation requires describing concurrent illnesses; the patient's personal, social, and family history (including current psychosocial functioning); any substance abuse; and the patient's personality and psychiatric status. General medical, neurological, cognitive, and mental status examinations are focused on describing systems that have been implicated in the history but also should include important "inspections," such as the checking of vital signs, airway and cardiovascular status, exclusion of injuries, repeated assessment of alertness, assessment of dangerousness (inquiring about violent or suicidal ideas), and assessment of reality testing.

In the general hospital setting, laboratory data are often essential for accurate differential diagnosis. Blood tests can help to identify infection, anemia, electrolyte disturbances, or biochemical abnormalities that may explain delirium. Likewise, toxicology screens and serum drug concentrations may help to identify acute intoxications and chronic substance use. Urinalysis, microbiological cultures (of blood and urine), and chest X ray may be helpful in certain circumstances (e.g., in immunosuppressed patients or patients with dementia). If seizures are a possibility, an electroencephalogram (EEG) should be performed. When obtundation, evidence of recent head trauma, or another reason to suspect an acute intracranial event is present, brain imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) should be obtained. In most circumstances, a brain CT is adequate. A

high index of suspicion for intracranial hemorrhage (e.g., subdural hematoma) is appropriate because those who are violent toward others are at higher risk for being victims of violence themselves.

The integration of the clinical data leads to a case formulation and differential diagnosis, as well as a summary narrative that depicts the *setting–sequence–outcome* chain of the aggressive episode (and also articulates the contributions of *host, agent, and circumstance*). The formulation addresses the following questions:

- ♦ Does the patient have a mental illness, personality vulnerability, cognitive impairment, delirium, or other condition that predisposes him or her to aggressive behavior?
- ♦ Is the aggression linked to specific aspects of illness such as psychomotor agitation, disinhibition, command hallucinations, aphasia, or acute pain?
- ♦ Can the aggression be explained by medications causing confusion, akathisia, or intoxication?
- ♦ Is the aggression associated with a specific activity or with interpersonal conflicts?
- ♦ How is the environment contributing to the behavior?
- ♦ Is the environment uncomfortable, noisy, overcrowded, or frightening?

It is also important for psychiatrists to remember that many impulsively aggressive patients have a relatively high risk for suicidal behavior. Several psychiatric disorders manifesting aggressive and violent behavior, particularly alcohol dependence and personality disorders, are associated with suicidal behavior. Thus, the evaluation of aggression also must include an assessment of the risk for self-injury and suicide.

Disorders Associated With Aggressive Behavior

Many disorders can manifest with aggression and violence in the general hospital (Table 7–2). Thus, the psychiatrist's task will include a consideration of these disorders in the differential diagnosis of violent behavior in patients.

Psychoses and Chronic Serious Mental Illness

As noted earlier in this chapter, several major mental disorders can produce violent behavior. Irritable patients with mania, depression, schizophrenia, or other major psychoses may commit impulsive violent acts. This risk for impulsive violence is greatest during acute presentations and is particularly high when patients have been brought to treatment against their will. Clinicians should therefore

maintain high levels of vigilance when evaluating the irritable psychotic patient, especially when the patient is seen in the ED or soon after being involuntarily hospitalized.

Deliberate premeditated violence also can arise from psychotic disorders—usually as a response to delusional beliefs—but generally the content of psychotic patients' delusions is focused on familiar individuals (people in the patients' daily life), public figures, or imaginary persecutors rather than on the health professionals caring for them. It also should be noted that many patients with chronic mental illness have maladaptive coping responses to stress or conflict and thus may react with violence during interpersonal conflicts. Therefore, a crucial aspect of the psychia-

trist's role is to educate nonpsychiatric physicians, nurses, and others caring for these patients. When patients with major mental illness are admitted to nonpsychiatric settings, the psychiatrist's role as consultant should include educating the medical team about the illness (its current status and treatment) and the fact that most such patients can communicate their concerns and symptoms, will cooperate with care, and are nonviolent (even when psychotic). Treatment recommendations should include ways of approaching the patient (e.g., approaching the patient from within his or her visual field and calling out a greeting so that he or she is not startled), ensuring that the patient's current psychotropic regimen is prescribed, and pointing out any known habits or preferences that can be accommodated (e.g., arranging for regular smoking breaks, preferred meals, or a favorite television show). The patient's physicians and nurses should be educated about early signs of agitation, such as pacing, restlessness, staring, and refusal of medications, and contingency plans for managing these symptoms or states should be specified—what behavioral approaches (such as positive reinforcement and pacification) and tranquilization strategies should be used and how the psychiatrist can be contacted when his or her expertise is urgently needed.

Personality Disorders

Violence associated with personality disorders is usually embedded in the individual's behavioral repertoire. Personality disorders that frequently manifest violent behavior are shown in Table 7-2; of these, antisocial personality is the most likely to be associated with habitual aggression. Antisocial individuals usually are thrill seeking, have low frustration tolerance, and have high rates of substance abuse, criminal behavior, and violence. They often present to the ED with injuries resulting from violence (such as stab and gunshot wounds) and with a variety of medical complications of substance abuse (including severe intoxications, wound infections, head injuries, and hepatitis); they often require admission to the medical or surgical ward for treatment of these conditions. Antisocial patients who are intoxicated can become very dangerous because of their mood instability, lowered frustration tolerance, and behavioral disinhibition. While in the hospital, they may become aggressive when their demands—for pain medication, more food, cigarettes, and so on—are not met. In making these demands, they may verbally threaten, intimidate staff with boasts and gestures, or become violent.

Many antisocial patients are repeatedly hospitalized for treatment of problems arising from their lifestyle, especially the medical complications of addictions and risk-taking behaviors. This often arouses resentment and animosity from physicians and nurses, who may believe that

their efforts to care for the patient are unwanted and futile. Health care professionals may be provoked into angry verbal (and, rarely, physical) retaliation. Such patients have earned notoriety from their behavior during earlier hospitalizations, which may put them at risk for punitive interventions such as suboptimal care, inadequate pain treatment, and premature discharge. Staff may understandably prefer to focus care on patients who are seen as cooperative, appreciative, and “innocent victims” of disease. This puts the aggressive antisocial patient at higher risk for missed diagnoses and medical errors. Thus, psychiatrists involved in caring for such patients need to know their reputation on the unit and the feelings of the physicians and nurses caring for them. This information is valuable for formulating a plan of care that ensures adequate evaluation and treatment for the patient and appropriate safeguards for the staff. One of the psychiatrist's responsibilities with such patients is to help physicians, nurses, and other staff appropriately handle their anger and frustration, avoiding both overreaction (e.g., yelling at patients, inappropriate precipitous discharge) and underreaction (e.g., failing to set limits, failing to discharge when indicated). Antisocial patients are not immune to other conditions that may explain aggression, including delirium, substance withdrawal, and psychosis. Therefore, psychiatrists should pursue a systematic psychiatric and general medical assessment whenever antisocial patients are encountered in nonpsychiatric settings.

Borderline personality disorder is characterized by intense emotionality, intense relationships, rejection sensitivity, manipulative behaviors, impulsiveness, recklessness, low self-regard, irritability, aggressiveness, and a tendency to extreme reactions. Most patients with borderline personality disorder are women. Their violent acts usually are impulsive and typically occur during interpersonal conflict. They also have a high potential for self-injury and suicidal acts and thus are often seen in the ED. Borderline patients can be very difficult to manage because they may demand specific conditions or individuals before submitting to an interview or examination. They are capable of angrily refusing care or of violent temper tantrums. Thus, a major challenge in their care is maintaining limits on behavior and managing the intense negative countertransference feelings that they may stir up. In caring for them, psychiatrists must maintain an empathic stance and assist the staff in doing so, often despite deliberate provocation.

Individuals with borderline personality seen in the ED should be screened for depression, substance abuse, and domestic violence because these conditions are highly comorbid. On medical units, borderline patients can become disruptive when their expectations are not met. Psychiatrists should educate their physicians and nurses about the

need to define behavior limits, meet expectations agreed on with the patient, and maintain a consistent approach to the patient's care. This is best accomplished in an interdisciplinary care conference, with the psychiatrist assisting the staff in constructing a written treatment contract to be negotiated with, and signed by, the patient.

Other personality disorders are less frequently associated with violent behavior, although narcissistic individuals may threaten or act (e.g., slap a nurse) in retaliation for perceived slights or to satiate their sense of entitlement, and individuals with paranoid personality disorder may become aggressive in response to perceived mistreatment.

Intermittent Explosive Disorder, Episodic Dyscontrol Syndrome, and Hypothalamic–Limbic Rage Syndrome

Intermittent explosive disorder, episodic dyscontrol syndrome, and hypothalamic–limbic rage syndrome describe disturbances that are characterized by explosive episodes of aggression and violence. *Intermittent explosive disorder*, as defined by DSM-IV (American Psychiatric Association 1994) and its text revision, DSM-IV-TR (American Psychiatric Association 2000), refers to a disturbance characterized by recurrent episodes of explosive anger not explained by psychosis or some other mental disorder. *Episodic dyscontrol* is a similar construct, denoting recurring episodes of uncontrollable rage. It has been used as a label for males who have a history of conduct disorder, unstable employment, poverty, intimate partner violence and other sexual assaults, criminal behavior, and substance abuse (typically alcohol) (Cummings and Mega 2003). Neurological signs such as short attention span, poor coordination, and mild gait abnormalities have been found in some cases; temporal lobe EEG abnormalities also are sometimes seen. Whereas intermittent explosive disorder denotes a relatively narrow clinical spectrum of explosive aggression, episodic dyscontrol refers to episodic, impulsive violence in a broad, ill-defined group of mostly antisocial individuals. Because episodic dyscontrol syndrome overlaps widely with several psychiatric categories (including intermittent explosive disorder, ADHD, conduct disorder, and antisocial personality disorder), it lacks face validity and is of limited clinical usefulness.

Although rare, rage attacks in association with neoplastic and surgical lesions of the hypothalamus and amygdala have been described (Demaree and Harrison 1996; Tonkonogy and Geller 1992). These attacks, which have been repeatedly reproduced in experimental animals with lesion models and neurophysiological methods, have been termed *hypothalamic rage attacks* or *hypothalamic–limbic rage syndrome*. This disorder is characterized by provoked and unprovoked episodes of uncontrollable rage and may represent an acquired form of intermittent explosive disorder.

In addition to rage attacks, patients may have symptoms such as hyperphagia, polydipsia, excessive weight gain, or obesity; clinical findings suggesting thyroid, adrenal, or pituitary disease; a history of recently diagnosed pituitary, midbrain, or temporal lobe tumor; or recent brain surgery. Treatment involves correction of the underlying condition (including surgical resection of tumors) and behavioral and pharmacological approaches targeted at aggression. It should be noted, too, that hypothalamic lesions might be accompanied by “atypical” rage attacks with anxious and social features that suggest multifactorial origins (Savard et al. 2003).

Substance Use Disorders

Alcohol is the psychoactive substance most often associated with violence. Alcohol-related violence may result from a severely intoxicated state that produces gross impairment of self-restraint and judgment and/or a blackout. Pathological intoxication, which occurs in vulnerable individuals following the ingestion of only modest amounts of alcohol, may be associated with disorganized behavior, emotional lability, and violent outbursts. In severe cases, pathological intoxication may be accompanied by a delirium with hyperarousal, hallucinations, delusions, and terror, followed by amnesia for the event after recovery. Alcohol withdrawal also can be accompanied by irritability and low frustration tolerance, which predispose to directed aggression, or by seizures that are followed by aggression during a postictal state. Patients who develop delirium tremens may show poorly coordinated, resistive, or preemptive violence in response to hyperarousal, hallucinations, and terror.

Intoxication with other substances also can result in violence. Cocaine and amphetamine abuse is common and can produce impulsive, disinhibited intoxicated states during which violence may occur. Patients undergoing opioid, sedative, or cocaine withdrawal may experience anxious tension and irritability, during which interpersonal conflict or frustration may result in violent behavior. Although phencyclidine is not commonly abused, phencyclidine intoxication can manifest with severe impulsively directed violence. Even less common is violence that occurs in individuals who have taken Ecstasy, lysergic acid diethylamide (LSD), or other hallucinogens; as an apparent consequence of severe perceptual disturbances; and in patients who abuse anticholinergic agents, in whom delirium may be accompanied by aggressive behavior.

Epilepsy

In evaluating episodes of aggression in patients with epilepsy (see also Chapter 32, “Neurology and Neurosurgery”), psychosomatic medicine psychiatrists must carefully consider whether the aggression is directly related to a seizure,

a feature of mental state changes associated with seizures, or a complication of other conditions that increase the risk of aggressive behavior. In addition, psychiatrists must be aware that certain seizures can be misinterpreted as intentional violent behavior. Violent behavior may be observed during complex partial seizures but never during grand mal seizures.

Ictal violence is rare, and most cases are characterized by spontaneous, undirected, stereotyped aggressive behaviors. Typical characteristics are as follows: 1) the seizure episode occurs suddenly, without provocation, and is of very short duration (usually a few minutes); 2) automatisms and other stereotypic phenomena of the patient’s habitual seizures accompany the aggressive act, and the act is associated with these phenomena from one seizure to the next; 3) the patient’s consciousness is impaired; 4) the aggressive behavior is poorly directed and involves few skills; and 5) purpose and interpersonal interaction are absent (Marsh and Krauss 2000). In practice, it can be difficult to determine whether a violent behavior should be attributed to a seizure event. This determination requires the integration of findings from interview, clinical history, and video EEG monitoring to make the diagnosis. Abnormal nonseizure EEG phenomena (such as sharp waves) are nonspecific findings and should not be used as evidence that violence is ictal. Widely applicable criteria for attributing a specific violent act to an epileptic seizure have been developed (Treiman 1986) and are presented in Table 7–3.

Although uncommon, a prodromal state of affective instability preceding a seizure episode by several hours or days may be associated with directed aggression (Marsh and Krauss 2000). The affective symptoms may be specific to the preictal state or an exacerbation of interictal phenomena; these states and their aggressive features usually resolve after the seizure.

Violent behavior in epilepsy is most frequent during postictal confusional states. These states are usually brief but can vary widely in duration because they are influenced by the type and severity of the preceding seizures. Abnormal moods, paranoia, hallucinations, and delirium may occur and result in violence by heightening aggressive propensities or causing misinterpretations of stimuli in the immediate environment. In general, episodes of postictal violence are longer in duration than episodes of ictal violence, are associated with amnesia for the event, and are out of character for the individual. In some males, stereotypic episodes of severe postictal aggression can occur after clusters of seizures (Gerard et al. 1998). Postictal delirium can be detected clinically by assessing the patient’s level of consciousness and awareness and performing an EEG—which shows diffuse slowing (and no ictal activity). Typically, the delirium is brief, and a gradual return to normal

consciousness follows, but prolonged or repetitive seizures can extend the duration. Violence occurring during postictal delirium is usually relatively undirected; resistive violence is fairly frequent, usually occurring when attempts are made to help or restrain a patient after the seizure.

Many episodes of postictal violence are motivated by a postictal psychosis. The psychosis may emerge from postictal confusion or a lucid state and tends to follow a psychosis-free interval of several hours to a few days after a seizure (or cluster of complex partial seizures) (Marsh and Krauss 2000). Postictal psychosis usually manifests as grandiose affective psychoses (mania or depression with mood-congruent psychotic phenomena) or with thought disorder, hallucinations, and paranoid ideational psychoses reminiscent of schizophrenia. Although usually transient (of no longer than several hours’ duration), these states may last up to several weeks. Postictal psychosis has a tendency to recur and may become chronic. Violence in the context of postictal psychosis may be motivated by paranoid delusions and hallucinations, in which case it manifests as well-directed violence. In fact, violence is more likely to occur in individuals with postictal psychosis, compared with those with interictal psychosis or postictal confusion (Kanemoto et al. 1999). Most episodes of postictal psychosis resolve spontaneously or following treatment with low doses of an antipsychotic, and improved control of the epilepsy then becomes the focus of treatment. However, some patients require chronic maintenance treatment with antipsychotics (see also Chapter 10, “Psychosis, Mania, and Catatonia,” and Chapter 32, “Neurology and Neurosurgery”).

Most violent behaviors in patients with epilepsy have no particular association with ictal or postictal states. For example, studies that report higher prevalence rates of epilepsy in prisoners than in nonprisoners rarely identify connections between criminal acts and specific seizure episodes, and prevalence rates for epilepsy are not higher in

violent criminals than in nonviolent criminals (Treiman 1986). Thus, the increased risk for violence in prisoners who have epilepsy can be attributed to other factors such as cognitive dysfunction and adverse social circumstances. The assessment of violence in patients with epilepsy should therefore also elicit a contextualized description (*setting–sequence–outcome*) of the act and other biological and psychosocial factors that may mediate the expression of aggression. These forms of aggression are well directed and are associated with stressors and triggers. They typically occur around other people and are purposeful, nonstereotyped, and highly coordinated. The aggression is “explained” by the situation at hand, is associated with the buildup of negative emotions concerning some circumstance, and may be of relatively prolonged duration.

Brain injury and cognitive impairment are important risk factors for interictal aggressive behavior. In addition, interictal psychiatric phenomena, such as depression, hallucinations, and delusions, and sociopathic personality traits, such as impulsivity, remorselessness, self-absorption, and superficiality, also predispose patients with epilepsy to aggressive behavior. Furthermore, violence can be learned behavior in patients whose educational and social disadvantages are a correlate or result of their epilepsy.

Delirium

States of heightened arousal often accompany the confusion and fluctuating alertness of delirium and may predispose patients to violent behavior. The presence of hallucinations and delusions also increases the potential for violence in patients with delirium, as it does in patients with epilepsy. The presence of delirium in an aggressive patient should prompt a thorough search for an underlying cause. When ambiguity exists about the presence of delirium, the diagnosis can be established by noting day-to-day variability in scores on the Mini-Mental State Examination (or other short cognitive battery) in a relatively short period (several hours) or by slowed cerebral activity on the EEG. A more detailed discussion of delirium is presented in Chapter 5, “Delirium.”

Executive Dysfunction Syndromes

Executive dysfunction syndromes, more commonly called *frontal lobe syndromes*, are manifestations of brain injury characterized by varying combinations of inattention, impulsivity, disinhibition, emotional dysregulation, absence of insight, impairment of judgment, and diminished initiative (Lyketsos et al. 2004). These frontal-subcortical syndromes result from a range of etiologies, including trauma, infection, neoplasm, stroke, and neurodegenerative disease. Explosive violence is often a feature, particularly in patients in whom impulsivity, disinhibition, or affective

dysregulation predominates. In many individuals with habitual impulsive violence, formal neuropsychological testing indicates deficits in executive cognition (see section “Mechanisms of Aggression” earlier in this chapter); these individuals may be viewed as having occult executive dysfunction syndromes. Further discussion of these syndromes is presented in Chapter 32, “Neurology and Neurosurgery.”

Dementia

Aggression is common in patients with dementia, with the risk increasing with dementia severity, concurrent medical illness, crowding, noise, poor quality of interpersonal relationships, and sleep disorder (Lyketsos 2000). The presence of motor restlessness, depression, hallucinations, misinterpretations, paranoia, or delusions in patients with dementia also should alert the clinician to the risk for aggressive behavior. Type of dementia appears to have limited influence on the likelihood of aggression, even though patients with vascular dementia and Huntington’s disease may be less cognitively impaired than their counterparts with other forms of dementia.

In elders with dementia, aggression generally manifests as relatively simple behaviors such as throwing objects, pushing, shoving, kicking, pinching, biting, and scratching; destruction of property is uncommon (Cohen-Mansfield and Billig 1986). Impulsive, intrusive, aggressive sexual behaviors may be manifest, and intimacy-seeking sexual behaviors may also be complicated by reactive aggression when the patient is thwarted (de Medeiros et al. 2008). It is unusual for elderly persons with dementia to have well-coordinated and goal-directed physical aggression, but such violence does occur and can be serious, especially when committed by younger patients with dementia.

Aggression in patients with dementia often occurs during routine care activities, such as bathing, morning grooming, and toileting. In these situations, the aggression may result from adversarial interactions with caregivers or from unsophisticated caregiving. Thus, it is important for the physician evaluating violence in the patient with dementia to be cognizant of the circumstances of the act and to search carefully for environmental or caregiver factors that may be triggers for aggression. Careful identification of such “external” factors facilitates their removal or modification (see also Chapter 6, “Dementia”).

Developmental Disorders

Violent behavior also occurs in patients with neurodevelopmental syndromes such as mental retardation. Few patients with mental retardation are habitually or impulsively aggressive. However, because many patients with mental retardation also have severe communication or

language deficiencies, they may be prone to temper tantrums and violence when frustrated or in discomfort (e.g., from pain). They are also at increased risk for psychiatric symptoms, such as irritability, impulsivity, disinhibition, and low frustration tolerance, and affective and psychotic conditions, which may occasionally contribute to aggressive behavior.

Domestic Aggression Presenting in Medical Settings

Elder Abuse

Elder mistreatment, in the form of abuse or neglect, may provoke aggression by the mistreated elder. Mistreatment begets aggression, but aggressive elders also are more likely to be mistreated by caregivers, whether at home or in an institutional setting. Psychiatrists must be alert to this possibility and screen for mistreatment if an elder presents with an unusual pattern of agitated behavior—for example, if the elder is only aggressive with a particular caregiver or in a particular setting (e.g., while being bathed or dressed) or if he or she presents with physical signs of mistreatment, such as shin bruises or unexplained persistent skin tears. For a comprehensive discussion of elder mistreatment and how to screen for and manage it, the reader is referred to a review published by the National Academies of Sciences (2003).

Intimate Partner Violence

As understanding of violence during intimate relationships has grown, early terms like *wife abuse* that focused on the battery of married women have become obsolete. It is now widely recognized that violence can occur in marital, cohabitation, and dating relationships; in heterosexual and homosexual relationships; and during separation and divorce. *Intimate partner abuse* refers to emotional, psychological, physical, and/or sexual coercion within an intimate relationship, and *intimate partner violence* (IPV) denotes battery of an intimate partner (McHugh and Frieze 2006).

The majority of victims of IPV are women; it has been estimated that 25% of all women and 14% of all men have suffered a lifetime episode (Breiding et al. 2008). It is estimated that 10%–20% of women have received IPV from more than one partner (Thompson et al. 2006), and the frequency is especially high for younger women, single mothers, those who are poorly educated, and those who suffered abuse in their childhood. IPV is a widespread, cross-cultural problem, with high rates worldwide (Garcia-Moreno et al. 2006). Cultural attitudes may contribute to IPV (Uthman et al. 2009a, 2009b), but individual characteristics such as low education, poverty, abuse of alcohol and other substances, and certain psychological attributes appear to

be more important. Alcohol abuse is common among both perpetrators and victims of severe IPV (McKinney et al. 2010), with a stronger association in clinical than in non-clinical samples (Foran and O'Leary 2009). Perpetrators also tend to have high rates of exposure to IPV during their childhood (Ernst et al. 2009). Perpetrators of impulsive IPV have been found to have more frequent and severe psychopathology than is the case with perpetrators of premeditated IPV (Stanford et al. 2008).

IPV results in high utilization of health care services (Bonomi et al. 2009a), particularly for mental health. These patients are seen frequently in a variety of ambulatory care settings, in the general hospital, and in psychiatry wards. Victims of IPV experience adverse health outcomes besides injury (and death), such as cigarette smoking, asthma, musculoskeletal disease, complications of pregnancy and childbirth, sexually transmitted diseases (including HIV/AIDS), substance abuse, somatoform and conversion disorders, family and social problems, anxiety, and depression (Bonomi et al. 2009b). Exposed children sustain emotional injury living in an environment of domestic aggression and may themselves be victims of accidental or intentional violence. Many of these children will later in life show a wide range of psychopathology and are prone to becoming abusive men and abused women themselves.

Victims of IPV are frequent visitors to clinics and EDs, and although some are too afraid to discuss their experiences with a physician, many are willing. Unfortunately, most cases remain undetected. Several factors account for this, including inadequate training in the detection and management of IPV, physicians' feelings of discomfort and powerlessness, and pressures on physicians to spend less time with patients. A patient's reluctance may derive from negative past experiences, pessimism, low self-confidence, fear of retaliation, or their emotional and/or financial dependence.

Vigilant clinicians can recognize patterns suggestive of IPV, such as repeat visits for vague or minor complaints or chronic pain (especially pelvic), evasive and anxious behavior, inability to recall events leading to the presenting problem, inadequate or baffling explanations for injuries, domineering and obstructionist behavior in a partner, unexplained nonadherence to medication regimens and treatment plans, and findings of child or elder abuse (Eisenstat and Bancroft 1999). In addition, certain physical findings should raise the possibility of battery: injuries to the head, neck, or mouth; multiple injuries; bruises in various stages of healing; defensive injuries of the forearms; dental trauma; and genital injuries. It is prudent to screen for IPV in patients with somatoform, anxiety, and substance abuse disorders and in those with suicidal ideation or attempts.

Routine screening of all women is widely recommended by advocacy organizations and professional associations but has lately become controversial. Many formal screening tools have been developed, but their psychometric properties have not been fully characterized and their effectiveness remains uncertain (Rabin et al. 2009). Victims of IPV may prefer self-completed questionnaires to face-to-face questioning (MacMillan et al. 2006). Computer-based screening approaches can improve rates of screening in the ED (Trautman et al. 2007) but are not likely to be widely implemented. A simpler screening strategy is to incorporate probe questions into the clinical interview. However, two considerations limit the utility of routine screening for IPV: 1) the uncertain reliability of current tools and methods for detecting (or ruling out) IPV (Wathen et al. 2006) and 2) a dearth of data showing that screening reduces violence. The results of a recent large controlled trial indicated that a screening program did not lead to improved outcomes (MacMillan et al. 2009); however, further study is needed, given that sample attrition in the study reached 43%. Also, it is likely that screening must be coupled with structured, individualized psychosocial and mental health interventions to be effective.

In Table 7-4, we provide some sample questions that may be used to initiate the screening process. Incorporating screening questions into the routine interview process can minimize physician and patient discomfort.

When abuse or IPV is identified, descriptions of current, recent, and past battery, including dates and circumstances, should be elicited and carefully documented. Legal intervention may rely on this documentation so the find-

ings should be described in precise language, quoting the specific words spoken by the patient when possible. A complete history and thorough examination should be performed, all injuries should be carefully described (body maps are very useful for this purpose), and photographs should be taken if the patient consents. Strict confidentiality of the disclosure is needed to protect the patient from retaliation; this may require restricted access or sequestration of the disclosure records. On completion of the medical evaluation, a social work evaluation and referral to services such as the National Domestic Violence Hotline (1-800-799-SAFE) and local advocacy organizations should follow. It is usually best to respect the patient's wishes regarding when to report the violence to legal authorities and when to flee the situation. However, in some states, the physician is required by law to make a report. In the United States, mandatory reporting is the norm whenever evidence of child abuse is found (see also Chapter 2, "Legal Issues").

Management of Aggressive Behavior

Education and Relationship Building

Ideally, health care providers and staff have been educated about the management of aggression in the general hospital. This is one component of the psychiatrist's liaison role, performed through seminars, bedside teaching, care conferences, and continuing education. Important content includes recognition of the early signs of incipient aggression (e.g., restlessness, staring, pacing) and behavioral interventions, including verbal de-escalation techniques (nonthreatening approaches such as speaking calmly, using gentle eye contact, adopting a problem-solving stance, and knowing when to disengage), and guidance on when and how to use a "show of force," pharmacological tranquilization, and physical restraint. This teaching serves to broaden the skill set of the medical team members and to increase their confidence in their ability to manage these patients, which can result in fewer aggressive incidents, reduced likelihood of patient or staff injury during episodes, more effective treatment of the underlying conditions, and more productive collaboration in patient care.

Safety of the Environment

The safety of the environment should be ensured before any aggressive patient is evaluated. The psychiatrist should check that actual weapons, such as guns and knives, and potential weapons, such as scissors, belts, and ropes, have been removed. In the ED, this is often accomplished by routinely using hand searches and metal detectors and by keeping any discovered items safely locked away. On inpatient units, monitoring and controlling what the patient

TABLE 7-4. Helpful questions for intimate partner abuse screening by clinicians

1. Do you and your partner argue a lot? Does it ever get physical? Has either one of you ever hit the other? Has either one of you ever injured the other?
2. Do you ever feel unsafe at home?
3. Has anyone ever hit you or tried to injure you in any way?
4. Has anyone ever threatened you or tried to control you?
5. Have you ever felt afraid of your partner?
6. Is there anything particularly stressful going on now? How are things at home?
7. I see patients in my practice who are being hurt or threatened by someone they love. Is this happening to you? Has this ever happened to you?

Source. Question 1 from J.L. Levenson (personal communication, October 2003); Questions 2-5 from Eisenstat and Bancroft 1999; Questions 6-7 from Gerbert et al. 2000.

can keep, conducting periodic room searches, and providing plastic utensils for meals are common interventions. A safe environment also should allow for the examiner's easy escape, as well as observation and easy entry by other health care personnel. The psychiatrist should use what information is available to anticipate what precautions and emergency interventions may be needed before starting the evaluation and should make sure that the medical team is ready to intervene in the event that the patient becomes severely agitated or violent.

Psychiatric Evaluation

Effective management of the aggressive patient requires a comprehensive psychiatric evaluation, ultimately leading to the identification of potentially modifiable factors at which interventions are targeted. In many instances, formulation of the case results in the diagnosis of a psychiatric disorder, and specific treatment is instituted with the expectation that remission of the disorder will lead to resolution of the aggression (e.g., an antipsychotic for acute psychosis in a patient with schizophrenia). However, in many patients with aggression, the psychiatric diagnosis only partially explains the behavior and does not indicate what the appropriate treatment strategy should be. This situation is often observed in patients with personality disorder, brain injury, or dementia but is frequently also true for patients with major mental disorders such as schizophrenia. In most such situations, careful characterization of the patient's background and careful description and decoding of the aggressive behavior will inform the approach to treatment.

Positive Therapeutic Alliance

The first step in the management of the aggressive patient is to develop a positive therapeutic alliance (Beauford et al. 1997). In all cases, and particularly in patients who are chronically aggressive or have recurrent violent episodes, it is crucial to actively seek the patient's collaboration in the treatment process. A positive therapeutic alliance facilitates the patient's compliance with behavioral expectations and with prescribed treatments and makes it easier to mediate patient-staff conflicts and de-escalate aggressive episodes. Also, a positive alliance facilitates the development of a psychotherapeutic relationship that may enable the psychiatrist to eventually reduce the patient's propensity to violent responses when anticipated precipitants occur in the future (O'Connor 2003).

Behavioral Approaches

Verbal de-escalation techniques (shown in Table 7-5) are often effective for controlling and terminating mild to moderate aggression (threats and belligerence) and are

used frequently in the ED and acute psychiatric inpatient unit. These techniques can be used in general medical settings by those who have been taught how to use them. Although verbal de-escalation should be conceptualized as a semistructured intervention (see Table 7-5), in practice, it is often deployed as an instinctive, commonsense reaction to the patient's behavior rather than as a systematic intervention. The basic goal of de-escalation is to manage a patient's anger and hostility by conveying empathy and understanding, personalizing the clinician, helping the patient to articulate grievances and frustrations, and actively involving the patient in problem solving and treatment planning (Stevenson 1991). Verbal de-escalation techniques are most useful in situations that involve patient-staff conflict, but they also can be used to manage pathological aggression and to set the stage for pharmacological interventions.

More sophisticated behavioral approaches have been successfully applied to the management of chronic aggression, particularly in patients with dementia and brain in-

TABLE 7-5. Verbal de-escalation techniques

Communication

Nonverbal

- ◆ Maintain a safe distance
- ◆ Maintain a neutral posture
- ◆ Do not stare; eye contact should convey sincerity
- ◆ Do not touch the patient
- ◆ Stay at the same height as the patient
- ◆ Avoid sudden movements

Verbal

- ◆ Speak in a calm, clear tone
- ◆ Personalize yourself
- ◆ Avoid confrontation; offer to solve the problem

Tactics

Debunking

- ◆ Acknowledge the patient's grievance
- ◆ Acknowledge the patient's frustration
- ◆ Shift focus to discussion of how to solve the problem

Aligning goals

- ◆ Emphasize common ground
- ◆ Focus on the big picture
- ◆ Find ways to make small concessions

Monitoring

- ◆ Be acutely aware of progress
- ◆ Know when to disengage
- ◆ Do not insist on having the last word

jury. These approaches include behavioral analysis, operant conditioning, differential reinforcement strategies, validation, manipulation of ambient light and/or sound, activity programs, and environmental modification (Lyketsos 2000). Evidence for the use of these approaches derives primarily from uncontrolled studies.

Seclusion and Restraint

It is not unusual for de-escalation and other behavioral techniques to fail to calm the patient who is very agitated, particularly in the ED and other acute care settings. Also, in some settings, de-escalation techniques may be impractical because the patient is unable to communicate meaningfully (as a result of confusion, cognitive impairment, or communication disorders), is known to be explosive, is too severely agitated to cooperate, or is already engaging in violent behavior. In such cases, the use of physical restraint, which may involve *manual restraint* (wherein the patient is restrained by several health care workers) and *mechanical restraint* (wherein an appliance is used to restrain the patient), may be needed to terminate dangerous behavior. Sometimes, physical restraint is needed to administer tranquilizers or to protect other medical interventions (e.g., to keep the patient from pulling out intravenous lines, chest tubes, urinary catheters, or other vital lines or tubes). For a brief period immediately after the application of physical restraints (or the administration of tranquilizers), it is prudent to observe the patient in isolation (in his or her own room or a designated safe room) to ensure that the violent episode, its consequences, and identifiable triggers have been successfully managed. Because improper use of restraints can result in injury to the patient or to health care workers, such use should be directed and implemented only by experienced personnel. Training courses in the use of manual and physical restraints are widely supported, and many jurisdictions have developed certification programs.

During the past decade, the use of seclusion and physical restraints has come under intense criticism. As a result, governmental and judicial regulation of restraint use has steadily increased (see also Chapter 2, "Legal Issues"). In response to these trends, the Academy of Psychosomatic Medicine issued guidelines (Bronheim et al. 1998, p. S20) that state the following:

Constant observation and restraints should be implemented for the shortest possible time with the least restrictive, though effective, means available; these interventions must not be made solely for the convenience of medical staff. Assessment and treatment of underlying psychiatric conditions that contribute to the patient's need for these measures should be expeditiously undertaken.

These guidelines are consistent with those developed by other medical associations, with regulatory standards, and with the general opinion of the courts. In general, the standards for the clinical use of restraints are as follows: 1) restraints should be used only when necessary to protect the patient or others from harm; 2) restraints should not be used solely to coerce the patient to accept treatments or remain in the treatment setting; and 3) when restraints are being used, the patient should be closely monitored and his or her condition frequently reassessed. The clinical and regulatory issues involved in the use of restraints are complex; thus, it is often necessary for psychiatrists to help other medical colleagues explore the various options for managing an aggressive patient and to address any staff discomfort with the use of restraints, while keeping in mind the clinical and legal risks involved in using or forgoing restraints.

Pharmacological Approaches

Data indicating that neurotransmitter systems modulate aggression have stimulated the development of pharmacological approaches for the clinical management of aggression. This pharmacotherapy for aggression is based more on contemporary intuitions of the neurotransmitter effects of medications and how these effects modulate the expression of aggressive behavior and less on evidence from controlled trials. Medications are indicated for impulsive and pathological forms of aggression. In general, treatment of clinically relevant aggression falls into two broad categories: 1) treatment of *syndromic* aggression separate from the diagnostic context and 2) focused treatment of conditions that manifest *symptomatic* aggression, such as schizophrenia, delusional disorders, major depressive disorders, and delirium. The discussion that follows focuses mainly on the treatment of syndromic aggression; treatments for specific conditions are covered in detail in other chapters of this text.

Pharmacological agents are indicated for both acute and chronic aggression. In the treatment of acute aggression, the goal is typically rapid tranquilization (which refers to the use of medications to achieve a rapid termination of agitated or aggressive behavior). A survey of U.S. psychiatrists who specialize in emergency psychiatry found that benzodiazepines (particularly lorazepam) were the preferred agents for treating acute aggression (Allen et al. 2001) because they are relatively free of adverse effects that are typically associated with antipsychotics, such as the acute dystonias, akathisia, and parkinsonism. Antipsychotics, especially haloperidol, also were considered first-line agents, particularly for acute aggression associated with psychosis. The survey predates the introduction of parenteral formulations of ziprasidone and olanzapine, which

are now used in many centers. A controlled trial found the combination of lorazepam and haloperidol to be superior to lorazepam or haloperidol alone for the treatment of acute agitation in patients with psychosis (Battaglia et al. 1997), suggesting that the combination also may be more effective for acute aggression. Newer antipsychotics—for example, the atypical antipsychotics risperidone and olanzapine—are also being increasingly used for the management of acute agitation and aggression (Allen et al. 2001). For rapid tranquilization, drugs that can be given parenterally are advantageous. Lorazepam (intramuscular, intravenous) and haloperidol (intramuscular, intravenous) are typically used for this purpose. Intramuscular formulations of three atypical antipsychotics—ziprasidone, olanzapine, and aripiprazole—are also available.

A wider range of pharmacological agents is used for the treatment of chronic aggression (see Table 7–6). Of these agents, antipsychotics are the most widely used. The relative dearth of evidence from placebo-controlled trials and the phenotypic and neurobiological heterogeneity of aggression may explain the diversity of agents used to treat chronic aggression. It is noteworthy that placebo-controlled trials of treatments for agitation and aggression in elderly patients have yielded placebo responses as high as 60% in some studies, underscoring the importance of rigorous methodology in the evaluation of treatments (Lyketos 2000). However, despite the limited availability of data from controlled trials, considerable empirical support exists for the use of several psychotropic classes in treating aggression.

Antipsychotics are the preferred agents for treating agitation and aggression in the general medical setting, especially when these phenomena arise in a patient with delirium. Antipsychotics are also used to treat aggression in psychotic patients and to tranquilize patients with severe aggression (regardless of cause). Tranquilization may terminate an episode of aggression, but sometimes it does not reduce the frequency or severity of future episodes of impulsive aggression.

In clinical trials of typical antipsychotics for the treatment of impulsive aggression in patients with personality disorders, results have been mixed; however, the atypical agents (which selectively block 5-HT₂ receptors—an action associated with reduced aggression in animals) may be more effective in treating chronic impulsive aggression (Coccaro and Siever 2002). In a randomized comparative study, clozapine was the most efficacious agent in reducing hostile aggression (independent of its effectiveness in relieving psychosis); olanzapine, risperidone, and haloperidol were equal in effectiveness (Citrome et al. 2001). Although these results would seem to recommend clozapine as a first choice for treating aggression in psychotic patients, in prac-

TABLE 7–6. Medications used in the treatment of chronic aggression

Antidepressants

- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants
- Serotonin–norepinephrine reuptake inhibitors
- Trazodone
- Mirtazapine

Antipsychotics

- Haloperidol
- Fluphenazine
- Loxapine
- Risperidone
- Paliperidone
- Aripiprazole
- Ziprasidone
- Olanzapine
- Clozapine
- Quetiapine

Anticonvulsants

- Divalproex sodium
- Carbamazepine
- Oxcarbazepine
- Phenytoin

Others

- Lithium
- Buspirone
- Propranolol, nadolol
- Amantadine
- Progesterone
- Leuprolide
- Prazosin

tice, the drug is typically reserved for severe or treatment-resistant cases because of its adverse-effect profile.

Antipsychotics are also used to treat aggression in patients with brain diseases. In multicenter trials in patients with dementia, risperidone and olanzapine were found useful in reducing aggression (Ballard and Waite 2006; Lyketos 2000), but results from the CATIE-AD (Clinical Antipsychotic Trials in Intervention Effectiveness—Alzheimer’s Disease) study indicated that their effects are modest and are offset by adverse effects (Schneider et al. 2006). As with other antipsychotics, both risperidone and olanza-

pine are associated with cerebrovascular events, extrapyramidal symptoms, and increased mortality in dementia. Clinicians must balance their modest efficacy and associated risks against the risks of untreated aggression in patients with dementia (Salzman et al. 2008). It is prudent to reserve their use for those dementia patients whose aggression poses significant risk or causes marked distress. In cases of aggression in dementia successfully treated with an antipsychotic, planned withdrawal of the drug after 3 months is recommended (Ballard et al. 2008; Onyike 2008). There is a growing consensus among specialists that behavioral interventions should be the first line of treatment for aggression in dementia, with pharmacological interventions reserved for behavioral emergencies and refractory cases. Recent evidence indicates that memantine, a treatment for dementia, can reduce aggression and psychosis (Wilcock et al. 2008). It seems reasonable to consider memantine as the first pharmacological intervention when a patient with dementia becomes aggressive. It is uncertain whether cholinesterase inhibitors reduce agitation, aggression, and violence in dementia (Rodda et al. 2009).

Data showing that experimental and pharmacological modulation of serotonin neurotransmission can reduce levels of aggression in nonhuman primates and smaller animals (Walsh and Dinan 2001), and other results showing low CSF levels of serotonin metabolites in impulsively aggressive patients, violent offenders, and suicide attempters (discussed earlier, in the section "Mechanisms of Aggression"), constitute compelling reasons to treat impulsive aggression with selective serotonin reuptake inhibitors (SSRIs), lithium, buspirone, and other drugs that may enhance central serotonin levels. In addition, SSRIs, lithium, and buspirone have been effective, in small placebo-controlled trials, in reducing impulsive nonviolent aggression in patients with personality disorders, autism, and depressive disorders (Coccaro and Siever 2002), although this is not consistently observed (e.g., Lee et al. 2008).

Anticonvulsants may be effective in reducing impulsive aggression. A recent Cochrane Library review of placebo-controlled clinical trials (Huband et al. 2010) showed that valproate/divalproex, carbamazepine, oxcarbazepine, and phenytoin reduce recurrent impulsive aggression in a broad spectrum of patients, including male psychiatric outpatients and prisoners, adults with personality disorders, and (valproate only) children and adolescents with conduct disorder. It has not been demonstrated that anticonvulsants reduce aggression in children and adolescents with pervasive developmental disorders. Another review of controlled trials, using less stringent inclusion criteria, concluded that topiramate and lamotrigine may reduce impulsive aggression in adults with personality disorders (Stanford et al. 2009). With respect to dementia, a recent controlled trial

found that valproate was ineffective and poorly tolerated (Herrmann et al. 2007). In blinded, placebo-controlled trials, carbamazepine reduced aggression in nursing home patients with dementia (Tariot et al. 1998). Oxcarbazepine did not reduce aggression in dementia in another trial (Sommer et al. 2009). Gabapentin is prescribed frequently for impulsive aggression, although no empirical evidence supports this practice. Small trials suggest that topiramate might reduce aggression in individuals with borderline personality disorder (Nickel and Loew 2008; Nickel et al. 2004, 2005). Levetiracetam did not reduce aggression in a recent trial (Mattes 2008), and there is evidence that it causes impulsivity and aggression when used in epilepsy treatment (Helmstaedter et al. 2008).

Because overactivity in the noradrenergic system has been implicated in the expression of aggression, noradrenergic blockade has emerged as another therapeutic strategy. The typically used agents are propranolol and nadolol, both beta-adrenergic blockers. Clinical trials have found them to be effective in patients with traumatic brain injury, dementia, and psychosis (Allan et al. 1996; Ratey et al. 1992; Shankle et al. 1995; Sorgi et al. 1986). Beta-blockers may cause hypotension and bradycardia and therefore should be used with caution. In fact, low-dose treatment may be effective for certain patients; one study found that low-dose propranolol (10–80 mg/day) reduced aggression in patients with dementia (Shankle et al. 1995).

Table 7–6 provides a summary of other medications that may be helpful for treating aggression. Progesterone and leuprolide are used for some patients with aggressive sexual behavior. In routine practice, psychiatrists often use combinations of medications from different classes because the response to single-agent therapy is usually modest.

Conclusion

Aggression is a major clinical and public health problem. In clinical settings, it represents a difficult, disruptive, and dangerous problem for psychiatrists, nonpsychiatric physicians, nurses, and other health care workers. Fortunately, strategies exist to manage this problem. A careful description of the aggressive episode, in the context of a comprehensive psychiatric examination, informs clinical management. Out of the clinical examination comes an appreciation of the fundamental nature of the problem (for instance, whether the aggression is impulsive or premeditated), the factors that have produced and/or sustained it, and the approaches to treatment.

The treatment of aggression requires awareness that psychiatric diagnosis alone is often not enough to inform the treatment and, therefore, an individualized approach

is required. For most patients, aggression is managed empirically with a combination of approaches, behavioral, environmental and pharmacological. In the general hospital, the management of aggressive patients involves active collaboration among psychiatrists, nonpsychiatric physicians, nurses, and other health care workers. This collaboration works best when the ground has been prepared beforehand through the liaison efforts of the psychiatrist and will maximize the effectiveness of interventions while minimizing the risk of injury to patients and medical staff.

Finally, it is also important to keep in mind that many aggressive patients, particularly those with impulsive aggression, are also at risk for suicidal behavior and require a careful suicide risk assessment and appropriate interventions. Recent research has yielded much insight into the neurobiology of aggression and violence, but more work is needed to develop predictive methods and more effective preventive and treatment modalities.

Depression

Madeline Li, M.D., Ph.D., F.R.C.P.C.

Gary Rodin, M.D., F.R.C.P.C.

MEDICAL AND DEPRESSIVE illnesses are common conditions that frequently coexist in the general population. This association is to be expected both because of coincidence and because the risk of depressive disorders is increased in most medical conditions. This elevated risk is due, in part, to the association of most, or all, serious medical illnesses with a variety of nonspecific risk factors for depression. However, there also has been much speculation about whether specific biological mechanisms may account for the comorbidity of depression with particular medical conditions.

Depression is frequently undiagnosed and untreated in medical and primary care populations, despite its frequency, negative effect on health, and responsiveness to a variety of interventions. This diagnostic and therapeutic neglect may occur for several reasons, including the stigma associated with psychological distress, the difficulty of distinguishing normative from pathological distress, the physical symptom overlap between depression and medical illness, the frequent lack of sufficient training in or comfort of medical caregivers with emotional inquiry, and mistaken beliefs among both medical caregivers and patients about the untreatability of depression that is “understandable.” Untreated depression is of concern in medical populations because it is associated with greater somatic symptom burden (Katon et al. 2007) and morbidity and with worse quality of life (Katon 2003) in common medical disorders. Depression is also associated with higher rates of health care utilization, with medical costs up to 50% higher

than those attributed to medical illness alone, and with poorer medical treatment compliance, functional capacity, and occupational productivity (Unutzer et al. 2009).

In this chapter we review the prevalence and clinical features of depression in the medically ill; describe screening, diagnostic, and treatment approaches to depressive disorders in medical populations; and consider potential mechanisms to account for the etiology, course, and outcome of depression in specific medical illnesses.

The Continuum of Depression: From Experience to Disorder

The experience of sadness is a normal, expectable response to the multiple adverse effects of a serious medical illness. These effects include changes in bodily appearance and functioning; pain and physical distress; limitations in the capacity to work and to engage in pleasurable activities; a perceived alteration in the anticipated life trajectory; fears of disability and dependency; and alterations in intimate relationships, family life, social relationships, and other activities. Nonpathological sadness and grief lie at the milder end of the continuum of depression in medical populations. In the middle lie adjustment disorders and sub-threshold depressions, which are the most prevalent depressive disorders among medically ill patients (Rowe and Rapaport 2006). At the more severe end of the continuum are depressive symptoms that may clearly meet diagnostic

criteria for one of the depressive disorders specified in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition, Text Revision (DSM-IV-TR; American Psychiatric Association 2000). These categorical distinctions have heuristic and communicative value but the boundaries that distinguish them from each other and from nonpathological sadness are somewhat arbitrary and often difficult to determine, particularly in medically ill patients.

The six major categories of depressive disorders specified in DSM-IV-TR are major depressive disorder (MDD), dysthymic disorder, mood disorder due to a [specified] general medical condition, substance-induced mood disorder, adjustment disorder with depressed mood, and depressive disorder not otherwise specified, which includes minor depressive disorder. In this chapter, we emphasize the syndromes of MDD and dysthymic disorder. A categorical diagnosis of MDD is based on the presence of five or more symptoms, which must include a depressed mood or anhedonia for at least 2 weeks, representing a significant change from previous functioning. Neurovegetative symptoms in these criteria include impairment in sleep or appetite, loss of energy, and psychomotor retardation or agitation. Psychological criteria include feelings of worthlessness, hopelessness or excessive guilt, cognitive impairment, and recurrent suicidal ideation (American Psychiatric Association 2000). Dysthymic disorder is characterized by less severe depressive symptoms that have been continuously present for at least 2 years, in contrast to minor depression, in which the symptoms of dysthymic disorder need be present for only 2 weeks. Subthreshold disorders that do not meet criteria for MDD can nevertheless substantially impair quality of life and the capacity to comply with medical treatment. Further research is needed to determine their responsiveness to pharmacological and psychosocial interventions.

To avoid pathologizing the profound but normative distress that may follow the loss of a close relationship, the DSM-IV-TR excludes from the diagnostic criteria for a depressive disorder depressive symptoms that persist for up to 2 months following bereavement. Initial grief reactions and subsequent mourning are common following the onset of a serious or terminal illness and can be regarded as normative and nonpathological but have nevertheless not been excluded from the DSM-IV-TR diagnostic criteria for MDD (Horwitz and Wakefield 2007) (reviewed in detail in Chapter 41, "Palliative Care"). Indeed, it may be argued that the onset, exacerbation, or progression of a serious medical illness may be at least as distressing as the loss of a loved one. The diagnosis of adjustment disorder is based on emotional or behavioral symptoms "in excess of what would be expected" from exposure to an identifiable stressor. However, the operational criteria for this diagnosis, including what constitutes an "excessive" response to the

multiple and chronic stressors of medical illness, are not clear. Despite this ambiguity, the heuristic and nonstigmatizing appeal of the category of adjustment disorder cause it to remain one of the most common psychiatric diagnoses in medical patients (Li et al. 2010).

Epidemiology

Depressive disorders are extremely common in the general population, with up to 17% of adults in the United States having had at least one episode of MDD during their lifetime (Kessler et al. 2003), and 2%–4% suffering from a current MDD (Burvill 1995). Medical illness has been consistently shown to be a risk factor for depression. Dysthymic disorder and minor depression are the most common depressive syndromes in medical populations, reported in up to 26% of medical outpatients, a rate several times higher than that in the general population (Rowe and Rapaport 2006). Presumably based on differences in medical disease severity, the prevalence of MDD has been found to increase progressively from community samples (2%–4%), to primary care settings (5%–10%), to medical inpatient settings (6%–14%) (Burvill 1995). Similarly, the risk of a depressive episode in patients in primary care (Barkow et al. 2002) and in the community (Wilhelm et al. 1999) rises with the number of comorbid medical diseases. The reported prevalence of MDD in specific medical conditions, including cancer, diabetes, cardiovascular disease, chronic obstructive pulmonary disease (COPD)/asthma, HIV/AIDS, stroke, epilepsy, multiple sclerosis, Alzheimer's disease, and Parkinson's disease, is listed in Table 8–1.

Etiology

Depressive symptoms and depressive disorders have been found to occur at increased rates in virtually all medical conditions in which they have been studied. There have been claims and hypotheses that specific biological mechanisms cause depression in specific medical conditions, including stroke, Parkinson's disease, type 1 diabetes, and some types of cancer. However, such specificity has not been substantiated in any of these conditions, although each is associated with multiple nonspecific risk factors that may increase the prevalence of depression. In fact, depression in the context of medical illness is a prime example of the biopsychosocial model of disease, with interacting pathophysiological and psychosocial factors contributing to this comorbidity. The final common pathway to depression resulting from the interaction of disease-related, psychological, and social risk and protective factors is shown in Figure 8–1.

TABLE 8-1. Prevalence of major depressive disorder in selected medical illnesses

Medical illness	Prevalence (%)	Reference
Cancer	0–38	Massie 2004
Diabetes	9–26	Musselman et al. 2003
Heart disease	17–27	Rudisch and Nemeroff 2003
COPD/asthma	20–50	Cleland et al. 2007; Van Lieshout et al. 2009
HIV/AIDS	5–20	Cruess et al. 2003
Stroke	14–19	Robinson 2003
Epilepsy	20–55	Kanner 2003
Multiple sclerosis	40–60	Wallin et al. 2006
Alzheimer's disease	30–50	Lee and Lyketsos 2003
Parkinson's disease	4–75	McDonald et al. 2003

Note. COPD=chronic obstructive pulmonary disease.

Potential biological contributors to depression in medical illness include the physical effects of illness and treatment, medications, neurological involvement, genetic vulnerability, and systemic inflammation. In this regard, greater pain and treatment intensity (Kaasa et al. 1993), more advanced disease (Manne et al. 2001), and proximity to death (Butler et al. 2003) have all been shown to increase the risk of depression. Individuals with a genetic vulnerability to depression are also more likely to develop it in the context of medical illness (Levinson 2006) and common genetic vulnerabilities may account for the frequent comorbidity of depression and Alzheimer's disease (Kim et al. 2002), Parkinson's disease (Mossner et al. 2001), and coronary artery disease (Su et al. 2009). Immune-activated systemic inflammation (Dantzer et al. 2008), manifest as cytokine-

induced sickness behavior, is a recently proposed common pathophysiological mechanism that may underlie depression in a wide range of medical disorders including cancer (Raison and Miller 2003), cardiovascular disease (Parissis et al. 2007), diabetes (Musselman et al. 2003), Alzheimer's disease (Leonard 2007), stroke (Arbelaez et al. 2007), multiple sclerosis (Wallin et al. 2006), asthma (Van Lieshout et al. 2009), and infectious diseases such as HIV/AIDS (Leserman 2003).

Psychosocial factors that affect the likelihood of a comorbid depressive disorder in medical illness include the stigma and personal meaning associated with the medical condition, illness-related disability (Talbot et al. 1999), maladaptive coping styles (Wallin et al. 2006), low self-esteem, impaired spiritual well-being (Rodin et al. 2007b), and capacity to express affect (Classen et al. 2008). Low social support (Lewis 2001), including poor communication with medical caregivers (Gurevich et al. 2004), also increases the likelihood of a comorbid depressive disorder. More recent evidence suggests that expectations of support and the capacity for flexible use of social support, captured in the construct of attachment security, may provide protection from the emergence of depressive symptoms in medically ill patients (Rodin et al. 2007b).

Age is inversely related to the severity of depressive symptoms (Cleland et al. 2007; Gottlieb et al. 2004). Postulated explanations for age-related differences in depression severity include greater disruption of the life trajectory and lesser stigma associated with emotional distress in younger patients, a diminishing tendency with more advanced age to experience or communicate distress, and growth in attachment security and spiritual well-being over the life span (Lo et al. 2010). Finally, although depression in the

**FIGURE 8-1. Pathways to depression.**

general population has been strongly associated with female gender (Lucht et al. 2003), this gender difference has not been found consistently in depression in medical populations (Cleland et al. 2007; Rodin et al. 2007b; Miller et al. 2010). It may be that the overriding common stressors related to the medical illness obliterate gender-related differences that would otherwise emerge.

Clinical Features and Diagnosis

The diagnosis of depressive disorders in medical populations is fraught with difficulty for a variety of reasons, including the following:

1. Many physical symptoms of medical illness (e.g., fatigue, anorexia, weight loss, insomnia, psychomotor retardation, diminished concentration) resemble those of depression. In addition, a variety of emotional disturbances, such as “emotionalism,” pathological crying, apathy, or fatigue, in poststroke patients (Bogousslavsky 2003) or in those with multiple sclerosis (Chwastiak and Ehde 2007), can be mistaken for depression. It may also be difficult to distinguish depression from the apathy associated with hypoactive delirium or dementia, or from the akinesia and masked facies that are the hallmark of Parkinson’s disease.
2. Thoughts of death and the desire for death in patients with advanced medical disease have been associated with depression and demoralization in the terminally ill (Breitbart et al. 2000). However, they may also reflect adaptive death acceptance or an attempt at cognitive mastery, rather than depression (Nissim et al. 2009).
3. Physical suffering and disability, in the absence of comorbid depression, may diminish the capacity to experience pleasure in many formerly enjoyable activities. Presence of a depressed mood or withdrawal from social or physical activities that is disproportionate to physical disability increases the likelihood that the loss of pleasure is secondary to depression.
4. In medical populations, depressive symptoms may manifest in atypical or masked forms, including the amplification of somatic symptoms (Katon et al. 2007) and noncompliance with or refusal of medical treatment (DiMatteo et al. 2000). These phenomena may contribute to both the underdiagnosis and the overdiagnosis of MDD in medical populations.
5. The categories of MDD, mood disorder due to a general medical condition, and substance-induced mood disorder may overlap in the context of medical illness. The latter two diagnoses imply that the etiology of the

depression is a direct physiological consequence of the specified general medical condition or substance. However, no medical illness or substance has been shown to have a linear causal relationship to depression.

Various approaches have been proposed to diminish the confounding effect of medical symptoms in the diagnosis of MDD. DSM-IV-TR suggests a combined “exclusive” and “etiological” approach, which specifies exclusion of symptoms that are judged by the clinician to be etiologically related to a general medical condition or that are not more frequent in depressed than nondepressed patients with such conditions (Bukberg et al. 1984). This approach is intended to avoid attributing symptoms of physical illness to a depressive syndrome, although the wording in DSM-IV-TR leaves unclear whether the exclusion applies only to the physiological consequences of the medical condition or also extends to psychological reactions to the condition (Koenig et al. 1997). In practice, the exclusive approach is usually applied only to the somatic symptoms of depression, although this does not take into account that depressed medical patients report significantly more physical symptoms than matched nondepressed medical patients (Simon and Von Korff 2006). In any case, the criteria for determining which symptoms are due to a medical illness and which are due to other factors unrelated to the medical illness are unclear.

Another approach to the diagnosis of MDD in the medically ill is “substitutive” (Endicott 1984). In this approach, symptoms that are more likely to be affective in origin—such as irritability, tearfulness, social withdrawal, and feeling punished—are substituted for symptoms that are most likely to be confounded with the effects of medical illness, such as loss of energy, weight loss, and impaired concentration. This substitution eliminates the need to distinguish symptoms of medical illness from those of depression but may underestimate depression prevalence by excluding some somatic symptoms that are core manifestations of more severe forms of depression. Furthermore, the criteria to determine which symptoms should be substituted are not clearly established, and this approach has not been widely adopted.

Evaluating the rates of depression in hospitalized elderly medical patients according to six different diagnostic schemes, Koenig et al. (1997) found no overall advantage of one diagnostic scheme over others. The exclusive/etiological approach identified the most severe persistent depressions, but an inclusive approach was the most sensitive and reliable. In cases in which the diagnosis remains unclear, a trial of treatment may be the most practical means of resolving the question.

Health Outcomes

The World Health Organization (WHO) projects that by the year 2020, depression will be the second leading cause of disability, surpassed only by heart disease (Michaud et al. 2001). Although the impact of depression has often been underestimated, the WHO World Health Survey (Moussavi et al. 2007) found that depression reduces overall health significantly more than do chronic diseases such as angina, arthritis, asthma, or diabetes and that the comorbid state of depression and medical illness worsens health more than any combination of chronic diseases without depression. Comorbid depression is also associated with a significant economic burden, including an almost twofold higher rate of health care utilization and workplace disability (Stein et al. 2006), longer inpatient lengths of stay (Saravay et al. 1996), and at least a twofold increase in emergency room visits (Himelhoch et al. 2004). Comorbid depression is also associated with a threefold risk of noncompliance with medical treatment, thereby contributing to increased morbidity and mortality (DiMatteo et al. 2000). Such noncompliance may include not taking treatments that are prescribed, not following diet or lifestyle recommendations, and not attending medical appointments.

The finding that the comorbidity of depression and medical illness is associated with worse medical outcomes and higher mortality rates has been replicated in a variety of medical conditions. It has been associated with more rapid progression of HIV disease (Leserman 2003) and with increased mortality with cardiovascular disease (van Melle et al. 2004) and in cancer (Onitilo et al. 2006). This increased mortality rate, which persists even after controlling for such factors as smoking, disease severity, and alcohol consumption (Schulz et al. 2000), may be due to several different factors. Biological mechanisms in depression may increase mortality rates in the medically ill via effects on the autonomic nervous system and on related cardiac outcomes. The association of suicide with depression may also increase mortality rates in medical populations, a finding that has been demonstrated in medical conditions, such as cancer (Steel et al. 2007), multiple sclerosis (Stenager et al. 1996), and Huntington's chorea (Almqvist et al. 1999). Depression may be associated with other health risk behaviors—such as cigarette smoking, overeating, physical inactivity, obesity, and excess alcohol consumption—that increase the prevalence of associated medical illness and affect its course adversely.

Screening for and Detection of Depression

Obstacles to Diagnosis in Medical Settings

Depression and other forms of distress are often underdiagnosed and undertreated in medical settings (Fallowfield et al. 2001). In fact, a recent study in the United Kingdom suggests that less than one-half of cases of depression are correctly diagnosed by general practitioners (Mitchell et al. 2009). This is of concern because missing the diagnosis of MDD, or even of a minor depressive disorder, may forgo the opportunity to improve quality of life, decrease the risk of suicide, shorten hospital stay, and improve treatment compliance in the medically ill. There are many explanations for the low rate of detection of clinical depression in medical settings. The structure of medical care, with medical visits often lasting less than 15 minutes, with multiple other clinical concerns that may need to be addressed during each visit, and with the frequent lack of privacy in clinic and hospital settings, may inhibit disclosure or elaboration of symptoms. Furthermore, some clinicians avoid emotional inquiry because they fear that they lack sufficient time or skill to manage emotional reactions. Some patients are reluctant to disclose depressive symptoms because of perceived stigma or anticipated lack of interest of their medical caregivers. However, most patients welcome the opportunity to discuss psychosocial issues that are raised by their health care providers (Rodin et al. 2009). In some cases, both patients and clinicians may have difficulty differentiating the somatic symptoms of depression from those of medical disease. They may also both dismiss clinically significant depression as an “understandable” reaction to the multiple stresses of medical illness, mistakenly assuming that treatment for such reactions is unnecessary or ineffective.

Paradoxically, time-pressured medical clinic visits that preclude adequate assessment of mood can also lead to the overdiagnosis of depression. This may occur due to the misattribution of the symptoms of physical illness to depression and to the employment of low diagnostic thresholds of depression, with a readiness to prescribe antidepressant medications and/or to refer for specialized psychiatric assessment (Boland et al. 1996) because of inadequate resources or training to explore or manage psychological distress (Aragones et al. 2006). The more appropriate utilization of limited specialized psychiatric resources may be facilitated by the use of validated depression screening tools in medical settings.

Screening for Depression: General Considerations

Screening for depression may be particularly helpful in medical settings where routine assessment of mood might otherwise not occur. The ideal screening instrument would be easy to administer and score, acceptable to patients, and, most importantly, accurate. However, the utility of screening for depression depends not only on the measure used but also on whether its results are routinely communicated to medical caregivers and whether such communication leads to timely and effective intervention. Failure to ensure that such a response loop is implemented may account for the failure of distress screening to result in better management of depression or improved outcomes (Palmer and Coyne 2003).

Screening Instruments Commonly Used in Medical Populations

There is no true gold standard for the diagnosis of depression, particularly in the context of medical illness, but clinical interviews have traditionally been used to confirm diagnoses and to establish prevalence rates. Such interviews may be unstructured—with an inclusive or substitutive approach to counting symptoms—or more structured, utilizing diagnostic instruments such as the Structured Clinical Interview for DSM Disorders (SCID; First et al. 1997), the Composite International Diagnostic Interview (CIDI; World Health Organization 1997), the Mini-International Neuropsychiatric Interview (Sheehan et al. 1998), the Present State Examination (PSE; Hall et al. 1999), or the Primary Care Evaluation of Mental Disorders (PRIME-MD; Spitzer et al. 1999).

Depression rating scales can be used to measure depression severity or symptom change over time, but the diagnosis of depression requires a second-stage clinical diagnostic interview with those who score above the cutoff. Numerous psychometric measures have been developed to measure depressive symptoms, with criterion validity and optimal cutoff scores usually established with some form of clinical interview. The cutoff scores selected determine the sensitivity and specificity of the measure, and, therefore, the proportion of false-negative and false-positive cases. Higher cutoffs that avoid false positives may be preferable for research purposes and for determining resource allocation for more severe cases. Lower thresholds may be preferable in well-resourced treatment settings in which a premium is placed on avoiding false negatives and on detecting subthreshold disorders. Table 8-2 lists validation studies of rating scales commonly used to assess and screen for depression in medical populations, including the Center for Epidemiologic Studies Depression Scale

(CES-D; Radloff 1977), the Hospital Anxiety and Depression Scale (HADS; Zigmond and Snaith 1983), the Beck Depression Inventory-II (BDI-II; Beck et al. 1996), and the Patient Health Questionnaire—depression module (PHQ-9; Kroenke et al. 2001). A brief discussion of each of these instruments follows.

The CES-D Scale is a 20-item self-report measure of depressive symptoms, in which only 4 of the 20 items are somatic. Originally designed as a measure of depressive distress in nonpsychiatric community samples, the CES-D has also been extensively used in medically ill samples with evidence of good psychometric properties. A cutoff score of 17 was originally recommended to identify clinically significant depression (Radloff 1977), but the low positive predictive value (PPV) of the CES-D suggests that it might be a better measure of general distress than of depression. The reported sensitivity and specificity of various cutoff scores in a variety of medical populations are shown in Table 8-2.

The HADS is a 14-item self-report scale specifically designed for use in the medically ill, with separate 7-item subscales for anxiety and depression. The depression subscale emphasizes anhedonia and does not include somatic items. The HADS is highly acceptable to patients and has been extensively used in the medically ill (Herrmann 1997). It has good concurrent and discriminant validity and acceptable sensitivity to change (Flint and Rifat 1996), but it has not been extensively validated as a screening instrument. There have been conflicting reports regarding its accuracy (Herrmann 1997), and some empirical studies (Chaturvedi et al. 1996; Razavi et al. 1990) have found that the total score (HADS-T) more accurately predicts the presence of MDD or minor depression than does the depressive subscale (HADS-D). The most widely recommended cutoff scores are 8 on the HADS-D (Berard et al. 1998) and 16 on the HADS-T (Chaturvedi et al. 1996).

The BDI-II is the most widely accepted measure of depressive distress. Originally developed as a measure of symptom severity in psychiatric patients, this 21-item self-report scale has been used in numerous studies of depression in the medically ill. Concerns have been raised about its validity in patients with medical illness (because of its preponderance of somatic items) and about the acceptability to patients of its forced-choice format and complex response alternatives (Koenig et al. 1992). However, several studies evaluating the accuracy of the BDI-II as a screening instrument in medically ill samples found it to be an accurate self-report measure of depressive symptoms (Berard et al. 1998; Craven et al. 1987). The cutoff most commonly recommended in the medically ill is 15–16 (Berard et al. 1998).

The PHQ-9 is the nine-item depression module of the PHQ, which is a self-administered version of the PRIME-MD, a freely available diagnostic instrument for common

mental disorders specifically designed for use in primary care settings. The PHQ has been studied in thousands of primary care and medical specialty outpatients in the United States, Europe, and China. Its depression subscale, the PHQ-9, measures each of the nine DSM-IV-TR criteria for a major depressive episode with scores ranging from 0 (not at all) to 3 (nearly every day). When assessed against an independent structured interview performed by mental health professionals, a PHQ-9 cutoff score of 10 or greater had a sensitivity of 88% and a specificity of 88% for the diagnosis of MDD. PHQ-9 scores of 5, 10, 15, and 20 represented mild, moderate, moderately severe, and severe depression, respectively (Spitzer et al. 1999). A recent meta-analysis reported a summary sensitivity of 77% and specificity of 94% with a PPV of 59% in unselected primary care populations and a PPV of 85%–90% in populations at increased risk for depression (Wittkamp et al. 2007).

Single-Item and Very Brief Screening Scales

There has been great interest in single-item screening tests for depression, although recent pooled analyses of such tools in cancer (Mitchell 2007) and in primary care (Mitchell and Coyne 2007) revealed PPVs of only 34% and 38%, respectively. The most widely known single-item scale is the Distress Thermometer, a 0- to 10-point visual analogue scale measuring level of distress in the past week (A.J. Roth et al. 1998). Recommended for distress screening by the National Comprehensive Cancer Network, the Distress Thermometer was found to have 79% sensitivity and 83% specificity but only a 41% PPV for detecting depression in cancer patients (Grassi et al. 2006). Single-item questions such as “Are you depressed?” (Chochinov et al. 1997) demonstrated a sensitivity of 55% and specificity of 74% in detecting MDD in patients on a palliative care ward (Lloyd-Williams et al. 2003) and a sensitivity of 42% and specificity of 86% in cancer patients undergoing radiotherapy (Kawase et al. 2006). The question “Do you often feel sad or depressed?” had a sensitivity of 86%, a specificity of 78%, and a PPV of 82% for depression in stroke patients (Watkins et al. 2001). Pomeroy et al. (2001) demonstrated in elderly medical patients that both the 1-item Mental Health Index (Berwick et al. 1991) and the 4-item Geriatric Depression Scale (Yesavage et al. 1982) were as effective as the 30- or 15-item Geriatric Depression Scales.

Kroenke et al. (2001) evaluated the two-item version of the PHQ (PHQ-2), which was derived from the PHQ-9 module for depression. The PHQ-2 includes the first two items of the PHQ-9: Over the last 2 weeks, how often have you been bothered by 1) little interest or pleasure in doing things and 2) feeling down, depressed, or hopeless? In a sample of 1,619 medical outpatients, the PHQ-2 demonstrated 87% sensitivity and 78% specificity for MDD and

79% sensitivity and 86% specificity for any depressive disorder, validated against the SCID (Lowe et al. 2005). These same two questions were able to identify 99% of cases diagnosed by SCID interview in patients with multiple sclerosis (Mohr et al. 2007).

The lower sensitivity and specificity of single-item or ultrabrief self-report measures of depression may limit their utility, although measures such as the PHQ-2, which focus on the core features of a depressed mood and/or anhedonia, may be most useful. However, the most common shortcoming in the detection of depression is not in the nature of the instrument used or in the questions posed in the clinical setting but rather in the failure to screen for depression using *any* method.

Depression in Specific Medical Conditions

The association of depressive disorders with specific medical diseases is of concern because of their impact on the treatment, course, and outcome of these conditions. There has been particular concern that depression in coronary artery disease (CAD) is associated with increased mortality (see also Chapter 18, “Heart Disease”). There has also been attention to the comorbidity of depression with diabetes mellitus and HIV disease because of its effect on treatment adherence. The occurrence of depression in neurological and other medical conditions has been of interest because of diagnostic complexities related to the clinical features of these conditions. We do not attempt here to review depression in all medical conditions; the reader is referred to the chapters on specific medical conditions in this textbook for more information. In the following subsections we selectively focus on representative medical disorders that have been more extensively investigated in relation to depression.

Coronary Artery Disease

MDD (May et al. 2009; Surtees et al. 2008), and even less severe symptoms of depression (Wulsin 2004), have been associated with a significantly increased relative risk for cardiac complications in patients with coronary artery disease. There has also been speculation that a specific symptom cluster within the MDD profile may account for the association between depression and coronary events. For example, the cluster of vital exhaustion, which includes excessive fatigue, low energy, feelings of demoralization, and irritability, has been observed to predict recurrent coronary events, including myocardial infarction, following percutaneous transluminal coronary angioplasty (Mendes de Leon et al. 1996). However, it remains to be established whether other depressive symptoms, such as anhedonia, psychomo-

tor retardation, and diminished attention and concentration are also associated with CAD disease severity or with prolonged disability in CAD patients.

Depressive symptoms may increase cardiac risk through their impact on the motivation to initiate and sustain heart-healthy lifestyle changes, such as smoking cessation, modification of diet, and exercise programs. CAD patients who are depressed may also have a greater sympathetic and neuroendocrine response to stress, as well as decreased heart rate variability and baroreflex sensitivity, and higher resting heart rate (Huffman et al. 2006; Parissis et al. 2007). These sympathoexcitatory states lower the threshold for hypertension and progression of the atherosclerotic process and for clinically significant cardiac events. Such autonomic effects may partly account for the frequent association between depression and increased mortality (van Melle et al. 2004), although Huffman et al. (2006) suggested that recent improvements in cardiac outcomes may account for the failure to confirm this association in more recent studies.

The American College of Cardiology regards depression as a secondary risk factor for CAD, because of its independent association with CAD; it does not meet their criteria for a Category I risk factor, which would require evidence that a decrease in symptoms of depression leads to a decrease in morbidity or mortality among patients with CAD (Pearson and Fuster 1996). Selective serotonin reuptake inhibitors (SSRIs) have beneficial pleiotropic effects, such as reduction of platelet activity (Serebruany et al. 2003), and improvement in heart rate variability (Yeragani et al. 2002), and have demonstrated effectiveness in treating MDD in CAD (Lesperance et al. 2007). However, randomized trials of antidepressant treatment, such as the Sertraline AntiDepressant Heart Attack Randomized Trial (SADHART; Glassman et al. 2002), and the Myocardial Infarction and Depression—Intervention Trial (MIND-IT; van den Brink et al. 2002) failed to demonstrate a reduction in risk for cardiac events. Similarly, no beneficial effects on cardiac outcomes were found in studies of psychotherapeutic interventions such as the Montreal Heart Attack Readjustment Trial (MHART; Frasure-Smith 1995) and the Enhancing Recovery in Coronary Heart Disease Patients (ENRICH; Berkman et al. 2003) trials. More recently, a study of enhanced depression treatment in patients with acute coronary syndrome demonstrated a reduction in major adverse cardiac events in intervention patients compared with usual-care patients (Davidson et al. 2010). Unique aspects of this study were a flexible treatment model in which patients could choose problem-solving therapy and/or antidepressants and selection for persistent (>3 months) depression. A better understanding of the temporal and mechanistic relationships between de-

pression and CAD will be crucial for the design of future trials in order to clarify potential medical effects of antidepressant treatment (Dickens et al. 2007). (See also Chapter 18, “Heart Disease.”)

Cancer

Prevalence rates for MDD in cancer have varied widely in the literature depending on the conceptualization of depression and on the diagnostic scheme employed, with reported rates ranging from 0% to 38% (Massie 2004). These prevalence rates also vary with disease severity, with consistently higher rates found in patients with more advanced disease, in hospitalized samples, and in patients with lower performance status. There has long been the speculation that pancreatic cancer has a specific association with depression and that depression often precedes the cancer diagnosis. More recently, however, it has been suggested that this association may have been overestimated and that depressive symptoms in this context are closely linked to pain and other physical symptoms (Makrilia et al. 2009). Certain chemotherapeutic agents used to treat cancer, including the cytokines (e.g., interleukin-2, interferon-alpha), corticosteroids (e.g., prednisone, dexamethasone), and *Vinca* alkaloids (e.g., vincristine, vinblastine), are also associated with higher rates of depression (Capuron et al. 2001).

Depression in cancer is associated with many adverse health outcomes. Several studies have suggested that it is an independent predictor of mortality (Lazure et al. 2009; Lloyd-Williams et al. 2009), although others have failed to find such an association (Akechi et al. 2009; Phillips et al. 2008). Other reported adverse sequelae include decreased compliance with medical treatment, increased length of hospital stays, impaired quality of life, and reduced capacity to cope with pain and other physical symptoms (Pellier et al. 2002; Pirl and Roth 1999). The emergence of MDD has also been associated with significantly higher rates of treatment discontinuation in patients with malignant melanoma receiving interferon-alpha (Musselman et al. 2001) and with a heightened desire for hastened death in hospitalized cancer patients (J.M. Jones et al. 2003) and outpatients with metastatic cancer (Rodin et al. 2007c).

Evidence that treatment of depression in cancer improves medical outcomes is limited. In a randomized controlled trial of a 6-month course of fluoxetine versus placebo in early-stage breast cancer patients undergoing adjuvant therapy, Navari et al. (2008) reported that fluoxetine reduced depressive symptoms, improved quality of life, and increased the percentage of patients who successfully completed adjuvant treatment. Studies have yet to be published on recurrence or survival rates associated with treatment of MDD. Although the question of whether psychotherapy can improve survival in cancer has been a hotly

debated one (Coyne et al. 2009; Kraemer et al. 2009), the preponderance of the evidence demonstrates that the psychosocial interventions that are effective in reducing depressive symptoms do not confer a survival benefit in cancer (Kissane 2009). (See also Chapter 23, "Oncology.")

Type 1 Diabetes

Type 1 diabetes mellitus is a chronic medical condition associated with considerable treatment demands, including multiple daily tests of serum glucose levels and injections of insulin, and adherence to a restrictive diet. Individuals with diabetes must also live with the risk of multiple medical complications, including blindness, renal failure, amputations, neuropathy, and cardiovascular disease. The burden of this disease and its frequent medical comorbidity would be expected to increase the risk for depression although it also has been suggested that the metabolic impairment in type 1 diabetes mellitus may contribute to mood disturbances via neurobiological mechanisms (Musselman et al. 2003).

Depression in individuals with diabetes mellitus is an important risk factor because it is associated with poorer adherence to the diabetic dietary and medication regimen and with poorer quality of life (Van Tilburg et al. 2001). Poor glycemic control has been associated with MDD in some studies (Lustman et al. 2000a), although this finding has not been consistently reported (A.M. Jacobson et al. 1990). However, depression has been associated with an increased risk of diabetes-related medical complications, including sexual dysfunction, retinopathy, nephropathy, heart disease, and stroke (de Groot et al. 2001), and with increased mortality (Milano and Singer 2007). Because of the reciprocal relationship between depression and metabolic control, attention to both mood disturbances and measures to enhance diabetes management is necessary to prevent or delay the progression of such complications (see also Chapter 22, "Endocrine and Metabolic Disorders").

Neurological Disease

The relation between neurological disorders and depression has been of particular interest both because of the frequent comorbidity of these conditions and because understanding the interface between depression and disorders of the central nervous system (CNS) may help to clarify the neuroanatomic pathways involved in depression. Sheline (2003) noted that the sites of damage in neurological disorders associated with late life depression, including the frontal cortex, hippocampus, thalamus, amygdala, and basal ganglia, overlap with those implicated in early onset recurrent MDD. In particular, the limbic-cortical-striatal-pallidal-thalamic tract, which is intimately involved in emotional regulation, has been associated with structural

brain abnormalities, particularly volume loss, in computed tomography (CT) and magnetic resonance imaging (MRI) studies of patients with primary unipolar depression. Mechanisms that have been postulated to account for this volume loss in early onset recurrent depression include chronic stress-induced hypercortisolemic neurotoxicity, inhibition of neurogenesis, decreased brain-derived growth factor, and loss of neuroplasticity (Benedetti et al. 2006). However, no specific neurobiological lesions or disorders have yet been shown to be associated with elevated rates of depression, after controlling for the effects of disability and disease severity.

Parkinson's Disease

Depressive symptoms are common in patients with Parkinson's disease; indeed, melancholia was included in the original description of the condition by James Parkinson in 1817. Such depression may be caused by the psychosocial stress of this progressive incurable and disabling disorder and its implications for the future of the affected individual. However, neurobiological factors also may play an etiological role. For example, neurodegeneration of subcortical nuclei and disturbances in the circuit connecting the basal ganglia to the thalamus and frontal cortex have been shown to correlate with clinical symptoms of depression in patients with Parkinson's disease (McDonald et al. 2003). It also has been postulated that degeneration of dopamine-, serotonin-, and norepinephrine-containing neurons in the ventral tegmental area and in the substantia nigra, which project to mesocortical, mesolimbic, and striatal areas, may contribute to depression in these patients (McDonald et al. 2003).

The assessment of depression in patients with Parkinson's disease is particularly challenging. It may be difficult to differentiate depressive symptoms, such as psychomotor retardation, affective restriction, fatigue, and disturbances in sleep and concentration, from the core features of Parkinson's disease. Furthermore, the akinesia and restricted facial expression that are characteristic of Parkinson's disease, as well as the apathy and cognitive impairment that may accompany comorbid dementia, may all be mistaken for symptoms of depression. However, evidence indicates that screening instruments, such as the BDI-II, are still useful for assessment of depression in Parkinson's disease, despite the overlap of somatic items with symptoms of Parkinson's (Leentjens et al. 2000). Depressive disorders in patients with Parkinson's disease have been associated with increased impairment of fine motor performance, decrements in cognitive function, and reduced perceived quality of life (McDonald et al. 2003). In fact, in a randomized multisite treatment study, depressive symptoms were the single most important determinant of patient quality-of-

life ratings, exceeding the effects of both disease severity and medication (Global Parkinson's Disease Survey Steering Committee 2002).

Stroke

Strokes are the third leading cause of mortality and the most common serious neurological disorder, accounting for 50% of all acute hospitalizations for neurological disease (Robinson 2003). Depression adversely affects functional rehabilitation and cognitive functioning in the post-stroke period (Tharwani et al. 2007) and may be associated with a heightened risk of mortality after 1 year (House et al. 2001) and 10 years (Morris et al. 1993), even after controlling for medical and other background variables.

It has been suggested that early poststroke depression is associated with lesions in the left anterior and left basal ganglia regions (Robinson 2003) and that chronic post-stroke depression is associated with lesions in the subcortical white matter, thalamus, basal ganglia, and brain stem (Bogousslavsky 2003). However, meta-analysis has failed to show any association between poststroke depression and left anterior or left hemisphere lesions (Carson et al. 2000). More recently nonlocalized central nervous system inflammation, resulting in platelet and adrenocortical hyperactivity, have been proposed to explain the association between depression and stroke (Arbelaez et al. 2007).

Tricyclic antidepressants (TCAs) such as nortriptyline and SSRIs such as citalopram are effective in treating post-stroke depression (Robinson et al. 2000) and some evidence suggests that this may also result in a reduction in associated cognitive impairment (Kimura et al. 2000). The evidence has been mixed on whether prophylactic treatment with SSRIs can prevent the emergence of depression or other morbidity in stroke patients. Six months of prophylactic treatment with the SSRI sertraline was not found to prevent this complication (Almeida et al. 2006), and two of three randomized controlled antidepressant trials (Narushima et al. 2002; Rasmussen et al. 2003) found that cardiovascular morbidity and mortality may be reduced in stroke patients who receive antidepressant medication, particularly SSRIs.

Dementing Disorders

Depression is one of the most common neuropsychiatric, noncognitive symptoms of Alzheimer's dementia (Lee and Lyketsos 2003). The prevalence of MDD ranges from 20% to 32% in Alzheimer's dementia (Lyketsos et al. 2002; Migliorelli et al. 1995) with minor depression reported to occur in an additional 25% (Migliorelli et al. 1995). However, symptoms of Alzheimer's dementia, such as emotional lability, may be easily mistaken for depression, and other symptoms, such as apathy, may arise additively from both

conditions. In that regard, apathy was found in 27% of patients with Alzheimer's dementia alone and in 56% of those with comorbid MDD (Lyketsos et al. 2001). The diagnosis of depression is often difficult to make, however, in cognitively impaired patients because of the associated impairments in communication and insight (Lee and Lyketsos 2003).

In some circumstances, depressive symptoms have been associated with an increased risk for the development of mild cognitive impairment (Barnes et al. 2006). In particular, both late-onset depression and depression associated with reversible cognitive impairment (i.e., pseudodementia) have been shown to be highly correlated with the eventual diagnosis of Alzheimer's dementia (Alexopoulos et al. 1993). It has been postulated that noradrenergic neuronal loss in the locus coeruleus and serotonergic cell loss in the dorsal raphe nucleus in Alzheimer's dementia may contribute to these high rates of reported antecedent depression (Forstl et al. 1992). However, the findings regarding the treatment of depression in Alzheimer's dementia have been equivocal. Some studies have found antidepressants to be efficacious in the treatment of depression in this population, whereas others have reported minimal treatment effects (Lee and Lyketsos 2003). Further research is needed, given that depression in Alzheimer's dementia is associated with more adverse outcomes, such as earlier nursing home placement, diminished activities of daily living, more rapid cognitive decline, and increased mortality (Kopetz et al. 2000; Lyketsos et al. 1997).

Epilepsy

Depression is the most common psychiatric condition found in patients with epilepsy, with prevalence rates linked to the adequacy of seizure control. MDD has been found in 20%–55% of those with poorly controlled seizures but in only 3%–9% of those whose seizures are well controlled (Kanner 2003). The relation between depression and epilepsy appears to be bidirectional. Depression may be caused by a seizure disorder, particularly with complex partial seizures (Kanner 2003). Conversely, monoamine depletion, which may occur with depression, may contribute to seizure activity (Jobe et al. 1999). The interictal period is a time of increased risk for depression with temporal lobe epilepsy (Quiske et al. 2000), and abnormalities in 5-hydroxytryptamine (5-HT; serotonin) receptor binding have been identified outside of the epileptogenic zone (Savic et al. 2004). A history of depression was found to be 17 times more common in patients with complex partial seizures than in control subjects (Forsgren and Nystrom 1990). Although antidepressants may lower the seizure threshold, this risk is small and more common with TCAs than with SSRIs or venlafaxine (Kanner 2003). Bupropion,

maprotiline, and amoxapine are the antidepressants most likely to trigger seizures and should be avoided in this population (Pisani et al. 2002).

Other Neurological Disorders

The lifetime risk for depression in patients with multiple sclerosis ranges from 40% to 60% (Beal et al. 2007; Wallin et al. 2006). Some evidence indicates that depressed patients with multiple sclerosis are more likely than comparable nondepressed patients to have white matter demyelinating plaques involving the arcuate fasciculus (Pujol et al. 1997). Interferon-beta-1b, used to treat multiple sclerosis, is associated with depression in up to 40% of patients with that condition (Mohr et al. 1996). Increased expression of the inflammatory cytokine interferon-gamma is related to depression severity in multiple sclerosis patients, with levels decreasing following psychotherapy or pharmacotherapy (Mohr et al. 2001). Huntington's disease, an autosomal dominant disorder affecting the basal ganglia and characterized by involuntary movements and cognitive impairment, has been associated with MDD in up to 32% and with bipolar disorder in 9% of patients (Folstein et al. 1983). These and other neurological disorders are discussed more fully in Chapters 6 ("Dementia") and 32 ("Neurology and Neurosurgery").

Depression Caused by Medications

A broad range of prescription medications have been purported to be etiologically linked to depression (Sadock et al. 2007). These include many which are standard of care in the treatment of medical illnesses (e.g., L-dopa in Parkinson's disease, calcium channel blockers in hypertension, analgesics and nonsteroidal anti-inflammatory drugs [NSAIDs] in arthritis, phenobarbital in epilepsy). The association of these medications with depression has largely been based on case reports, with relatively few empirical studies, and those conducted have been hampered by methodological and conceptual problems. Some reports in the literature have been uncritical, either misinterpreting drug-induced symptoms as indicative of depression (e.g., weakness, sedation, bradykinesia, fatigue, anorexia, insomnia) or misattributing preexisting depression to the drug. Consequently, controversy surrounds both the claims that specific drugs cause depression (e.g., beta-blockers) and the attempts to quantify the magnitude of risk (e.g., isotretinoin). In their review of the literature on drug-induced depression, Patten and Barbui (2004) concluded that no medications directly cause the typical MDD syndrome, although some may cause substance-induced alterations in mood. Valid evidence linking the drug to atypical depres-

sive syndromes was found only for corticosteroids, interferon-alpha, interleukin-2, gonadotropin-releasing hormone agonists, mefloquine, progestin-releasing implanted contraceptives, and propranolol. Most of these drugs and their psychiatric side effects are discussed in other chapters of this textbook.

Treatment

Several recent studies have reported that both pharmacological and psychotherapeutic interventions are effective for the treatment of depression associated with medical disorders such as type 1 diabetes mellitus (Musselman et al. 2003), CAD (Lesperance et al. 2007), chronic obstructive pulmonary disease (I. Wilson 2006), cancer (Rodin et al. 2007a), HIV infection and AIDS (Olatunji et al. 2006), renal disease (Tossani et al. 2005), stroke (Chen et al. 2006), multiple sclerosis (Wallin et al. 2006), Alzheimer's disease (Thompson et al. 2007), and Parkinson's disease (Lagopoulos et al. 2005). However, despite the evidence for the effectiveness of treatment for depression in medical populations, it has been estimated that more than 60% of primary care patients with depression do not receive adequate care for this condition (Kessler 2003).

Psychopharmacological Management of Depression

SSRIs, heterocyclic antidepressants and TCAs, novel antidepressants, and psychostimulants have been evaluated in the treatment of depression comorbid with medical illness. All antidepressants are discussed more fully in Chapter 38 ("Psychopharmacology"); we summarize some key points here.

Selective Serotonin Reuptake Inhibitors

SSRIs are generally regarded as first-line pharmacological treatment in the management of depression in the medically ill because of their tolerability and relative safety. Randomized controlled trials have shown various SSRIs to be effective and safe in patients with cardiac disease (Glassman et al. 2002), stroke (Wiat et al. 2000), cancer (Pezzella et al. 2001), HIV infection (Rabkin et al. 1999), Alzheimer's disease (Lyketsos et al. 2000), multiple sclerosis (Mohr et al. 2001), and diabetes (Lustman et al. 2000b). SSRIs have been regarded generally as safer and less toxic than TCAs, although significant side effects still may occur with these medications, particularly in the medically ill (Richard et al. 1999). All SSRIs can cause nausea, headache, sexual dysfunction, and tremor. Other frequent side effects include nervousness, insomnia, sedation, diarrhea, constipation, and dry mouth. Rare but potentially serious side effects of

SSRIs include the syndrome of inappropriate antidiuretic hormone secretion and platelet dysfunction leading to bleeding (van Walraven et al. 2001). Some reports indicate that SSRIs may worsen motor symptoms in some patients with Parkinson's disease (Richard et al. 1999).

Drug interactions or hepatic disease may affect SSRI metabolism and excretion and alter antidepressant pharmacokinetics (Hiemke and Hartter 2000). A reduced initial dose with slow titration of the shorter-half-life SSRIs is recommended for patients with hepatic disease because the metabolism of SSRIs is decreased by significant hepatic disease (Joffe et al. 1998). Fluvoxamine should be avoided because of its propensity for drug interactions. Paroxetine is a strong inhibitor of cytochrome P450 (CYP) 2D6, which has been found to decrease levels of the active metabolite of tamoxifen frequently used in breast cancer (Jin et al. 2005). Sertraline and citalopram appear to present the lowest risk for drug interactions. Drug interactions are reviewed in detail in Chapter 38 ("Psychopharmacology") as well as in the chapters in Part III (Specialties and Subspecialties) of this volume.

Novel Antidepressants

Novel antidepressants include venlafaxine, duloxetine, bupropion, mirtazapine, nefazodone, and moclobemide (not available in the United States). Venlafaxine, duloxetine, bupropion, and mirtazapine, in particular, have become increasingly popular as alternatives to SSRIs in the medically ill, although there is little empirical evidence supporting their specific advantages in this population. Moclobemide was shown to be efficacious in reducing depressive symptoms in patients with Alzheimer's disease (M. Roth et al. 1996). A number of open trials point to the effectiveness of other novel antidepressants in patients with stroke (venlafaxine) (Dahmen et al. 1999), cancer (mirtazapine) (Theobald et al. 2002), and HIV infection (nefazodone) (Elliott et al. 1999). It has been suggested that greater depression remission rates may be achieved with the serotonin-norepinephrine reuptake inhibitors (SNRIs) venlafaxine and duloxetine, than with SSRIs (Smith et al. 2002), although this view is controversial. Similar to the SSRIs, venlafaxine is effective for hot flashes in breast cancer (Loprinzi et al. 2000) and both venlafaxine and duloxetine are effective for the treatment of neuropathic pain (Jann and Slade 2007). The main adverse effects of SNRIs are nausea and hypertension, particularly with high doses of venlafaxine, and elevation of serum transaminases and bilirubin with duloxetine. These side effects may limit their use in patients with hepatic or renal insufficiency.

Mirtazapine increases norepinephrine and serotonin concentrations through blockade of inhibitory receptors but does not appear to cause the nausea, insomnia, anxi-

ety, or sexual dysfunction associated with the SSRIs (de Boer 1996). As a result of its serotonin₃ receptor-blocking antiemetic effects, mirtazapine may be useful in treating medically ill patients who are experiencing nausea. It may also rapidly improve insomnia and anorexia, which are common in depressed medically ill patients. The most problematic side effects of mirtazapine are sedation and weight gain, although the latter effect may be desirable in some cachectic patients. Mirtazapine has minimal drug interactions (de Boer 1996).

Bupropion is a norepinephrine and dopamine modulator that has not been associated with sedation, weight gain, sexual dysfunction, or cardiotoxicity (Golden et al. 1998). It may be particularly useful in treating patients with prominent neurovegetative symptoms, such as fatigue (Raison et al. 2005). Side effects can include agitation, insomnia, and (at higher dosages) seizures. Because of the latter concern, single doses greater than 150 mg and daily dosages greater than 300 mg should be avoided in patients with brain tumors or a history of seizures (Golden et al. 1998).

Tricyclic Antidepressants

TCAs have been shown to be efficacious in poststroke depression, cancer, HIV infection, Parkinson's disease, Alzheimer's disease, multiple sclerosis, diabetes, and renal failure (Gill and Dansky 2003). They have also proven to be effective as analgesics in the treatment of chronic pain syndromes, including pain related to cancer (reviewed in Magni et al. 1987). Because of their analgesic and sedating effects, TCAs may be particularly useful in depressed patients with significant pain and/or insomnia.

TCAs are variably noradrenergic and/or serotonergic. Their side effects are related to their central and peripheral anticholinergic effects, their central antihistaminic properties, and their effects on cardiac conduction and on the peripheral autonomic nervous system. TCAs should be avoided in patients with cardiac disease in whom they may cause hypotension and arrhythmias (Glassman et al. 1993). TCAs should also be used with caution in patients with diabetes because of their anticholinergic, orthostatic, and other adverse cardiovascular effects (Carney 1998). Anticholinergic side effects of TCAs may also exacerbate cognitive impairment and cause delirium in patients with CNS disorders, especially dementia (Reynolds 1992). TCAs that are more anticholinergic are generally not recommended for the treatment of depression in immunocompromised patients, such as those with HIV or AIDS, because these medications promote candidiasis or thrush infections (Rabkin et al. 1994). TCAs also may not be suitable for patients who are at increased risk for bone fractures or who have skeletal weakness, because the side effect of orthostatic hypotension increases the likelihood of falls (Shuster

et al. 1992). TCAs have been associated with seizures, but usually at high plasma levels such as may occur with an overdose (Preskorn and Fast 1992).

Up to one-third of medical patients are unable to tolerate TCAs because of side effects (Benton et al. 2007), and these drugs can be lethal in overdose. For insomnia or pain, doses of TCAs lower than those required for an antidepressant effect may be effective. Among the TCAs, the secondary amines, such as nortriptyline and desipramine, are better tolerated by the medically ill. In addition, nortriptyline has reliable serum levels and a defined therapeutic window that may guide clinical management, particularly in patients with liver disease or malabsorption (Potter et al. 1998).

Psychostimulants

Methylphenidate has been reported to alleviate depressive symptoms in a range of medical conditions, including stroke (Grade et al. 1998), HIV disease (Fernandez et al. 1995), and cancer (Grade et al. 1998), although its efficacy for this purpose has not yet been adequately demonstrated in randomized controlled trials. Psychostimulants are generally well tolerated and at relatively low doses can serve as adjuvant analgesics (Bruera et al. 1987). They may elevate mood rapidly, increase appetite, diminish fatigue, improve attention and concentration, and reduce sedation caused by opiates or other drugs (Orr and Taylor 2007). Many consider psychostimulants to be the antidepressants of choice in the palliative care setting because of their rapid onset of action (K. Wilson et al. 2000). Side effects are typically mild and dose-related and include agitation, nausea, and insomnia. Rarely, psychotic symptoms or tachycardia and hypertension may occur (Masand et al. 1991). Methylphenidate is typically given in divided doses (2.5–10.0 mg) in the morning and afternoon. Modafinil, a newer stimulant not associated with tolerance or dependence, is increasing in use as evidence of its effectiveness is accumulating (Ballon and Feifel 2006).

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is sometimes used in the medically ill as an alternative to antidepressants in the treatment of severe or refractory depression (Beale et al. 1997). It has been shown to be an effective treatment of depression in Parkinson's disease and also may improve the symptoms of the Parkinson's disease itself (Poewe and Seppi 2001). It has also been shown to improve poststroke depression and depression associated with multiple sclerosis, endocrine disorders, and renal failure (Krystal and Coffey 1997). ECT has been associated with improvements in cognition and mood in patients with dementia (Rao and Lyketsos 2000) and is considered safe for epilepsy pa-

tients with severe or refractory depression (Lambert and Robertson 1999). It should be considered early in the course of psychotic depression and for depression associated with severe suicidal ideation or failure to maintain adequate nutritional status. ECT and its risks are reviewed in detail in Chapter 40 ("Electroconvulsive Therapy").

Psychotherapeutic Treatment

The relationship with the primary medical caregiver may be the most important psychotherapeutic tool to prevent or treat depression for many patients with a serious medical illness. In addition, specific psychological therapies may alleviate or prevent depression, without the risk of physical side effects or drug interactions, and may help to modify health behaviors that adversely affect disease outcomes. The indication to refer to a mental health professional for psychotherapy will depend on the severity of the depression and on the skill, interest, and availability of primary care practitioners. The specific psychotherapeutic intervention selected should also take into account the available support network and the patient's capacity to learn new coping strategies and/or to engage in a process that may involve introspection and the expression of feelings. Unique features of psychotherapy in the medically ill are the importance of collaborative relationships between the therapist and the medical caregivers, the likelihood of frequent disruptions in treatment due to complications of the disease, and the need for flexible treatment goals that accommodate shifts in the patient's physical well-being and capacity to participate. In more advanced disease, issues related to hope, existential well-being, and advance care planning may be prominent (Rodin et al. 2009; Vamos 2006).

Specific psychotherapeutic approaches that may alleviate depression in medical populations include cognitive-behavioral therapy (CBT), interpersonal therapy, and supportive-expressive therapy delivered on an individual or a group basis. Peer support, self-help, and cognitive behavioral groups (e.g., psychoeducation, guided imagery/relaxation) also may protect patients from depression by diminishing stigma and feelings of isolation and by promoting self-efficacy and a sense of mastery. A recent Cochrane review of psychotherapy for depression among incurable cancer patients concluded that psychotherapy is effective in decreasing depressive symptoms, although no studies were identified that focused on patients with MDD (Akechi et al. 2008).

There is limited evidence that psychological interventions either reduce or prevent the emergence of depressive symptoms in patients with cancer (C.M. Jacobson et al. 2008), cardiovascular disease (Rivelli and Jiang 2007), diabetes (Musselman et al. 2003), HIV/AIDS (Olatunji et al. 2006), and multiple sclerosis (Wallin et al. 2006). Evidence

for the effectiveness of psychological therapies in stroke, heart failure or dialysis is also lacking. A randomized trial of CBT for poststroke depression found no evidence of benefit (Lincoln and Flannaghan 2003), and Cochrane reviews failed to identify any randomized controlled trials of psychological interventions for depression in either heart failure (Lane et al. 2005) or dialysis patients (Rabindranath et al. 2005).

The vast majority of research on psychosocial interventions for depression in medical illness has been conducted in cancer settings. Numerous systematic reviews and meta-analyses of psychosocial interventions in cancer have found treatment effects for depressive symptoms in 22%–83% of randomized controlled trials (Jacobsen 2006; Newell et al. 2002; S. Williams and Dale 2006), and two systematic reviews of psychosocial interventions for categorical diagnoses of MDD demonstrated a treatment effect in 50% of randomized controlled trials (Rodin et al. 2007a; S. Williams and Dale 2006). Based on a meta-analysis of 20 trials, Sheard and Maguire (1999) concluded that psychological interventions have no clinical effect in preventing depression in cancer. However, Kissane et al. (2007) published the first randomized controlled trial demonstrating that supportive-expressive group therapy was effective in preventing the emergence of MDD in women with metastatic breast cancer.

In other medical illnesses, Barrett et al. (2001) found that paroxetine and a problem-solving approach to support active coping strategies were equally effective for the treatment of minor depression or dysthymic disorder in a primary care sample but were no more effective than watchful waiting for the treatment of minor depression. Teri et al. (1997) found that patients with Alzheimer's disease and depressive symptoms showed significant improvement in depressive symptoms following a behavioral intervention for patient–caregiver dyads focused on either pleasant events or caregiver problem solving. Lustman et al. (1998) showed in patients with type 2 diabetes that an intervention that included CBT and diabetes education produced a depression remission rate three times higher than that in a control condition and was associated with a significant improvement in glycosylated hemoglobin 6 months after the end of treatment.

There is growing evidence in medical and nonmedical populations that combined psychotherapy and pharmacotherapy may be more effective than either modality alone. A multicompont randomized controlled trial in patients with a recent myocardial infarction examined the effects of treatment with CBT plus group therapy when feasible, supplemented with SSRIs in patients who had elevated and/or persistent depressive symptoms. Results revealed improvement in the treatment group that was significantly greater

than that in the usual-care group (Berkman et al. 2003). Kelly et al. (1993) found that both cognitive-behavioral and support group brief therapies equally reduced depressive symptoms in depressed HIV-infected individuals, while Markowitz et al. (1998) found that depressed HIV-positive patients had greater improvement in depressive symptoms with interpersonal therapy or supportive psychotherapy plus imipramine than did subjects who received supportive therapy or CBT alone.

These studies of psychotherapeutic interventions to treat depression in a variety of medical populations indicate some degree of effectiveness, which is often improved when combined with antidepressant medication. Numerous other nonspecific psychotherapeutic and educational interventions also may be effective in reducing depressive symptoms and in protecting individuals from their emergence. The full range of psychosocial interventions designed to improve adjustment in medical populations is discussed at more length in Chapter 39 (“Psychotherapy”) and in other chapters of this textbook.

Conclusion

Clinical depression, particularly MDD and dysthymic disorder, is common in the medically ill and is associated with impaired quality of life, decreased compliance with medical treatment, and increased medical morbidity and mortality. The elevated prevalence of depression in the medically ill is most often the result of multiple nonspecific risk factors, although there is continued speculation that specific biological mechanisms operate in certain medical conditions. The diagnosis of depressive disorders in medical patients is complicated by the frequent overlap between symptoms of depression and those of medical illness. This overlap may contribute to underdiagnosis, when symptoms of depression are assumed to be features of the medical condition, or to overdiagnosis, when symptoms of a medical illness are attributed to a depressed mood. However, the neglect of simple inquiry about the symptoms of depression may be the most common reason that the diagnosis of depression is overlooked in a medical population. Screening tests may be useful for drawing the attention of clinicians to these symptoms and identifying patients in medical clinics who are most likely to have depressive disorders.

Psychopharmacological and psychotherapeutic approaches are both effective in the treatment of depressive disorders in the medically ill and are often even more effective when used together. Medical patients may be more sensitive to the side effects of pharmacological treatments, and careful attention must be paid to the dosage, to the potential for drug–drug interactions, and to impairment in hepatic or renal function, which can affect drug metabolism.

Suicidality

John Michael Bostwick, M.D.

James L. Levenson, M.D.

ONE OF THE MOST COMMON questions posed to any psychiatrist, including psychosomatic medicine specialists, is whether a patient is suicidal. Suicidal ideation, frequent and ubiquitous in medical settings, challenges the psychiatrist to discern what drives the patient's suicidal statement. Compared with suicidal ideation, completed suicide is rare in psychiatric patients and rarer still in medically ill patients.

Completed suicides are statistically uncommon events. Many risk factors are recognized, but none has a high positive predictive value (Mann 1987). As a low-base-rate phenomenon, screening for suicide risk has a high rate of false-positive results. Demographic risk factors alone will identify many more subjects potentially at risk than imminently in danger of dying (Goldberg 1987).

Despite hundreds of studies over decades that have drawn dozens of epidemiological correlations between suicide and particular descriptors, no effective screening paradigm has been identified. This situation is no different with suicidality in medical illness. Many medical illnesses have been associated with increased suicide attempts; for example, in one study, an elevated odds ratio (OR) for suicide was found in lung disease (OR = 1.8) and peptic ulcer disease (OR = 2.1) (Goodwin et al. 2003). A Canadian study showed elevated ORs for completed suicide in cancer (1.73), prostate disease (1.70), and chronic pulmonary disease (1.86) (Quan et al. 2002). In a Swedish study, visual impairment (OR = 7.00), neurological disorders (OR = 3.8), and malignancy (OR = 3.4) were independently associated with suicide (Waern et al. 2002). In U.S. dialysis patients, the OR for suicide was calculated at 1.84 (Kurella et al. 2005). Nevertheless, these increased rates are still too low to consider the medical diagnosis a predictor of suicide.

Moreover, no epidemiological risk factor represents an individual's suicide intent—the essential, highly personal variable in suicide prediction (Davidson 1993). Fortunately, the field of suicidology has shifted from trying to predict individual suicides to a more realistic goal of estimating probabilities of risk for particular subpopulations (Hughes and Kleespies 2001). Such data can then be used to inform the psychiatrist's assessment of an individual patient's suicide threat while also considering the personal meaning of the patient's communication.

A focus on probabilities of risk and general categories of psychiatric symptoms rather than individual diagnoses lends itself well to understanding suicidality in the medically ill. Medical illness by itself is rarely a sole determinant of suicide potential. Comorbid factors drive what is best understood as a multidetermined act (Hughes and Kleespies 2001). Shneidman (1989), the father of American suicidology, conceptualized a cubic model of suicidal states, incorporating *perturbation* (the state of being stirred up or upset), *pain* (psychological pain resulting from frustrated psychological needs), and *press* (genetic and developmental susceptibility to particular events). Moscicki (1995) envisioned two distinct but interactive groups of risk factors, with recent events—"proximal risk factors"—unfolding on a substrate of underlying "distal" conditions. According to both models, the assessment of a medically ill person—as with any suicidal person—demands attention not only to current events but also to what past characterological, temperamental, or experiential features push someone toward suicide.

In Mann's (1998) diathesis-stress model of suicidal behavior, *stresses* resemble Moscicki's proximal factors, and *diatheses* resemble her distal ones (Figure 9-1). Noting that

FIGURE 9-1. Diathesis-stress model of suicidal behavior: components of stress and diathesis.

Source. Adapted from Mann JJ: "The Neurobiology of Suicide." *Nature Medicine* 4:25-30, 1998. Copyright 1998. Used with permission.

two groups of patients, each with the same severity of depressive illness, attempt suicide at different rates, Mann proposed suicide diathesis components, including genetic predisposition, early life experience, chronic illness, chronic substance abuse, and certain dietary factors. Extreme stress alone, which Mann defined as acute psychiatric illness, intoxication, medical illness, or family and social stresses, is not typically enough to invoke suicidal behavior. A suicidal individual already has the predisposition, or diathesis, on which the stress is superimposed, resulting in the suicide attempt (Mann 1998).

Mann's subcategories adapt readily to the medically ill. Acute intrinsic psychiatric illness is represented by dementia, depression, delirium, and anxiety in the context of a general medical illness. Acute substance abuse appears in the form of intoxication or withdrawal syndromes. Acute medical illness includes not only the disease itself but also the effects of treatments. Acute family and social stresses could include fears of becoming a burden, financial consequences such as expense of treatment and lost income, and disruption in the family members' lives. These state phenomena occur against the background of trait characteristics, which Mann labels as *diathesis*. Diatheses include genetic predisposition to illness, coping styles and personality

characteristics (e.g., pain tolerance), and the long-term effects of chronic physical illness or substance abuse.

The Mann model, though comprehensive, does not inform the psychiatrist whether a particular patient is at immediate risk for suicide. Litman (1989) noted that the 95% prevalence of psychiatric illness among individuals who commit suicide is derived from psychological autopsies and retrospective studies, the scientific equivalent of Monday-morning quarterbacking. At any moment, very few of those who are "at risk" will die by suicide. Identifying the medical patient at high risk is just a first step in evaluation. The search for possible biological markers for suicide has focused on the midbrain dorsal and median raphe nuclei, with their serotonergic inputs to the ventral prefrontal cortex. Responsible for dampening aggressive or impulsive behavior, the ventral prefrontal cortex exerts its inhibitory effects on suicidal behavior less effectively when serotonergic hypofunction occurs (Kamali et al. 2001). A history of child abuse, a familial depression history, substance abuse, head injury, genetic variants, and low cholesterol levels are all associated with both lower serotonergic activity and greater suicide risk (Mann 1998). No practical test based on these psychobiological research advances currently exists. If a test were available, it would likely provide

only one more risk factor in a complex biopsychosocial formulation.

Kishi and Kathol (2002) identified four “pragmatic reasons” for suicidality: 1) psychosis, 2) depression, 3) poor impulse control, and 4) philosophical reasons. White et al. (1995) subdivided the suicidal medically ill into three general categories: 1) patients admitted to a medical–surgical bed after a suicide attempt, 2) patients with delirium and resultant agitation and impulsivity, and 3) patients with chronic medical illness causing frustration or hopelessness.

In this chapter, we integrate these two approaches first by reviewing the general epidemiology of suicide and suicide attempts and then by discussing psychodynamic and social factors. The next section concerns the management of the medical and surgical consequences of a suicide attempt and the care of high-risk patients on medical inpatient units. Suicide in the medically ill is reviewed next, exemplified by a focus on cancer, end-stage renal disease, and AIDS. Finally, we address physician-assisted suicide.

Epidemiology

Suicide assessment begins with demographic clues to the patient’s relative risk of suicide. Both descriptive and dynamic risk factors are important. In this section, we review descriptive risk factors—comparatively static characteristics of the individual. As the subsequent sections make clear, however, changes in psychiatric status coupled with recent life events are crucial in understanding suicidality in the medically ill.

Completed Suicide

Reported suicide was the eleventh leading cause of death in the United States in 2006, with 33,300 suicides comprising 1.4% of all deaths (McIntosh 2009). The known suicide rate today is nearly identical to what it was in 1900 (Monk 1987), but the epidemiology of suicide has been shifting over the past few decades. Between 1990 and 2001, suicide rates decreased in every age category, with the overall annual rate in the United States declining from 12.4 to 10.8 per 100,000. Over the most recent 5 years for which statistics are available, however, the rate has ticked up in several age groups—as has the overall rate, to 11.1 per 100,000. In 2006, annual suicide rates per 100,000 individuals increased over the life span—from 0.5 in 5- to 14-year-olds and 9.9 in 15- to 24-year-olds to 15.9 in those ages 85 years and older. In 15- to 24-year-olds, suicide ranks behind only accidents and homicide as a leading cause of death (McIntosh 2009). The suicide rate among men is 3.8 times higher than that among women. Nonwhite Americans killed themselves in 2006 at less than half the rate of white Americans (McIntosh 2009).

Over the course of the life cycle, men and women show different patterns of suicide. For men, suicide rates gradually rise during adolescence, increase sharply in early adulthood, and then decrease before starting an upward trajectory in midlife, increasing into the 75- to 84-year age bracket and beyond (Shneidman 1989). Suicide rates for women peak in midlife and then decrease, in contrast to the bimodal peaks for men. Men’s suicide methods tend to be more violent and lethal; men are more likely to die by hanging, drowning, and shooting. Women are less likely to die in suicide attempts because they are more likely to choose the less lethal methods of wrist cutting and overdose (Kaplan and Klein 1989; A. Morgan 1989). Traditionally, epidemiological studies have shown that suicide attempters are more likely to be younger, female, and married and to use pills, whereas completers are more likely to be older, male, and single and to use violent means (Fawcett and Shaughnessy 1988). However, anyone at any age may contemplate or execute suicide.

History of a suicide attempt is an important predictor of future suicide risk (Pokorny 1983). One of every 100 suicide attempt survivors will die by suicide within 1 year of the index attempt, a suicide risk approximately 100 times that for the general population (Hawton 1992). Twenty-five percent of chronically self-destructive or suicidal individuals will eventually kill themselves (Litman 1989). Of those who complete suicide, 25%–50% have tried before (Patterson et al. 1983). A Danish study of patients admitted to a psychiatric unit after a suicide attempt reported that 12% successfully completed suicide within the next 5 years, 75% within 6 months of their last admission (Nielsen et al. 1990). Bostwick and Pankratz (2000) found that depressed patients who had suicidal ideation or who had just made a suicide attempt had a lifetime prevalence of suicide of 8.6%. Palmer et al. (2005) determined that three-fourths of suicides in schizophrenic patients occur within 10 years of the first admission or first diagnosis.

It has been repeatedly shown in general population U.S. and European retrospective psychological autopsy studies over the last half-century that psychiatric illness—particularly depression and alcoholism—is associated with the vast majority of completed suicides (Barraclough et al. 1974; Dorpat and Ripley 1960; Robins et al. 1959; Roy 1989). Most patients had not been identified before death as being psychiatrically ill, however, and had not received treatment.

Many suicides are committed by patients with active alcohol and other substance use disorders. In one study, 43% of the suicide attempters were using alcohol at the time of the attempts (Hall et al. 1999). An Australian study of completed suicides by methods other than overdose found that 41% had been drinking alcohol and 20% had been using

illicit drugs (Darke et al. 2009). Although alcohol abusers may kill themselves at any age, especially when acute intoxication clouds their judgment and disinhibits them, those with chronic alcoholism tend to commit suicide after their relationships, work performance, and health are all in decay. Murphy and Weitzel (1990) estimated that 3.4% of alcoholic patients kill themselves, a rate that is nearly three times the lifetime risk in the general population (Murphy and Weitzel 1990). Most of the higher suicide rates among men may be accounted for by the higher rates of alcoholism among men (Klerman 1987).

Alcoholic patients often commit suicide in response to crises in their personal lives. One-third of alcoholic individuals who kill themselves have lost a close relationship within the previous 6 weeks, and another one-third anticipate such a loss (Murphy 1992). Alcoholic patients frequently have numerous other suicide risk factors, many resulting from their substance abuse, including comorbid major depression, estrangement from family and social supports, unemployment, and serious medical illness. People who abuse other psychoactive substances also have high suicide rates. For example, opiate-dependent patients kill themselves at 20 times the expected rate (Miles 1977), although inadvertent overdoses may constitute part of this number.

The audience for this chapter constitutes a group at particularly high risk. Physicians kill themselves at much higher rates than the people they treat. In comparison with the general population, male doctors have a relative risk of suicide of up to 3.4; for female doctors, the relative risk has been calculated to be as high as 5.7 (Center et al. 2003). Whereas suicide rates of men and women in the general population are widely disparate, they are nearly equal in male and female physicians (Center et al. 2003). More recent studies have found that the rate in female physicians now exceeds that in males (Lagro-Janssen and Luijckx 2008; Petersen and Burnett 2008). Medical students and residents are not immune. Although they begin medical school with the same rates of depression as their nonmedical peers, depression prevalence in medical trainees soon outstrips that in their peers (Rosenthal and Okie 2005). Suicide rates are also higher in trainees than their nonmedical counterparts (Reynolds and Clayton 2009).

Attempted Suicide

An estimated 832,500 suicide attempts occurred in the United States in 2006, 25 times more than completed suicides (McIntosh 2009). Although there are important differences, attempted suicides are not a discrete category from completed ones, particularly in the medically ill. Suicide attempts occur across spectra of lethality of intent and lethality of effect, which may or may not coincide. Some

patients deliberately plan death but naively choose a non-lethal method (e.g., benzodiazepine overdose), whereas others only intend gestures but unwittingly select a fatal method (e.g., acetaminophen overdose). At the more severe end of the spectrum, suicide attempters resemble completers. In a New Zealand study, Beautrais (2001) compared individuals who died by suicide with those who made very serious attempts. She found that they shared the same predictors, including current psychiatric disorder, history of suicide attempts, previous psychiatric care and contact, social disadvantage, and exposure to recent stressful life events.

Nonetheless, some characteristics distinguish surviving attempters from those who die. In the study by Hall et al. (1999) of serious suicide attempters, the patients, by and large, did not have long-standing mental illness or carefully considered plans. They did not have command hallucinations and were not particularly ruminative about their suicidal intent. Whereas 80% had symptoms of an anxiety or a depressive disorder, few had chronic symptoms. Patients who overdose are more likely to survive because they have time after the act to reconsider (or be found) and undergo medical treatment, infrequent options after a jump or a gunshot wound. As with completed suicides, demographics change over the life cycle. The ratio of attempts to death in the young is 100–200:1, but by old age, it narrows precipitously to 4:1.

Hackett and Stern (1991) reported that 1%–2% of all patients evaluated in the Massachusetts General Hospital emergency department had overdosed, and 47% of these required admission—one-half to medical-surgical wards and one-half to psychiatric units. Of the patients, 85% had overdosed on benzodiazepines, alcohol, nonnarcotic analgesics, antidepressants, barbiturates, or antihistamines/anticholinergics.

Medical illness is a common factor in suicide attempters admitted to general psychiatry units. In a 1-year sample of admissions to a Danish psychiatry unit, 52% of the individuals had a somatic disease, and 21% took daily analgesic medications for pain. The somatic group was older, and most had neurological or musculoskeletal conditions in conjunction with depression that was more severe than in the nonsomatic group (Stenager et al. 1994). In the study by Hall et al. (1999) of 100 serious suicide attempters, 41% had a chronic, deteriorating medical illness, and 9% had recently received a diagnosis of a life-threatening illness.

Psychodynamic and Social Factors

Litman (1989) described a *presuicidal syndrome*, a change in cognitive set, that characterizes lethal attempts and completed suicides. The presuicidal patient in crisis has con-

stricted choices and perception, a tunnel vision of life as hopeless, physical tension, and emotional perturbation. The tension and distress may be relieved by a fantasy of death. The hopelessness is combined with help rejection and distrust. Often the patient has a long-term disposition toward impulsive action, an all-or-nothing approach to problems, and the characterological attitude "my way or no way."

Klerman (1987) framed the presuicidal crisis in terms of a medical model—as the result of an underlying condition, the patient has lost the capacity for rational thought. The hopelessness and helplessness of severe depression may have reached irrational proportions. Auditory hallucinations may be commanding self-harm. Clouded sensorium, impaired judgment, and the disinhibition and misperceptions of delirium, intoxication, or substance withdrawal all may be causing the patient to act in uncharacteristically self-destructive or dangerous ways.

Gardner and Cowdry (1985) divided suicidal behavior into four categories, each with its own affective state, motivation, and outcome:

1. *True suicidal acts* are characterized by intense melancholia and despair, a wish for release from emotional pain, and the highest risk of completed suicide, given the likelihood of careful planning and a high-risk to low-rescue ratio.
2. *Retributive rage* is characterized by impulsiveness, vengefulness, and a nihilistic, constricted capacity to see other immediate options.
3. *Parasuicidal gesturing*, often repetitive and tinged with strong dependency needs, appears to be a form of communication, designed to extract a response from a significant other.
4. *Self-mutilation* serves the purpose of relieving dysphoria, a form of "indirect self-destructive behaviors" (N. Farberow 2000).

Only the first category includes the *intent* to die, but any of the four can be lethal.

An early study of personality factors and suicide among medically ill patients identified a "dependent-dissatisfied" behavior pattern among the patients who committed suicide (L. Farberow et al. 1966). Many subsequent investigators have added to the picture of the types of personality structure or cognitive styles that lend themselves to suicidal ideation or behavior. Berger (1995) observed that rational-seeming suicides were unusual in his study of the medically ill and that suicides in this population were correlated with maladaptive emotional reactions. Describing the role of hopelessness in the thinking of terminally ill cancer patients who wished for hastened death,

Breitbart et al. (2000) found the hopelessness to represent a pessimistic cognitive style rather than an accurate assessment of poor prognosis. That is, patients wished to speed death not because they were mortally ill but because they were chronically pessimistic. A similar finding came from Goodwin and Olfson's (2002) study of suicidal ideation in nearly 2,600 patients with physical illness diagnoses. Perception of poor health was a significant predictor of suicidal ideation, even after controlling for psychiatric disorders, physical conditions, and other factors. While a high score on a commonly used instrument such as the Beck Hopelessness Scale identifies a group at elevated risk, McMillan et al. (2007) caution that poor specificity limits the scale's utility in predicting which individuals in the group will actually kill themselves. Nonetheless, combating hopelessness per se in medically ill patients cannot be a bad thing, even if it doesn't pick out the suicidal among them.

One conclusion to be drawn from these studies is that a tendency of patients and medical providers alike to attribute hopelessness to the disease—the proximal factor—has resulted in a failure to recognize the mental disorder or personality type—the distal condition—that is actually speaking. "There has been a tendency to regard the suicide of a victim of severe medical illness, such as cancer, as a rational alternative to the distress caused by the disease," concluded Suominen et al. (2002) after analyzing a year's worth of suicides in Finland. "On the other hand, most suicide victims with physical illness have suffered from concurrent mental disorder....Mental disorders may thus have a mediating role between medical disorder and suicide" (p. 412).

Suicide is often a response to a loss, real or imagined. To help assess the meaning of suicidal ideation or behavior, psychiatrists must inquire about recent or anticipated losses and coping strategies that the patient has used with past losses (Davidson 1993). Fantasies of revenge, punishment, reconciliation with a rejecting object, relief from the pain of loss, or reunion with a dead loved one may be evident (Furst and Ostow 1979).

A patient's degree of autonomy and extent of dependency on external sources of emotional support can shed light on the level of psychic resilience (Buie and Maltsberger 1989). A recent loss of a loved one or a parental loss during childhood increases suicide risk. Holidays and anniversaries of important days in the life and death of the deceased person, when the loved one's absence is experienced more intensely, also increase the risk for suicide. In medical settings, what may be lost is a part of one's self. It may be tangible—an organ, a limb, sexual potency—or intangible—a sense of youthfulness, health, or invincibility. Glickman (1980) believed that a suicidal patient cannot be

judged safe until he or she has either regained the lost object, accepted its loss, or replaced it with a new object.

A social services intervention is likely to identify remediable contributors to suicidal states, particularly if the medical evaluation has not delved into the patient's social and interpersonal context. In the largest psychological autopsy study conducted to date, which interviewed informants for 100 individuals age 60 years or older who killed themselves, Harwood et al. (2006) found, not unexpectedly, that physical illness—particularly pain and increased physical dependence—contributed to 62 of the suicides. Interpersonal issues, including conflict and health worries about another person, factored in 31, and bereavement—both the recent death of a loved one and long-term social problems resulting from that death—influenced 25. Lesser contributors included impending relocation to a nursing home, financial distress, and occupational or retirement concerns. Once again, separate from whether these contributors to suicidal states are independent suicide predictors, they are stresses that in Mann's model help create the setting for a suicidal crisis.

Psychiatrists must monitor themselves for reactions and countertransference feelings toward suicidal patients. In medical settings, consulting psychiatrists help other health care professionals identify and overcome their countertransference reactions as well. These include the classic reactions of "countertransference hate" (Maltsberger and Buie 1974), in which aversion to the suicidal patient (conscious or unconscious) leads to acting angrily toward the patient or withdrawing to an aloof passivity, both of which increase the risk for suicide. Overidentification with seriously medically ill patients may lead to other countertransference reactions. For example, in response to a hopeless patient, the psychiatrist may become overly pessimistic or too reassuring.

Management in Medical Inpatient Settings

For a patient who survives a recent suicide attempt, the emergency department usually is the first stop for assessment and triage. If the patient is medically cleared, ideally a psychiatrist, but sometimes another mental health professional, evaluates the patient and decides whether psychiatric inpatient or outpatient management is the appropriate disposition. It is important for psychiatrists to form their own judgment about whether patients are truly medically stable enough for transfer out of the medical setting. Countertransference reactions to suicidal states frequently cause nonpsychiatric physicians to minimize the role of medical contributions and prematurely "clear" patients.

Once a patient is labeled "psychiatric," tunnel vision in initial evaluators may preclude performance of a comprehensive medical workup. For a patient with self-induced injuries severe enough to require additional medical or surgical care, admission follows, and a psychiatrist is consulted. Patients who are admitted to medical-surgical beds after suicide attempts represent a particularly dangerous subset of suicidal patients. Considering data from all of New Zealand's public hospitals, Conner et al. (2003) showed that individuals hospitalized with self-induced injuries have a relative risk of 105.4 for suicide within the next year and a relative risk of 175.7 for additional self-injury hospitalizations, compared with the New Zealand general population.

Divergent conditions such as delirium, psychosis, personality disorder, and intoxication and withdrawal syndromes have in common the impulsivity that must be anticipated and managed in medical settings. Withdrawal—particularly from alcohol or sedative-hypnotics—epitomizes impulsivity syndromes that can be deadly and must be recognized and aggressively managed with detoxification protocols. In the absence of a suitably equipped psychiatric unit, the psychiatrist will need to arrange medical admission.

In addition to trying to make the environment safe, egress must be controlled. In the general medical hospital, patients should be prevented access to open stairwells, roofs, and balconies, and all windows should be secured (Berger 1995; Bostwick and Rackley 2007). In a classic study of the dangers of hospitalizing impulsive patients in an unsecured environment, Reich and Kelly (1976) described 17 medical inpatients who attempted suicide while on the medical and surgical wards at Peter Bent Brigham Hospital between 1967 and 1973 and survived. They judged 15 of the 17 patients to have mental disorders, but the cardinal characteristics of depression and hopelessness were not present in this sample. "All...were impulsive acts, none of the patients gave warnings, left notes, expressed suicidal thoughts or appeared to be seriously depressed" (Reich and Kelly 1976, p. 300). The investigators considered most of these 17 attempts to be reactions motivated by anger at perceived loss of emotional support, usually from staff. They attributed this underlying impaired impulse control to personality disorders in 8 of the patients, to psychosis in 7, and to delirium in 3.

When a suicidal or an impulsive patient is too medically ill to be cared for on a locked general psychiatry unit, a medical-psychiatry unit—if a hospital has one—is the ideal disposition for such a patient. In the absence of such a specialty unit, medical intensive care units are more likely to provide one-to-one nursing care, although critical care physicians may argue that such observation in the ab-

sence of need for critical care is an inappropriate use of their service.

Case Vignette

Ms. C, a 22-year-old woman addicted to crack cocaine, developed severe cardiomyopathy after the birth of her third child. Four months later, no longer able to climb the two flights of stairs to her apartment without becoming short of breath, she was admitted to the hospital with congestive heart failure. A toxicology screen was positive for alcohol and cocaine.

After she arrived on the medical floor, Ms. C curled up in a fetal position and refused to speak to her nurse until she was found lighting a cigarette while receiving oxygen. When the nurse attempted to stop her, Ms. C began cursing and shrieked that if she were not allowed to smoke, she would overdose on digitalis she had hidden in the room.

Ms. C refused to submit to a room search. The psychiatric consultant recommended that security be called so that Ms. C could not leave before he could perform an emergency evaluation. Ms. C had to be placed in leather restraints when she assaulted the officers. After speaking with the psychiatrist, Ms. C agreed to take medication (5 mg of haloperidol and 1 mg of lorazepam). She then consented to a search of her belongings. A bottle of 50 digitalis tablets was found in her suitcase. Because of her threats and impulsivity, the psychiatrist recommended constant observation with sitters.

As Ms. C's case shows, the first task in the medical setting is ensuring the patient's safety (Gutheil and Appelbaum 2000). A safe environment must be created and maintained until the patient is stable enough for psychiatric transfer (Bostwick and Rackley 2007).

Patients who are most intent on suicide, as well as those who are most impulsive and unpredictable, may attempt suicide in the hospital. In order to secure a patient's room, staff must "think like a suicide" (Bostwick and Lineberry 2009)—that is, anything that patients could potentially use to injure themselves must be removed. Luggage and possessions should be searched with a suspicious eye and a morbid imagination. Staff must ferret out sharp objects, lighters, belts, caches of pills—anything that could inflict damage in either an impulsive or a carefully planned way. Special attention should be paid to items that could be used for self-strangulation, including drapery cords, belts, shoelaces, ties, and other items of clothing (Tishler and Reiss 2009). Objects that are being brought into the room must be regarded as potential hazards (e.g., the phlebotomist's needles, the pop-tops from soft drink cans, the custodian's disinfectants, the meal utensils). The rooms of the general medical hospital lack many of the safeguards that are routine on inpatient psychiatric units, such as locked unit entrances, secured windows, and collapsible shower heads, curtain rods, and light fixtures. Normally,

in the former, scissors and a variety of paraphernalia that can be "creatively" used for self-harm are easily accessible. The culture on medical inpatient units also differs from that on psychiatric units. On medical units, staff do not usually consider elopement a risk; they assume that patients are fundamentally compliant and that they will press their call buttons when they need help (Kelly et al. 1999).

Early reports focused on jumping as a means of suicide in medically hospitalized patients (N. Farberow and Litman 1970; Glickman 1980; Pollack 1957), a readily available and usually lethal method regardless of whether the patient actually intends to die. In the most recent study, White et al. (1995) identified impulsivity and agitation in many of the 12 patients who jumped from an Australian general hospital during a 12-year period. Five had been noted to be delirious on the day of the jump, 7 were dyspneic, and 10 were in pain. Ten of the 12 had two of these factors, and 1 had all three factors.

Modern hospitals are deliberately built without open stairwells and without windows that open or break easily; however, many older buildings remain in service, indicating the persistent need for corrective precautions. The inpatient suicide rate in a New York hospital dropped fivefold during the first 11 years after the hospital secured the windows and implemented educational programs encouraging staff members to pay closer attention to disruption in the doctor-patient relationship (Pisetsky and Brown 1979; Sanders 1988).

Shah and Ganesvaran (1997) found that one-third of 103 suicides committed by psychiatric inpatients at their hospital involved patients away on pass, and another one-third involved patients away from the hospital without permission. Methods readily available near the hospital include jumping in front of vehicles, leaping from buildings or bridges, and drowning in nearby bodies of water (H. Morgan and Priest 1991). Although these authors studied psychiatric inpatients, the same dangers exist with patients on medical units. Passes are rarely given from contemporary medical units, but elopements are all too common, with resultant ready access to potentially lethal means of suicide.

Constant observation by a one-to-one sitter is indicated for patients judged at high risk for impulsive self-harm. This may require compromising patients' privacy. Patients permitted to use the bathroom unobserved have been known to hang or cut themselves behind the closed door. A moment of privacy granted to the patient out of misplaced civility, or a few minutes of inattention or absence by the sitter, may be all the time a suicidal person needs to execute a suicide plan. All staff guarding suicidal patients should know how to summon security personnel

as reinforcements when they perceive that they have lost control of the patient or the situation. In an era of cost cutting, the consultant may feel pressure to limit the use of constant observation. Economizing on sitters could mean the life of a suicidal patient. On the other hand, staff anxiety may lead to overuse, initiating one-to-one sitters for every patient who has expressed any suicidal thoughts. In addition to wasting resources, overuse of sitters may desensitize them to the constant awareness needed for their role. The decision to use constant observation should be made on clinical grounds; constant observation is not just a protective intervention but also one that has therapeutic potential (Cardell and Pitula 1999). However, there are no published data examining whether constant observation reduces the risk of suicide in the hospital (Jaworowski et al. 2008). Prudent risk management supports avoiding under- and overuse of one-to-one sitters.

After the environment is secured, the medical psychiatrist should search for reversible contributors to the impulsive state, including delirium (see Chapter 5, "Delirium"), medical illness or medications that may be contributing to mood (see Chapter 8, "Depression"), anxiety (see Chapter 11, "Anxiety Disorders"), and psychotic disorders (see Chapter 10, "Psychosis, Mania, and Catatonia").

Agitation and active suicide attempts in the hospital often require chemical restraints and, rarely, physical restraints. Antipsychotics should be used in patients with hyperactive delirium or psychosis, and antipsychotics and/or benzodiazepines should be given to other agitated, anxious patients. Physical restraints may be required if other measures prove inadequate. In some cases, emergent electroconvulsive therapy may be necessary (see Chapter 40, "Electroconvulsive Therapy").

Suicide in the Medically Ill

Physical disease is present in a high proportion of people who commit suicide. Several large studies have identified the presence of medical illness in 30%–40% of the patients who committed suicide (Hughes and Kleespies 2001). However, most of these suicides do not occur during medical hospitalization. About 2% of Finnish suicides occurred in medical or surgical inpatients (Suominen et al. 2002). In Montreal, Quebec, about 3% of the suicides were in general hospital inpatients, of which one-third (1%) were medical-surgical patients (Proulx et al. 1997). During a 10-year period in a 3,000-bed Chinese medical hospital, there were 75 self-destructive acts, only 15 of which proved fatal (Hung et al. 2000).

Sanders (1988) reviewed six studies of inpatients at a general hospital who committed suicide. Most had one or

more chronic or terminal illnesses or sequelae that were painful, debilitating, or both, including dyspnea, ostomies, or disfiguring surgery. Harris and Barraclough (1994) compiled a list of 63 medical disorders noted in the medical literature as potentially having elevated suicide risk. In their meta-analysis, they concluded that the only disorders that actually elevated suicide risk were HIV and AIDS, Huntington's disease, cancer (particularly head and neck), multiple sclerosis, peptic ulcer disease, end-stage renal disease, spinal cord injuries, and systemic lupus erythematosus. More recent studies confirm or add to a seemingly arbitrary list of medical conditions associated with risk for suicide. In a Canadian study, cancer, prostate disease, and chronic pulmonary disease were associated with suicide ORs of 1.70–1.86 among adults older than 55 years with versus without the diseases (Quan et al. 2002). In the previously cited Chinese study of patients who committed suicide in a general hospital, 40% had cancer, 13% had neurological disease, 13% had cardiovascular disease, and 7% had liver failure (Hung et al. 2000). In the Montreal study, associated diagnoses included cardiovascular disease, abdominal pain, cerebrovascular disease, Parkinson's disease, and rheumatoid arthritis (Proulx et al. 1997). Of 12 patients who jumped from an Australian hospital between 1980 and 1991, 4 had delirium, 4 had terminal cancer, 2 had advanced lung disease, and 1 had irreversible cardiac failure (White et al. 1995). However, these studies were small and did not capture suicides in the medically ill attempted or completed outside the hospital, so they cannot be used to construct a list of "most suicidal" medical disorders.

A study drawing on the U.S. National Comorbidity Survey identified a dozen general medical diagnostic categories with statistically significantly elevated ORs for suicide attempts, most ranging from 1.1 to 3.2, except for AIDS (133.9) and hernia (10.4) (Goodwin et al. 2003). Clinically, however, use of a diagnosis alone in estimating suicide risk is not helpful. Even though the OR in each of the 12 categories achieved statistical significance, substituting a rate only slightly higher than the very low base rate offers little to guide clinical decision making, particularly if this is the only indicator being used to predict suicide.

What does appear useful is evidence that suicides in the medically ill—as in the general population—seem to be related to frequently unrecognized comorbid psychiatric illnesses, including depression, substance-related disorders, delirium, dementia, and personality disorders (Davidson 1993; Kellner et al. 1985). In their study of the role of physical disease in 416 Swedish suicides, Stensman and Sundqvist-Stensman (1988) concluded that although somatic disease was one important factor in the suicidal act, psychiatric conditions such as depression and alcohol abuse had even more significant roles.

Suicidality is also not a static phenomenon over an illness course. For example, there are two time periods during Huntington's disease—1) when the patient has become aware of neurological changes but does not yet have a confirmed diagnosis, and 2) when cognitive and physical symptoms have developed enough to curtail independent living—when suicidal ideation is particularly prominent (Paulsen et al. 2005). A Danish study of suicide risk in epilepsy showed an overall relative risk of 3.17 compared with the general population but found that both illness chronology and the presence of psychiatric comorbidity influenced risk, in some cases synergistically. For the overall group, suicide relative risk in the 6 months after diagnosis was 5.35. Psychiatrically ill patients with epilepsy had an overall relative risk of 13.7, with the relative risk in the first 6 months after epilepsy diagnosis more than double, at 29.2 (Christensen et al. 2007).

The presence of standard risk factors that transcend medical illness may be more predictive of suicidality than particular disease characteristics. In U.S. dialysis patients, advanced age, male sex, Caucasian or Asian race, substance dependence, geographic region of the country, and recent psychiatric hospitalization all reached significance as independent predictors of completed suicide (Kurella et al. 2005). In chronic pain patients, family history of suicide and access to potentially lethal medications, in addition to abdominal pain, were significantly associated with both passive and active suicidal ideation, while severity of pain and depression were not (Smith et al. 2004). Tending to these basic risk factors should not be overlooked, even in the face of devastating physical illness.

Rather than focusing on particular medical diagnoses, it will be more fruitful for the medical psychiatrist to determine whether a suicide-prone psychiatric condition is present in a medically ill patient, whether the patient is at a particularly emotionally difficult time in his or her illness course, and whether secondary effects of the medical illness—pain, physical disfigurement, cognitive dysfunction, and disinhibition—are present that add to the risk. Much can be done to help. In a review of the literature of suicide in chronic pain patients, in whom they estimate that suicide risk is doubled, Tang and Crane (2006) identified specific pain-induced risk factors, including sleep-onset insomnia, hopelessness, catastrophizing, desire for escape, and problem-solving deficits, all of which respond to psychological interventions. Reduction in intensity in any category may de-escalate suicidal urges.

It must be emphasized that no matter how horrific the medical condition, significant suicide risk is not the rule, and when suicidality does emerge, it is frequently linked to specific illness stages or mental states. According to Brown et al. (1986), most terminally ill patients do not develop se-

vere depression, and suicidality is closely associated with the presence of a depressive disorder. In the study of terminally ill cancer patients by Breitbart et al. (2000), only 17% had a high desire for hastened death, for which depression and hopelessness were the strongest predictors. Feeling that one is a burden on others is an important and underestimated factor contributing to suicidality in the terminally ill (Wilson et al. 2005). An important empirical finding in a Canadian study was that the will to live in the terminally ill fluctuates, mostly predicted by depression, anxiety, shortness of breath, and sense of well-being (Chochinov et al. 1999).

Three diagnoses—cancer, end-stage renal disease, and AIDS—are discussed here in detail to illustrate these points further. These comparatively common conditions underscore principles that can be extrapolated to the breadth of diagnoses and situations encountered in medical settings.

Cancer

Recent population studies replicate what has been known for decades: cancer patients have an elevated suicide risk compared with the general population. In a U.S. cohort of nearly 3.6 million individuals diagnosed with cancer between 1973 and 2002, the standardized mortality ratio (SMR) for suicide was 1.9 relative to the general population. Highest risks were found for lung and bronchial (SMR = 5.74), stomach (SMR = 4.68), oral-pharyngeal (SMR = 3.66), and laryngeal cancer (SMR = 2.83). As in the general population, older white men were at particularly high risk. The first 5-year period after diagnosis was the time of highest risk, although elevated risk persisted after 15 years (Misono et al. 2008).

In a U.S. sample of 1.3 million cancer patients, Kendal (2007) found that males had 6.2 times the suicide risk of females, a mirroring of general population statistics. Kendal's composite high-risk patient was a widower with metastatic head and neck cancer or myeloma (both painful) with limited social support and limited treatment options. His composite low-risk example was an African American married woman with localized cervical or colorectal cancer. Unlike terminally ill cancer patients, in whom elevated suicide risk is associated with hopelessness, cancer patients in remission had suicide risk factors similar to those established in the general population, including personal or family psychiatric illness and previous history of suicide attempts.

Through the lens of prognosis, a study from Western Australia sharpens the focus on which cancer patients are at increased risk and when (Dormer et al. 2008). With an SMR of 3.39, the poor-prognosis group had nearly four times the suicide risk of the good-prognosis group (SMR = 0.86). The first 3 months after diagnosis was the period of highest risk, with particularly marked lethality at this time in the poor-

prognosis group confronting the lack of treatment for their conditions. A second period of increased risk occurred at 12–14 months, the likeliest time of recurrence or acknowledgment of treatment failure. A U.K. study found that the relative risk of suicide in cancer patients was greatest in the first year after diagnosis and also greater in individuals diagnosed with cancers with high fatality (Robinson et al. 2009). A study in Taiwan found that almost half of suicides in cancer patients occurred within the first 2 weeks after hospital discharge (Lin et al. 2009).

Consistent with the Australian study, Björkenstam et al. (2005) in Sweden demonstrated a reciprocal relationship between cancer prognosis and suicide risk. The lower the survival rate, the higher the suicide rate, with the highest rates in pancreatic, esophageal, hepatocellular, and pulmonary cancers, conditions known for being painful and having strongly deleterious effects on quality of life. Among medical illnesses, cancer may even have a singular relationship to suicide. In a study using conditional logistic regression in a U.S. sample of 1,408 individuals age 65 years and older, cancer was the only medical diagnosis still associated with suicide in adjusted analyses, with an odds ratio of 2.3 (Miller et al. 2008).

Cancer patients who die by suicide are psychiatrically similar to noncancer patients, particularly when the cancer is in remission. In a case-control study of 60 suicides in individuals with cancer and 60 age- and sex-matched comparison suicides in individuals without a cancer history, Henriksson et al. (1995) found that most of the patients with cancer who committed suicide—as well as the control subjects without cancer—had a diagnosable psychiatric disorder. Terminally ill cancer patients had lower rates of depression and alcohol dependence than did patients in remission (72% vs. 96%), but nearly three-quarters still met criteria for a depressive disorder. As a group, cancer patients had fewer psychotic disorders than did control subjects. Allebeck et al. (1985) observed that the longer the time from diagnosis of cancer, the lower the relative risk for suicide in a Swedish cohort. In the first year after diagnosis, the relative risk was 16.0 for men and 15.4 for women. From 1 to 2 years, the ratio decreased to 6.5 for men and 7.0 for women. By 3–6 years, the ratio was 2.1 for men and 3.2 for women. By 10 years after diagnosis, the rate, at 0.4, was actually less than one-half that in the general population. A study of Japanese cancer patients found the highest risk of suicide soon after patients had been discharged from the hospital, with an elevated relative risk the first 5 years after diagnosis compared with the general population and disappearing thereafter (Tanaka et al. 1999).

The fear of pain, disfigurement, and loss of function that cancer evokes in patients' imaginations can precipitate suicide, especially early in the course of the disease. In a large

cohort of Italians with cancer, suicide accounted for only 0.2% of the deaths, but the relative risk during the first 6 months after diagnosis was 27.7 (Crocetti et al. 1998). The high relative risk of suicide just after diagnosis comes at a time of overwhelming fear and cognitive overload. In individual patients, important contributing factors (Filiberti et al. 2001) can include overly pessimistic prognosis, exaggerated impressions of anticipated suffering, a physician unintentionally undermining hope, fear of loss of control, or nihilism about treatment. Patients may fear or experience inadequate pain control, lost dignity, compromised privacy, or guilt at having habits that caused the disease. Surgical treatments may be disfiguring, chemotherapy debilitating, and side effects defeminizing or emasculating. As cancer patients live longer with their disease, most become less frightened and less susceptible to suicide.

End-Stage Renal Disease

More formidable than the suicide risk among cancer patients was the purported increase in relative risk of suicide among patients with end-stage renal disease. Abrams et al. (1971) reported very high rates of suicide and suicidal behavior among 3,478 renal dialysis patients studied at 127 dialysis centers. In their sample, 20 deaths were the result of suicide; 17 suicide attempts were unsuccessful; 22 patients withdrew from the program, knowing that doing so would hasten their deaths; and 117 deaths were attributed to noncompliance with treatment. The authors' calculated suicide rate of 400 times that in the general population has been widely quoted but is misleading. In arriving at a 5% figure for suicidal behavior in dialysis patients, they used an extremely broad definition of suicide that encompassed death caused by a wide range of causes, from willful acts of self-destruction to noncompliance. Contemporary studies place suicide risk in dialysis patients at less than double the risk in the general population (Kurella et al. 2005).

Most of the cases that Abrams et al. (1971) called suicide would never come to the attention of psychiatry today. Although their report has been widely cited, no other subsequent study (there have been nearly 20) has defined suicide so broadly (Bostwick and Pankratz 2000). In extreme cases, noncompliance is better understood as a function of personality-disordered behavior; in less dramatic examples, it can be an understandable human response to a burdensome treatment. Deciding to forgo dialysis is not equivalent to suicide (see also Chapter 21, "Renal Disease"). A U.S. study concluded that "most patients who decide to stop dialysis do not seem to be influenced by major depression or ordinary suicidal ideation" (Cohen et al. 2002, p. 889). Even so, depression may play a significant role in some cases and must therefore be ruled out (Cohen and Germain 2005). Treatment withdrawal, negotiated among

the patient, significant others, and the treatment team, has become routine as quality of life during dialysis fades. Using parameters of presence or absence of intent to die and presence or absence of collaboration with physicians and significant others in making the decision to die, a recently published model offers help in separating suicide from life-ending acts such as noncompliance and treatment withdrawal; physician-assisted suicide; and end-of-life decisions regarding palliative care (Bostwick and Cohen 2009). The model proceeds from the premise that lumping multiple acts under the rubric of suicide, as Abrams et al. (1971) did, obscures the complexities of end-of-life decision making and inflames critical conversations best undertaken with rational appreciation for distinctions between these diverse exit strategies from life.

In 1,766 Minnesota dialysis patients followed for 17 years, for example, only 3 killed themselves by frank suicide, representing only 2% of the 155 cases in which dialysis was discontinued (Neu and Kjellstrand 1986). The suicide rate in this sample of dialysis patients was only about 15 times that in the general population, which is a considerable rate but much lower than Abrams and colleagues' figure. Haenel et al. (1980) also found less dramatic suicide rates among European patients undergoing chronic dialysis between 1965 and 1978. In Switzerland, dialysis patients killed themselves at about 10 times the rate in the general population. When patients who refused therapy and died as a result were included in the suicide group, the rate was 25 times higher. They also found no statistically significant difference between suicide rates among patients with functioning cadaveric renal transplants and patients undergoing maintenance dialysis, suggesting that transplantation may not in and of itself be associated with decreased suicide risk. Overall, among dialysis patients pooled from all countries belonging to the European Dialysis and Transplant Association, the suicide rate was 108 per 100,000 per year (Haenel et al. 1980). Whether compared with the general population suicide rate of 4–5 per 100,000 in Mediterranean countries or 20–25 per 100,000 in central European or Scandinavian countries, the figure of 108 per 100,000 represents a higher suicide rate, although not orders of magnitude greater than that in the general population.

After nearly a half-century, during which dialysis has become routine treatment for end-stage renal disease, nephrologists have become more sophisticated at negotiating end-of-life decisions with their patients. Practices judged to be tantamount to suicide in the 1960s and 1970s are now considered the standard of care. A survey of U.S. and Canadian nephrologists found that those who perceived themselves as well prepared to guide end-of-life decisions were more likely to discontinue dialysis in general, to stop dialy-

sis in a patient with permanent and severe dementia, and to recommend time-limited dialysis courses and less likely to refer patients to hospice care (Davison et al. 2006). This last finding may not be a good thing. Compared with patients who withdraw from dialysis but do not use hospice, those who use hospice sustain less than half the patient care costs in the last week of life and have one-third the likelihood of dying in the hospital (Murray et al. 2006).

HIV/AIDS

Although the suicide risk has dropped over the past 30 years as HIV/AIDS has evolved from an almost inevitably terminal illness to a chronic one, HIV/AIDS patients continue to have a higher relative risk of suicide. Early data were primarily based on men who had sex with men in the United States in the 1980s, prior the introduction of anti-retroviral agents, when an AIDS diagnosis was a virtual death sentence. Much has changed, both in the demographics and geographic distribution of AIDS and in regard to advances in treatment, availability of mental health services, public education, and reduction in stigma and social hysteria. As rates of completed suicide have dropped, the contributions of comorbid risk factors in populations at highest risk for HIV/AIDS—men who have sex with men, injection drug abusers, and poor minority heterosexual women—have come into focus. These risk factors—substance abuse, psychiatric illness, and intimate partner violence—each contribute an independent elevated suicide risk.

In the first, terror-stricken decade of the AIDS epidemic, Marzuk et al. (1988) found a suicide rate in persons with AIDS 36 times that in an age-matched sample of men without AIDS and 66 times that in the general population in New York City in 1985. A dozen years later (1997), when the same group of investigators reexamined this question based on all suicides in New York City in 1991–1993, they concluding that positive HIV serostatus was associated with (at most) a modest elevation in suicide risk (Marzuk et al. 1997). In California in 1986, the rate was 21 times higher than that in the general population (Kizer et al. 1988). In the largest study to date, Cote et al. (1991) charted a continuous decrease in suicide rates over 3 years among AIDS patients in 45 states and the District of Columbia. From 1987 to 1989, a total of 165 suicides among AIDS patients were reported to the National Center for Health Statistics. Of these, 164 were committed by men. The relative suicide risk calculated for AIDS patients was 10.5 in 1987, 7.4 in 1988, and 6.0 in 1989. The authors attributed the decrease to advances in medical care, diminishing social stigma, and improved psychiatric services, while noting probable underreporting of deaths due to both AIDS and suicide (Cote et al. 1991). Frierson and Lippman (1988) suggested that suicide

risk also may be increased among HIV-positive but asymptomatic people who fear the eventual illness, HIV-negative people who are worried about contracting the disease, and people who enter suicide pacts with dying loved ones. In a comparison of 15 HIV-infected active-duty members of the U.S. Air Force who attempted suicide with 15 who did not, Rundell et al. (1992) identified several risk factors equivalent to risk factors for suicide in general, including social isolation, perceived lack of social support, adjustment disorder, personality disorder, alcohol abuse, interpersonal or occupational problems, and history of depression.

More recent studies reflect both the changing demographics of HIV and AIDS and the interplay between HIV-positive status and stable classic risk factors for suicidality. Roy (2003) found that almost half of a cohort of HIV-positive substance-dependent patients had attempted suicide. Significantly more of the patients who attempted suicide were young, female, and had a family history of suicidal behavior. Compared with nonattempters, attempters reported more childhood trauma and more comorbid depression and had higher neuroticism scores. A survey in HIV-infected Americans living in rural areas found that 38% had thoughts of suicide during the past week, associated with greater depression and more stigma-related stress and less coping self-efficacy (Heckman et al. 2002).

In a sample of 611 women, Gielen et al. (2005) compared rates of suicidal thoughts and attempts, anxiety, and depression among four subgroups based on HIV status (HIV-positive and HIV-negative) and experience of intimate partner violence (IPV-positive and IPV-negative). Women who were HIV-negative and IPV-negative were least likely to report ever having had suicidal ideation, suicide attempts, or problems with either anxiety or depression. IPV-positive women were more likely than HIV-positive women to report a history of suicide attempts, depression, and anxiety and equally likely to report suicidal ideation. Women positive for both IPV and HIV outstripped the other three subgroups in all four mental health indicators, being three times more likely to have a history of suicidal ideation, eight times more likely to have a history of suicide attempts, four times more likely to have a history of anxiety, and three times more likely to have a history of depression compared with women who were negative for both HIV and IPV.

In a study of 2,909 HIV-positive individuals, 75% of whom were men, 19% reported having suicidal ideation (albeit without intent in the vast majority) within the previous week (Carrico et al. 2007). Suicidal ideation was not evenly distributed, however, but was more likely to be reported by participants who were nonheterosexual, who were experiencing more severe HIV-related symptoms and medication side effects, who used marijuana regularly, and

who had depressive symptoms. Suicidal ideation was less likely in Latinos, individuals with a stable romantic relationship, and those who described themselves as having good coping skills.

In a study integrating elements of the Gielen et al. (2005) and Carrico et al. (2007) studies, Cooperman and Simoni (2005) found that having an AIDS diagnosis, acute psychiatric difficulties, or a physical or sexual abuse history significantly predicted both suicidal ideation and suicide attempts. Unexpectedly, having children and being employed also predicted suicidal ideation and suicide attempts, while possessing a well-developed spirituality was negatively associated with either suicidal ideation or suicide attempts. Alone among the three studies, Cooperman and Simoni (2005) identified specific periods of risk in the illness course. Since first receiving an HIV diagnosis, 26% of their sample had made a suicide attempt, 42% within a month of getting the news, and 27% within a week. Earlier studies have indicated that suicide attempts are more likely at the time that physical symptoms first appear and around the time that full-blown AIDS emerges, although the rate then drops again for those living with AIDS (McKegney and O'Dowd 1992; O'Dowd et al. 1993).

Finally, several studies have underscored the possibility that the contribution of HIV/AIDS status to suicidality is incidental or minimal next to more robust population-specific factors. Two studies, one from Italy (Grassi et al. 2001) and one from Brazil (Malbergier and de Andrade 2001), found that although psychiatric morbidity and suicidal ideation or attempts are common in HIV-positive intravenous drug abusers, they are equally common in those who are HIV-negative. A Swiss study of men having sex with men found a high rate of suicide attempts in both HIV-negative and HIV-positive individuals, with moderately more suicidal ideation in those who were HIV-positive (Cochand and Bovet 1998). Dannenberg et al. (1996) compared 4,147 HIV-positive U.S. military service applicants and 12,437 HIV-negative applicants disqualified from military service because of other medical conditions (matched on age, race, sex, and screening date and location); the relative risk for suicide was similar for each group: 2.08 in the HIV-positive and 1.67 in the HIV-negative applicants. These studies reinforce the point that psychopathology is implicated more potently than any specific medical diagnosis in suicidality.

Prevention and Treatment

The first priority in preventing suicide in the medically ill is the early detection and treatment of the comorbid psychiatric disorders covered throughout this volume. Patient and family education about the medical disease course and its treatment can help prevent excessive fear and pessimism.

Direct questions and frank discussion about suicidal thoughts, ideally part of every primary physician's care for any patient with a serious disease, can reduce suicidal pressures. Nonpsychiatric physicians often fail to recognize medically ill patients at high risk for suicide—for example, misattributing severe vegetative symptoms to medical illness and missing suicidal depression (Copsey Spring et al. 2007). One important role for psychiatrists is to restrain other physicians from automatically prescribing antidepressants for every medically ill patient who expresses a wish to die, particularly without also recommending psychotherapy to address cognitive misconceptions that may be encouraging hopelessness or impulsivity (Mann et al. 2005). Overdiagnosis of depression can lead to inappropriate pharmacotherapy, pathologization of normal feelings, or neglect of relevant personality traits potentially amenable to psychotherapeutic intervention. Soliciting patients' wishes and preferences regarding pain management and end-of-life care early on may reduce the fear of having no control of their dying that lures some patients toward suicide.

Palliative care for the terminally ill is essential in offering relief to those for whom life has become (or is feared) unbearable (see Chapter 41, "Palliative Care"). Psychiatrists can help elicit fears, guilt, impulses, and history that patients may be reluctant to share with their primary physicians. In addition to treating psychiatric symptoms, psychiatrists can monitor for illicit drug use, medication side effects, and emergent neuropsychiatric complications of the underlying medical illness. Psychotherapy can facilitate the exploration and expression of grief and restore a sense of meaning in life (Chochinov 2002; Frierson and Lippman 1988; see also Chapter 39, "Psychotherapy," and Chapter 41, "Palliative Care"). Psychotherapy also may be psychoeducational, reinforcing patients' and family members' accurate knowledge about the disease. Attention to patients' spiritual needs is very important as well; spiritual well-being offers some protection against end-of-life despair (McClain et al. 2003). Finally, for both patients and family, support groups and other community resources may be critical in making the difference between feeling life is worth living and giving up.

Physician-Assisted Suicide

In an editorial in *Medicine*, McHugh (1994) argued that assisted suicides and "naturalistic" ones occurred in different groups of people. Conceptually, physician-assisted suicide follows a rational request from a competent, hopelessly ill patient whose decision is not driven by psychiatric illness. It is legal in very few jurisdictions, where there are practice guidelines and legal safeguards.

In a pair of unanimous 1997 decisions, the U.S. Supreme Court ruled that there is no constitutional right to physician-assisted suicide and that states can prohibit physician conduct in which the primary purpose is to hasten death (Burt 1997). Three states have now legalized physician-assisted death (PAD). Proposals in many other states have been voted down by legislatures or voters. Oregon's Death With Dignity Act was passed in 1994 and enacted in 1997, with the first PAD occurring in 2008. Terminally ill Oregonians can ask their primary care physicians to prescribe lethal doses of medication, but the patients must be able to administer the killing doses themselves. Between 1998 and 2007, only 401 individuals—1 in 900, or 0.11% of Oregon's 365,204 deaths during that time period—elected this option (Oregon Department of Human Services 2008, 2009).

The first PAD in response to Washington State's newly enacted law occurred in May 2009. Montana's PAD law, passed in 2008, has yet to be enacted because of court challenges that are expected to reach the level of the U.S. Supreme Court (O'Reilly 2009).

The safeguards built into the Oregon process closely resemble criteria that have been in place in the Netherlands since 1973, outside the law for nearly three decades, until the Dutch Parliament passed the Termination of Life on Request and Assistance With Suicide Act in 2001 (Cohen-Almagor 2002). To meet the guidelines of the act, the patient must experience his or her situation as intolerable and voluntarily and repeatedly ask the physician for assistance with suicide. The request must be informed, uncoerced, and consistent with the patient's values, and all treatment options must have been exhausted or refused. Finally, the initial physician must seek a second opinion to confirm the diagnosis and prognosis and report the death to the designated municipal authorities (Cohen-Almagor 2002; de Wachter 1989; Singer and Siegler 1990). Quill et al. (1992) suggested an addition to these more legalistic safeguards—that physician-assisted suicide should be carried out only in the context of a meaningful doctor-patient relationship. Three other European countries—Belgium, Luxembourg, and Switzerland—permit variations on PAD (Steinbrook 2008).

The Oregon law is both more conservative and more specific than its Dutch counterpart. It requires applicants to have the capacity to make their own health care decisions. They must have an illness expected to lead to death within 6 months and must make their requests to the physician in the form of one written and two oral statements separated by 15 days from each other. The primary physician and the consultant giving a second opinion not only must agree on capacity, diagnosis, and terminal prognosis but also have the option of referring the patient for a men-

tal health evaluation if either suspects that depression or another psychiatric disorder is affecting the patient's judgment. Although most patients in Oregon who have received assistance in dying did not have depressive disorders, current practice may have failed to protect some patients whose choice to request a prescription for a lethal drug was influenced by depression (Ganzini et al. 2008). The primary physician is required to inform the patient of all feasible options, such as comfort care, hospice care, and pain management; only then can the patient be given a lethal prescription (Chin et al. 1999). The law specifically forbids active euthanasia, which is distinguished from physician-assisted suicide by the physician actively performing the killing act. Physician-assisted suicide is thus denied to patients who lack motor capacity (e.g., patients with advanced amyotrophic lateral sclerosis) (Rowland 1998). Such individuals may still wish for physician-assisted suicide; Ganzini et al. (2002) reported that one-third of amyotrophic lateral sclerosis patients discussed wanting assisted suicide in the last month of life, particularly those with greater distress at being a burden and those with more insomnia, pain, and other discomfort.

Although he postulated that a request for suicide could be rational, Muskin (1998) advocated a psychodynamic approach to a dialogue between the patient and the physician, a dialogue he believed any such request demands. He saw the query as "an opportunity for patient and physician to more fully understand and know one another" (Muskin 1998, p. 327) and asserted that "every request to die should be subjected to careful scrutiny of its multiple potential meanings" (p. 323). For example, is the patient asking the physician to provide a reason to live? Does the patient harbor revenge fantasies? Is the patient driven by inadequately treated pain or depression, by guilt or hopelessness, or by feelings of already being dead?

In contrast to Muskin's fundamentally intrapsychic approach, Hackett and Stern (1991) outlined diverse interpersonal factors to be considered in evaluating a patient requesting physician-assisted suicide, potentially life-threatening analgesics, or withdrawal of life support. The attending physician and consulting psychiatrist each must take sufficient time to understand the wishes of the patient. What has the patient pictured his or her clinical course to be? What are his or her values? What notions exist about the end of life? Is the patient clinically depressed? Where does the family stand? Do other family members understand the patient's request, and how do they affect it? At what point does the patient specify that the potential for meaning in his or her life has been exhausted? Does the patient fear that he or she will become a financial burden, a caregiving burden, or both? Has any of this been discussed

with the family? If the patient considers life devoid of value and meaning for himself or herself, does it have meaning for significant others? Does that affect the patient's thinking? Has the patient made any effort to achieve family consensus so that death can actually be a meaningful shared family experience?

Recent work by Ganzini et al. (2009) contradicts the notion that current physical discomfort or interpersonal issues drive patients' interest in PAD. In this survey of 56 Oregonians who had expressed interest in physician-assisted suicide at end of life, the most important motivations were desire to control the timing and location of death and desire to avoid loss of independence. Worries about future pain, compromised quality of life, and dependence on others for care came next. Least important were limited supports or current physical or mental symptoms. The overall portrait of a typical PAD requester was of a rugged individualist determined to be in charge of his or her destiny, even unto the moment of death.

The psychiatrist's role in physician-assisted suicide is to be available for consultation. In that psychiatrists are almost never primary care providers for terminally ill patients other than dementia patients, who—by definition—lack capacity and are thus not eligible for physician-assisted suicide, Oregon psychiatrists have not been writing lethal prescriptions (Linda Ganzini, personal communication, 2003). Moreover, mental health evaluation is not among the mandatory safeguards in the Oregon law. Despite the fact that numerous investigators have opined that primary care physicians are usually ill-equipped to tease out factors confounding a truly informed decision to take an active role in the timing of one's own death (Billings and Block 1996; Conwell and Caine 1991; Hendin and Klerman 1993), only 12.6% of the 356 patients requesting PAD between 1998 and 2006 were referred for psychiatric evaluation. In 2007, zero of 85 such patients were referred, a trend that continued in 2008, with zero of 60 patients requesting PAD referred (Steinbrook 2008; Linda Ganzini, personal communication, 2009). As Great Britain contemplates instituting a PAD law, Hicks (2006) has expressed concern that requests for PAD can be influenced by coercion, particularly in geriatric patients; can be affected by unconscious and unexamined motives in physicians, caregivers, and patients themselves; and risk being honored inappropriately, given the high rate of depression—often underrecognized by physicians—in terminally ill patients that can influence their decision making.

Block and Billings (1995) outlined five key clinical questions for psychiatrists to explore in clarifying decision-making capacity in terminally ill patients requesting euthanasia or assisted suicide:

1. Does the patient have physical pain that is undertreated or uncontrolled?
2. Does the patient have psychological distress driven by inadequately managed psychiatric symptoms?
3. Does the patient have social disruption resulting from interpersonal relationships strained by fears of burdening others, losing independence, or exacting revenge?
4. Does the patient have spiritual despair in the face of taking the measure of a life nearing its end while coming to terms with personal beliefs about the presence or absence of God?
5. Does the patient have iatrogenic anxiety about the dying process itself and the physician's availability as death encroaches?

Regardless of the status of the law, Block and Billings (1995) argued that requests to hasten death will come, and they explicitly acknowledged in a case example—as others have done in notorious publications (“A Piece of My Mind: It’s Over, Debbie” 1988; Quill 1991)—that some physicians participate in extralegal physician-assisted suicide. They enjoin the psychiatrist to perform several functions for a nonpsychiatric colleague wrestling with such a request, including “offering a second opinion on the patient’s psychological status, providing a sophisticated evaluation of the patient’s decision-making capacity, validating that nothing treatable is being missed, and helping create a setting in which the primary physician and team can formulate a thoughtful decision about how to respond” (Block and Billings 1995, pp. 454–455).

Making time and space for a comprehensive mental health evaluation for the presence of a treatable psychiatric disorder can result in a patient deciding to live longer and withdraw the physician-assisted suicide request (Hendin and Klerman 1993), particularly if “the demoralizing triad” of depression, anxiety, and preoccupation with death is confronted and dispelled. The Oregon experience has shown that intervening in any or all of Block and Billings’s five realms can forestall a physician-assisted suicide request actually being carried to completion. Only 1 in 6 requests resulted in the physician issuing a prescription, and only 1 in 10 of those initially requesting physician-assisted suicide ultimately used the medication to hasten death (Ganzini et al. 2001).

Although the U.S. Supreme Court in its 1997 decision specifically denied that physician-assisted suicide was a constitutional right, it endorsed making palliative care more available and acknowledged the legal acceptability of providing pain relief, even if it hastened death (Burt 1997; Quill et al. 1997). Terminal sedation (in which a patient is given narcotics, even to the point of unconsciousness) accompanied by withdrawal or withholding life-prolonging thera-

pies such as ventilatory support (see Chapter 19, “Lung Disease”), antibiotics, food, and water has become normative end-of-life management (see Chapter 41, “Palliative Care”).

The distinctions among, and propriety of, physician-assisted suicide, active euthanasia, and passive euthanasia remain controversial and beyond the scope of this chapter, but some clarifications should be noted. At present, all 50 states in the United States continue to outlaw active euthanasia, and since the 1997 Supreme Court ruling, no state is required to permit physician-assisted suicide within its borders. Some have worried that making physician-assisted suicide legal would undermine the availability of appropriate care, partly driven by financial exigencies such as strained health care resources. In the Netherlands, the availability of euthanasia appeared to have stunted the evolution of palliative care (Cohen-Almagor 2002), but in Oregon, the reverse appears to have happened. The availability of physician-assisted suicide has coincided there with a dramatic increase in the use of hospice. In 1994, when voters approved physician-assisted suicide, 22% of Oregonians died in hospice care. By 1999, that figure had risen to 35% without any appreciable increase in the geographic distribution or number of hospice beds in the state (Ganzini et al. 2001). The fear that physician-assisted suicide would become a ubiquitous and convenient way of prematurely disposing of Oregon’s dying patients also appears not to have been borne out: In the 11 years for which statistics are available, no more than 1.9% of Oregon deaths resulted from physician-assisted suicide (Oregon Department of Human Services 2008, 2009). Another concern among the public is whether allowing patients to decide to die through refusal of fluids and nutrition will cause undue suffering. The evidence clearly shows that this is not the case (Ganzini et al. 2003).

Psychiatrists will continue to be consulted frequently when patients request withdrawal of treatment or assisted suicide. Evaluation of the patient’s capacity for decision making follows the same principles as for other medical decisions (see Chapter 2, “Legal Issues,” and Chapter 3, “Ethical Issues”), but psychiatrists should strive to distinguish those who wish to die despite remediable contributors to their despair from those who primarily find the burdens of treatment outweighing the offered benefits. As with any “competency consultation,” the psychiatrist should always broaden the scope of examination to a full understanding of the patient and his or her predicament.

Conclusion

Compared with suicidal ideation, completed suicide is rare in psychiatric patients and rarer still in the medically ill. Although identifiable demographic factors are associated

with increased suicide risk, these factors by themselves will identify many more persons potentially at risk than imminently in danger of dying. Many medical illnesses have been associated with increased suicide attempts, but medical illness by itself is rarely the sole determinant of suicide potential. The assessment of a suicidal medically ill person—as with any suicidal person—demands attention to the role played by characterological, temperamental, or experiential features in the individual's immediate push toward suicide. Management begins with a search for reversible contributors to impulsivity, such as delirium, psychosis, and intoxication. A priority in preventing suicide in the medically ill is the early detection and treatment of comorbid psychiatric disorders.

One of the most frequent reasons for psychiatric consultation in medical hospitals is for evaluation for transfer of care of patients who have made suicide attempts. Because countertransference issues not infrequently lead non-psychiatric physicians to prematurely “clear” patients, it is critical for psychiatrists to form their own judgments about whether patients are truly medically stable enough for transfer out of the medical setting. If a suicidal patient must remain on a medical floor, the psychiatric consultant should keep in mind that rooms in the general medical hospital may lack safeguards routinely found on inpatient psychiatric units. Constant observation by a one-on-one sitter is indicated for patients judged to be at high risk.

Suicide is not synonymous with refusal of lifesaving treatment or with requests to hasten death in terminal illness. Psychiatrists are frequently consulted when patients request withdrawal of treatment or assisted suicide; in these situations, the clinician should evaluate the patient's capacity for decision making, the adequacy of pain management, and the role that treatable psychiatric illness may be playing in the request. Psychological distress, social disruption of interpersonal relationships, and spiritual despair must also be explored and addressed. Responding to these issues with concern and comfort may transform a desire for hastened death into a graceful and timely exit from life.

Psychosis, Mania, and Catatonia

Oliver Freudenreich, M.D.

Shamim H. Nejad, M.D.

Andrew Francis, Ph.D., M.D.

Gregory L. Fricchione, M.D.

PSYCHOSIS, MANIA, AND catatonia can greatly hamper the ability of patients to care for themselves and of medical staff to care for them. We discuss psychosis, mania, and catatonia in three subsections as if they were separate entities, with one of the symptoms dominating (and when the symptom is not the result of delirium or dementia; see Chapter 5, “Delirium,” and Chapter 6, “Dementia”); in clinical practice, the distinction cannot always be made: patients with mania can be psychotic, or catatonia may occur in the setting of a manic or psychotic patient. In each of the subsections, we use the “primary/secondary” distinction even though it is not officially sanctioned by our current classification system (i.e., DSM-IV-TR [American Psychiatric Association 2000]). Clinicians, however, base their diagnostic approach on this distinction: are psychiatric symptoms attributable to a primary psychiatric syndrome or are they secondary to medical diseases, substance use, or medication intoxication? In this chapter, we focus on the management principles of medically hospitalized patients who are psychotic, manic, or catatonic and place particular emphasis on the etiologies of secondary psychosis, mania, and catatonia. Psychotic symptoms due to toxic exposures are covered in Chapter 37, “Medical Toxicology.”

Psychosis in the Medically Ill

Epidemiology and Risk Factors

The prevalence and etiology of psychosis in the general hospital setting depend on the diagnostic criteria used and on the specifics of the hospital setting and service and its geographic location. In surgical settings, particularly if elderly patients are treated, delirium and dementia are often accompanied by psychosis. When a young patient presents to an inner-city emergency department with psychosis, illicit drug use is likely. In a patient who is evaluated in a first-episode outpatient program, the likelihood that a primary psychotic disorder is present is fairly high. In the seminal Northwick Park study, fewer than 6% of cases referred for a first episode of psychosis were thought to have an “organic” ailment (Johnstone et al. 1987).

Risk factors for the development of psychosis, particularly paranoid symptoms in an elderly patient, include cognitive problems and social isolation (Forsell and Henderson 1998) as well as hearing loss (Thewissen et al. 2005). The prevalence of any psychotic symptom in the general population of dementia-free individuals older than 85 years is about 10% (Ostling and Skoog 2002).

Clinical Features

The hallmarks of psychotic disorder due to a medical condition according to DSM-IV-TR (American Psychiatric Association 2000) are hallucinations and delusions. Hallucinations can occur in any sensory modality, but they lack diagnostic specificity (Carter 1992). If patients retain their insight into the abnormal nature of their hallucinations, the term *pseudohallucinations* is sometimes used (Berrios and Denning 1996). A good example of hallucinations that occur in patients who remain insightful (and as a consequence hesitant to divulge information about the experience unless specifically asked for fear of being labeled as insane) is the Charles Bonnet syndrome (Menon 2005). In this syndrome, generally pleasant, complex visual hallucinations occur in visually impaired individuals who are cognitively intact. Another example of complex visual hallucinations is peduncular hallucinosis, in which vivid, scenic images can emerge after focal damage to the thalamus or mesencephalic structures (Benke 2006; Mocellin et al. 2006). Some hallucinations occur only under very specific conditions. For example, auditory hallucinations heard only when the air conditioner is running are called functional hallucinations. Hypnagogic or hypnopompic hallucinations occur only in the transition to sleep or awakening, respectively.

The second hallmark of psychosis, delusions, can be fleeting and poorly formed or rather elaborate and entrenched. Delusions are often classified by their content and style (as being bizarre or nonbizarre). Some delusional syndromes are best known by their eponyms such as the delusions of infidelity (Othello syndrome) or delusions of nihilism (Cotard's syndrome) (Freudenreich 2007). As with hallucinations, however, the type of delusion lacks diagnostic specificity. For example, although the morbid jealousy in the Othello syndrome is traditionally associated with male alcoholic patients, it can occur as both a primary psychiatric disorder and a manifestation of organic etiology (Yusim et al. 2008). Kurt Schneider described classic psychotic experiences in patients with schizophrenia. His so-called Schneiderian first-rank symptoms include delusional perception; passivity experiences; and thought insertion, withdrawal, or broadcasting. In patients with first-episode psychosis, first-rank symptoms are common; in one representative sample, only 16% of the patients did not experience any first-rank symptoms (Thorup et al. 2007). The presence of a belief in duplicates and replacements is typical for a group of delusions known as *delusional misidentification syndromes* (Weinstein 1994). For example, in the Capgras delusion, a patient believes that a family member or close friend has been replaced by an exact double.

The course and prognosis of secondary psychosis are determined to a large extent by the underlying illness. It can

reasonably be expected that a pure drug-induced or medication-induced psychosis resolves once the inciting agent is removed. However, in some cases such as phencyclidine (PCP) psychosis, prolonged psychosis lasting several weeks can result. Some illnesses are treatable but require prolonged treatment with the very medication that caused the psychosis in the first place (e.g., steroids for systemic lupus erythematosus [SLE] or interferon for cancer). Unfortunately, many illnesses in which psychosis emerges are degenerative, progressive, and incurable. The emergence of psychosis in a degenerative disorder greatly complicates its management. For example, in a patient with Alzheimer's disease and psychosis, caregivers are more distressed, and patients are more likely to be transferred to a nursing home (Ballard et al. 2008). A more optimistic picture emerged in the only longitudinal follow-up study that used the DSM diagnosis, psychosis due to a general medical condition (Feinstein and Ron 1998). In this cohort of 44 patients with various neurological conditions who were followed up for an average of 4 years, most required only brief, intermittent treatment with antipsychotics, and none required maintenance treatment with antipsychotics.

Diagnosis and Assessment

Psychotic symptoms in a medically hospitalized patient fall into one of three possibilities:

1. *Primary psychiatric illness*
 - ◆ New-onset or an acute exacerbation of psychiatric illness associated with psychosis
2. *Secondary psychosis*
 - ◆ Psychosis due to a general medical condition (systemic or brain-based)
 - ◆ Substance-induced psychosis
 - ◆ Medication-induced psychosis
3. *"Secondary on primary"*
 - ◆ A patient with a primary psychotic disorder has psychosis unrelated to his or her primary psychotic disorder

The first step in the evaluation of any new-onset psychosis requires an assessment of the patient's safety and then a careful analysis of the longitudinal history of symptoms and the cross-sectional symptom profile, taking into account the clinical context. A preadmission baseline should be established with the help of collateral sources. For example, new-onset psychosis in an elderly patient is unlikely to result from a primary psychiatric disorder; it is more likely the result of a delirium or another intercurrent event such as a stroke or seizure. A physical examination

that identifies abnormal vital signs or focal neurological findings often points toward a secondary cause of psychosis. The possibility of unacknowledged drug abuse (withdrawal or drug use while in the hospital) should always be considered. A chart review should focus on medications administered during the hospitalization.

Determining that psychosis is present if the patient is not cooperating sufficiently during the interview is not always straightforward. A patient might be too suspicious to answer questions. Unless a patient is able to cooperate, cognitive limitations might not be apparent, and a delirium may be overlooked. Patients with a preexisting psychosis pose particular difficulties because psychosis in and of itself might not indicate an "organic" etiology, and exacerbations resulting from intercurrent illnesses that lead to secondary psychosis are missed. Repeat examinations over the course of the day and a comprehensive survey of psychotic phenomena, including Schneiderian first-rank symptoms, hallucinations in all modalities, and misidentification syndromes, may be necessary to make the diagnosis.

Well-established rating scales such as the Brief Psychiatric Rating Scale (BPRS; Overall and Gorham 1988) that were developed for schizophrenia could be used to track secondary psychosis during a hospital stay. However, their clinical utility in this setting is unclear. Routine screening (such as the CAGE questionnaire; Ewing 1984) for substance use problems at the time of hospital admission should be used to identify unrecognized substance use and to avoid withdrawal (including psychosis) during the hospitalization.

Unfortunately, no pathognomonic signs or symptoms differentiate primary from secondary psychosis or allow clinicians to determine the presence of a secondary psychosis on clinical grounds alone. For example, the presence of Schneiderian first-rank symptoms has been reported in a wide variety of "organic" conditions, particularly epilepsy and endocrine disturbances (Marneros 1988). In a chart review of 1,698 patients diagnosed with "organic mental disorder," Schneiderian first-rank symptoms were seen in 7% of the patients (Marneros 1988). Conversely, visual hallucinations, which many clinicians regard as indicative of "organicity," are clearly also part of the symptom spectrum in schizophrenia, bipolar disorder, and psychotic depression (Baethge et al. 2005).

Nevertheless, considering the phenomenology of the reported experience, including the presence or absence of first-rank symptoms, content of delusions, or modality of hallucinations, is still valuable. In a prospective study, Cutting (1987) comprehensively compared the psychopathology of patients with organic psychosis and acute schizophrenia with the Present State Examination (PSE) and found that only 3% of the patients with an organic condi-

tion experienced first-rank symptoms and that visual hallucinations were more common in these patients; mistaken identity was a common delusional theme. In an emergency department study that examined differences between substance-induced psychosis and primary psychosis, the presence of visual hallucinations on arrival at the emergency department was one of three key predictors of substance-induced psychosis, as opposed to a primary psychotic disorder (Caton et al. 2005). The other two predictors of substance-induced psychosis were parental substance abuse and dependence on any substance. Patients who experience gustatory or olfactory hallucinations, particularly if they have no associated delusions, might have organic problems, including paroxysmal disorders such as epilepsy or migraines. Delusional misidentification syndromes are possible in those with primary psychiatric disorders but strongly suggest a neurodegenerative process. Josephs (2007) reported that 81% of patients with Capgras' syndrome had a neurodegenerative disorder, mostly Lewy body disease. Even the remaining 19% of the patients with a nondegenerative disorder experienced delusions secondary to methamphetamine abuse or had just had a stroke in addition to primary psychotic disorders.

The extent of the medical evaluation of psychosis in medically ill patients is guided by the clinical picture and likely etiologies. It is important to eliminate causes of a delirium. Therefore, most patients who develop psychosis in the hospital will need a basic laboratory evaluation to assess gross organ dysfunction and infections. The information obtained from a lumbar puncture can be lifesaving. If seizures are considered or if a delirium is high on the list of potential causes, then an electroencephalogram (EEG) is indicated. A normal EEG result makes delirium as a cause of psychosis less likely. Also, a computed tomography (CT) or magnetic resonance imaging (MRI) scan is indicated if brain pathology is suspected. Syphilis and human immunodeficiency virus (HIV) infection are crucial to consider and specifically exclude. If no culprit is found on the basis of history and the initial evaluation, the search needs to be broadened to include less common medical causes of psychosis (such as thyrotoxicosis or Wilson's disease) before making a diagnosis of schizophrenia, which is a diagnosis of exclusion (see Table 10-1 for an initial medical evaluation of secondary psychosis, mania, or catatonia).

However, even if a medical disease, substance, or medication that can be associated with psychosis is discovered, establishing causality is not straightforward. Slater and Beard (1963) discussed this problem of causation in comorbid conditions in a classic essay on the psychosis of epilepsy. They outlined three levels of association: epilepsy and psychosis occurring together by chance; epilepsy precipitating schizophrenia; or epilepsy producing schizo-

TABLE 10-1. Initial medical evaluation for secondary psychosis, mania, and catatonia**Laboratory evaluation**

Complete blood count
Electrolytes including calcium and phosphate
Serum urea nitrogen/creatinine
Glucose
Thyrotropin
Liver function tests
Erythrocyte sedimentation rate
Antinuclear antibody
Human immunodeficiency virus test
Fluorescent treponemal antibody absorption (FTA-ABS) test for syphilis (rapid plasma reagin not sufficient)
Vitamin B ₁₂ and folate
Serum cortisol level
Ceruloplasmin
Urinalysis
Serum toxicology screen
Drug levels of prescribed medications, if indicated
Blood cultures
Urine culture

Brain imaging

Magnetic resonance imaging (generally preferred over computed tomography)

Electroencephalogram

If seizures or delirium are suspected

Note. This list of tests is based on the medical evaluation of a first episode of psychosis and is neither mandatory nor exhaustive. Other tests should be considered if the clinical history and the clinical picture suggest that they might be useful diagnostically (e.g., arterial blood gases, chest X ray, lumbar puncture, genetic testing). Note the overlap with a delirium evaluation.

Other tests such as a serum pregnancy test and an electrocardiogram (to monitor QTc) might need to be added to safely administer treatment.

Source. Based on Freudenreich et al. 2007.

phrenia-like symptoms. Only in the third case would treatment of the underlying illness alone be expected to lead to a concomitant remission of psychosis. In clinical practice, the causality determination is difficult: how much do drugs explain psychosis? Is the old lesion seen on brain scan large enough and located appropriately to “explain” psychosis?

Etiology and Differential Diagnosis

Secondary psychosis can be caused by a multitude of medical conditions, illicit drugs, and toxins, including medications. The diagnostic challenge lies not only in the sheer number of possible conditions that can cause psychosis

but also in the possibility that rare diseases (rare because of low absolute incidence or because of low local prevalence) that most clinicians will be unfamiliar with can present with psychosis, either typically (e.g., West African sleeping sickness) or atypically (e.g., adult-onset Niemann-Pick disease type C) (Freudenreich et al. 2009). Table 10-2 provides a comprehensive compilation of disorders that have been associated with psychosis.

Both systemic infections and infections of the brain can cause psychosis in the absence of a frank delirium. The exact pathogens will vary depending on geography, travel history, and immune status and include infective agents leading to tuberculosis, cerebral malaria, toxoplasmosis, and neurocysticercosis. Herpes simplex, neurosyphilis, and HIV are important considerations for any hospitalized patients with unexplained psychosis. In one case series in the antibiotic era, neuropsychiatric symptoms alone were seen in 51% of confirmed cases of neurosyphilis (Timmermans and Carr 2004). (See also Chapter 27, “Infectious Diseases,” and Chapter 28, “HIV/AIDS.”)

Endocrine diseases can be accompanied by psychotic symptoms. Affective symptoms are most common, but psychosis can also occur. The classic example is thyrotoxicosis (Brownlie et al. 2000). As a special case, in a woman presenting with postpartum psychosis, postpartum thyroiditis must be ruled out (Bokhari et al. 1998). However, psychosis has been reported with a wide variety of endocrine diseases, including hypothyroidism (“myxedema madness”), Addison’s disease, Cushing’s disease, hyper- and hypoparathyroidism, and hypoglycemia. (See also Chapter 22, “Endocrine and Metabolic Disorders.”)

Many neurological conditions can be accompanied by psychosis. Epilepsy and psychosis share a long history, with psychosis potentially occurring ictally, postictally, or interictally (Sachdev 1998; Toone 2000). Temporal lobe epilepsy is most likely to lead to psychosis, but psychosis also can occur with frontal lobe seizures (Lautenschlager and Foerstl 2001). Postictal psychosis typically occurs close in time to a seizure, with psychosis emerging a day or several days after the seizure. Interictal psychosis typically occurs in patients with poorly controlled seizures, after a decade or more of seizures. Dementing illnesses are frequently accompanied by neuropsychiatric symptoms, including psychosis. In Alzheimer’s dementia, psychosis emerges in 41% of patients (Ropacki and Jeste 2005). The severity of cognitive impairment is a risk factor for psychosis. Delusions, which are more common than hallucinations, are typically concrete and simple. If seen in the context of cognitive difficulties, delusions are understandable (e.g., delusions of theft in the elderly person who forgot where he put an item, misidentification delusions, or delusions of infidelity) (Klimstra and Mahgoub 2009). In

TABLE 10-2. Selected causes of secondary psychosis

Psychomotor seizures
Head trauma (history of)
Dementias
Alzheimer's disease
Pick's disease
Lewy body disease
Stroke, including CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy)
Space-occupying lesions and structural brain abnormalities
Primary brain tumors
Secondary brain metastases
Brain abscesses and cysts
Tuberous sclerosis
Midline abnormalities (e.g., corpus callosum agenesis, cavum septi pellucidi)
Cerebrovascular malformations (e.g., involving the temporal lobe)
Hydrocephalus
Demyelinating diseases
Multiple sclerosis
Leukodystrophies (metachromatic leukodystrophy, X-linked adrenoleukodystrophy, Marchiafava-Bignami syndrome)
Schilder's disease
Neuropsychiatric disorders
Huntington's disease
Wilson's disease
Parkinson's disease
Friedreich's ataxia
Autoimmune disorders
Systemic lupus erythematosus and other forms of CNS vasculitis
Paraneoplastic syndromes
Infections
Viral encephalitis
Neurosyphilis
HIV infection
CNS-invasive parasitic infections (e.g., cerebral malaria, toxoplasmosis, neurocysticercosis)
Tuberculosis
Sarcoidosis
Cryptococcal meningoencephalitis
Prion diseases (e.g., Creutzfeldt-Jakob disease)

TABLE 10-2. Selected causes of secondary psychosis (continued)

Endocrinopathies
Hypoglycemia
Addison's disease
Cushing's disease
Hyper- and hypothyroidism
Hyper- and hypoparathyroidism
Hypopituitarism
Narcolepsy
Nutritional deficiencies
Magnesium deficiency
Vitamin A deficiency
Niacin deficiency (pellagra)
Thiamine deficiency
Vitamin B ₁₂ deficiency (pernicious anemia)
Metabolic disorders (partial list)
Amino acid metabolism (Hartnup disease, homocystinuria, phenylketonuria)
Porphyrias (acute intermittent porphyria, porphyria variegata, hereditary coproporphyria)
GM ₂ gangliosidosis
Fabry's disease
Niemann-Pick disease type C
Gaucher's disease, adult type
Chromosomal abnormalities
Sex chromosomes (Klinefelter's syndrome, XXX syndrome)
Fragile X syndrome
Velo-cardio-facial syndrome

Note. CNS = central nervous system; HIV = human immunodeficiency virus.

Source. Adapted from Freudenreich et al. 2008.

Lewy body dementia, recurrent and well-formed visual hallucinations are a core feature (McKeith et al. 2005). Rarely, stroke can lead to poststroke psychosis, although the possibility of complicating seizures should be considered (Chemerinski and Robinson 2000). Interestingly, among the demyelinating disorders, rare leukodystrophies are more frequently associated with psychosis than is the prototypical demyelinating disease, multiple sclerosis (Ghafar and Feinstein 2007). Basal ganglia disorders, including Huntington's disease, are also a cause of psychosis (Rosenblatt and Leroi 2000), although in Parkinson's disease, the effects of treatment with dopamine agonists must be considered.

Numerous legal and illegal drugs can cause psychosis. Some drugs produce psychosis reliably in most people (e.g., PCP). Cannabis rarely leads to anything more than mild, transient paranoia in most people. In susceptible individuals, however, cannabis is considered a risk factor for the emergence of schizophrenia and can trigger a psychotic episode (Moore et al. 2007). Psychosis in alcoholic patients has a large differential diagnosis, including alcohol withdrawal, delirium tremens, alcoholic hallucinosis, Wernicke-Korsakoff syndrome, pellagra, hepatic encephalopathy, Marchiafava-Bignami syndrome, central pontine myelinolysis, and alcohol-associated dementia (Greenberg and Lee 2001). Paranoia and morbid jealousy that can reach delusional conviction (i.e., the Othello syndrome) are well-recognized complications of severe alcoholism (Michael et al. 1995).

Among prescription medications, certain drugs are clearly associated with the potential for inducing psychosis. In reviewing patient charts, particular attention should be paid to drugs with a high potential for medication-induced psychosis, such as high-dose steroids used for autoimmune diseases, L-dopa for the treatment of Parkinson's disease, or interferon for the treatment of chronic hepatitis C. Table 10-3 provides a list of more common offending agents.

TABLE 10-3. Selected medications that can cause psychosis at therapeutic doses

Important offenders

Anticholinergics and antihistaminics
Dopaminergic drugs (e.g., L-dopa, amantadine)
Interferon
Stimulants
Corticosteroids

Others

Cardiovascular drugs: antiarrhythmics, digitalis
Anesthetics
Antimalaria drugs: mefloquine
Antituberculous drugs: D-cycloserine, ethambutol, isoniazid
Antibiotics: ciprofloxacin
Antivirals: human immunodeficiency virus medications (e.g., acyclovir; efavirenz at high plasma levels)
Anticonvulsants (high doses)
Antineoplastics (especially ifosfamide)
Sympathomimetics (including over-the-counter preparations)
Pain medications: opioids (especially meperidine, pentazocine), indomethacin
Miscellaneous: baclofen, disulfiram, cyclosporine, ephedra-containing dietary supplements

Effects of Psychosis on Medical Disorders

The presence of psychosis can greatly jeopardize the cooperation necessary for a successful hospital stay. Psychosis can be disruptive because of ancillary symptom clusters (e.g., fear or agitation) or because of its thought content (e.g., a patient refusing cooperation with surgery because of conspiracy theories). Because patients who are overtly psychotic and agitated may pose a risk to themselves and the ward, staff might be rightly afraid and limit interactions. However, patients also can be quietly psychotic and appear withdrawn (i.e., secondary negative symptoms). Patients who are suspicious, mildly disorganized, or apathetic can get "blamed" for their inability to conform to ward routines or participate in their treatment (Freudenreich and Stern 2003). Lack of insight into the need for psychiatric treatment can require legal involvement, resulting in treatment delays. In any patient who requests discharge against medical advice (AMA), a psychotic process should be ruled out.

Patients with schizophrenia have a reduced life expectancy compared with those in the general population (Brown 1997; Colton and Manderscheid 2006). The reasons for this survival gap include deaths from suicides but also an increased risk for cardiovascular disease (Goff et al. 2005; McEvoy et al. 2005). The reasons for this disparity are complex and not well understood. Added iatrogenic morbidity related to second-generation antipsychotics has possibly increased the mortality gap (Saha et al. 2007). Some factors are the same as in the general population, such as socioeconomic status, unhealthy diet, substance use, or smoking. However, it is also well documented that patients with schizophrenia receive substandard medical care compared with those in the general population (Druss et al. 2001). Unrecognized staff fears, biases, and misconceptions about psychosis therefore almost certainly contribute to the delivery of substandard care in this population (Leucht et al. 2007). Stigma is responsible for the poor care provided to patients who have a psychotic disorder diagnosis, with serious downstream consequences for patients.

Given the already increased medical morbidity and mortality, improving adherence to medical treatment (as opposed to just the psychiatric treatment) is an important long-term management consideration for physicians who care for patients with schizophrenia. In one pharmacy record study of patients with a chronic psychotic disorder, adherence was equally problematic regarding use of antipsychotics and drugs for medical conditions (antihypertensives, antihyperlipidemics, or antidiabetics), with 12-month prescription fill rates ranging from 52% to 64% (Dolder et al. 2003). In another sample of patients with serious mental illnesses and HIV infection, only 40% achieved

90% adherence to prescribed HIV medications (Wagner et al. 2003). The solution to possible nonadherence requires its recognition and a plan to remedy it based on individual patient and organizational factors. Health care systems that integrate medical and psychiatric care offer the best hope for improving medical outcomes for patients with psychotic disorders (Fleischhacker et al. 2008; Goff 2007).

Treatment of Secondary Psychosis

General Principles of Management

Safety for all parties involved, identification of the etiology of psychosis, and treatment of psychosis are the three initial goals in the care of psychotic patients in the hospital. Patients who are psychotic can be quite agitated and restless; they often require a sitter or restraints to prevent injury. Involuntary treatment can be required. During the evaluation, even when the etiology of psychosis seems clear, additional causes should be considered and unnecessary central nervous system (CNS)-active medications discontinued. In the early phase of treatment, frequent reassessment of the clinical situation is required to determine the best course of action and to assess the efficacy and ongoing necessity of interventions. Although benzodiazepines are routinely used as an ancillary treatment to calm patients with primary psychotic disorders, they should be used only judiciously in medical settings because they might paradoxically worsen agitation in medically compromised patients.

Psychiatric consultants can perform important liaison functions (including making judgments about potential dangerousness, helping with an appropriate disposition [e.g., Can the patient be discharged home? Does he need further inpatient psychiatric care? Is the psychiatric facility able to handle medical complexity?]), and coordinating care with the outpatient psychiatrist. Education about psychosis can be provided to patients, family members, and staff.

Discharge planning should take into account dangerousness and iatrogenic morbidity and mortality. Dangerousness to self or others must be considered when the patient has command hallucinations, and dangerousness to other people must be considered if the patient has delusions such as the Othello syndrome or delusional misidentification syndromes (Leong et al. 1994; Silva et al. 1994). Patients should be discharged with a plan that takes into account effects of psychosis on behavior and only when the patient has the ability to follow the treatment plan. In some cases, medication supervision by a family member or a visiting nurse will be required. Discharge planning also should take into account the long-term risks of antipsychotics, particularly the risk for tardive dyskinesia (TD)

and metabolic problems such as dyslipidemias and glucose intolerance. In one prospective study of patients older than 45 years who were taking first-generation antipsychotics, about a quarter of the patients developed TD after 1 year of treatment (Jeste et al. 1995). Given the age-related increase in TD risk, the cumulative dose of antipsychotics should be kept to the absolute minimum in all patients but particularly in the elderly. Patients successfully treated with an antipsychotic for delirium or secondary psychosis who do not require long-term antipsychotic maintenance treatment should have a clear plan in place for the discontinuation of the antipsychotic (if this has not been accomplished prior to transfer).

Specific Treatment Considerations for Secondary Psychosis

Often, antipsychotics are needed to treat secondary psychosis. Antipsychotics may be withheld if psychosis is mild and expected to resolve within hours (e.g., substance-induced psychosis). Instead, benzodiazepines such as diazepam (10 mg orally) can be given to alleviate distress. However, in instances when distress from psychosis is severe; when psychosis can be expected to last longer than a few hours; or when psychosis jeopardizes the medical treatment and safety of patients, staff, or visitors, antipsychotics are the treatment of choice for psychosis. Depending on the underlying cause of psychosis, treatment strategies other than antipsychotics are sometimes indicated. For example, in dementia of the Lewy body type, rivastigmine has been shown in a controlled trial to have beneficial behavioral effects, perhaps through reversing a proposed cholinergic deficit (McKeith et al. 2000). If psychosis is the result of alcohol or sedative withdrawal, benzodiazepines are the treatment of choice. Thiamine must be administered when Wernicke's encephalopathy arises and should always be given before glucose in cases of suspected hypoglycemia. Valproate was effective for alcoholic hallucinosis in one controlled treatment trial (Aliyez and Aliyez 2008).

In the ideal situation, the medical team will effectively treat the medical disease responsible for the psychosis, and the psychiatrist will control psychosis until the medical condition is cured. With time, psychosis resolves, and the antipsychotic can be reduced and discontinued. In some instances, control of the medical condition alone, without using antipsychotics, might resolve the psychosis—as, for example, in the case of seizures (Nadkarni et al. 2007), although the best course of action for psychosis in epilepsy is not well established (Farooq and Sherin 2008). If the underlying medical disease (e.g., a degenerative condition) cannot be cured, then a decision must be made as to the duration of antipsychotic treatment. Interestingly, in the earlier-mentioned longitudinal study of patients diag-

nosed with psychosis due to a general medical condition, no temporal association between the neurological illness and psychosis was seen, and intermittent but not maintenance treatment was sufficient for the treatment of psychosis (Feinstein and Ron 1998).

The choice of an antipsychotic should be determined by the specifics of the situation (including urgency, access, medical comorbidities, and tolerability). In general, second-generation antipsychotics were, until recently, considered preferred for the long-term management of schizophrenia (and, by inference, medical disorders that require long-term management with antipsychotics) because of their better tolerability, particularly with regard to extrapyramidal symptoms (EPS) and TD risk (Correll et al. 2004). Tolerability of antipsychotics is clearly a concern in medically complex patients with secondary psychosis. Patients with HIV infection or AIDS, for example, are very sensitive to first-generation antipsychotics. However, in schizophrenia care, the assumption of better effectiveness (i.e., efficacy and tolerability) of second-generation antipsychotics over first-generation antipsychotics is increasingly being challenged by large randomized trials (Jones et al. 2006; Kahn et al. 2008; Leucht et al. 2009; Lieberman et al. 2005; Sikich et al. 2008), with particular concerns being raised about the development of metabolic syndrome (Stahl et al. 2009). Both first- and second-generation antipsychotics have now been shown to also be associated with sudden cardiac death (Ray et al. 2009).

Antipsychotics might not be effective and safe for all instances of psychosis either. For example, they have been shown to be relatively ineffective for the neurobehavioral problems associated with Alzheimer's disease (Schneider et al. 2006). In a randomized trial, nursing home patients with Alzheimer's disease who took antipsychotics for 1 year were 7% more likely to have died compared with patients who were switched to placebo (Ballard et al. 2009), leaving clinicians with no good options for the treatment of psychosis in demented patients (Jeste et al. 2008). In all patients, but particularly in the elderly, treatments that increase anticholinergic tone (e.g., low-potency first-generation antipsychotics or high-potency antipsychotics requiring ancillary anticholinergics) are to be avoided to reduce the risk of delirium or anticholinergic-associated cognitive problems.

Mania in the Medically Ill

Mania associated with a variety of conditions has been described in the literature. It was not, however, until Krauthammer and Klerman's (1978) classic article on secondary mania that a category was created to separate this condition from "functional" primary bipolar mood disorder.

Epidemiology and Risk Factors

Goodwin and Jamison (2007) reported that the annual risk of having a manic episode is 0.24%–0.77% in the general U.S. population; however, no studies have used formal instruments to report the incidence or prevalence of mania in the medically ill. In a retrospective chart review of 755 patients evaluated by a psychiatry consultation service in a general hospital, Rundell and Wise (1989) found that in a 1-year period, 13 of the 15 (87%) patients diagnosed with mania met criteria for secondary mania. A positive family or personal history of bipolar illness might steer clinicians toward diagnosing primary mania, but such a history could merely indicate an increased susceptibility for secondary mania. Postpartum mania might be considered a special case of secondary mania in which sudden hormonal changes induce a manic episode in a patient with increased (genetic) susceptibility to mood episodes. Vascular disease is a risk factor that seems to predispose some elderly to late-onset mania (Subramaniam et al. 2007).

Clinical Features

The clinical features of secondary mania mimic those of mania in bipolar disorder and often develop in stages, potentially extending from mild hypomania to delirious psychotic mania (Carlson and Goodwin 1973). Early symptoms in secondary mania include mood lability, feeling "high," and disrupted sleep. As in primary mania, grandiosity, racing thoughts, euphoria, irritability, and hostility may appear, and progression to flight of ideas, gross disorganization, and frank psychosis may occur.

The course and prognosis of secondary mania depend in part on the underlying illness. When secondary mania is caused by drugs such as methamphetamine, cocaine, or methylenedioxymethamphetamine, the behavior and mood changes generally resolve once the offending agent is stopped. However, when mania arises via CNS injury, infections, neoplasm, or neurodegenerative processes, symptoms may persist. In addition, medications to treat the underlying illness also may precipitate secondary mania, often presenting treatment dilemmas, because their continued use may be required for ongoing care (e.g., interferon for cancer, steroids for organ transplantation or autoimmune disorders). In these cases, the consultation psychiatrist may play a critical role in controlling the symptoms of secondary mania to ensure that optimal medical treatment can be delivered safely.

Diagnosis and Assessment

Although the symptoms of secondary mania are the same as those seen in primary mania, a DSM-IV-TR diagnosis of secondary mania requires only a prominent and persis-

tently elevated, expansive, or irritable mood. DSM-IV-TR makes no mention of number or duration of symptoms. Because both delirium and mania have similar clinical presentations, their differentiation can be difficult. Both syndromes are abrupt in onset and have accompanying symptoms of inattention, agitation, erratic sleep, and the presence of paranoia and psychosis. The waxing and waning course of delirium, along with decreased arousal and clouding of consciousness, should help differentiate it from secondary mania.

Once new-onset mania is diagnosed, the differentiation between primary mania due to bipolar disorder and secondary mania should be attempted. Secondary mania often develops within a short period (e.g., hours or days) from the physiological insult and may occur throughout the life span. In contrast, episodes due to bipolar disorder typically occur during the first three decades of life (Goodwin and Jamison 2007), and although there has been increasing discussion about late-onset bipolar illness, new-onset primary mania tends to be rare after age 50 (Ooster-vink et al. 2009). In addition, the diagnosis of secondary mania is more likely when cognitive dysfunction or focal neurological signs are present, no personal history or family history of bipolar disorder exists, or treatment of the mood disorder with standard interventions is ineffective (Arora and Daughton 2007).

As with psychosis, the clinical history, physical examination, and laboratory evaluations are important elements in distinguishing primary and secondary mania (see Table 10–1 for laboratory evaluation). In addition, the neurological examination should particularly focus on the presence of nondominant hemispheric lesions associated with secondary mania, including left-sided hemiparesis, hyperactive deep tendon reflexes, presence of Hoffmann's and Babinski's signs, along with the snout, palmomental, and glabellar reflexes. Attentional deficits, including left-sided neglect, anosognosia, and constructional dyspraxia, also should be assessed. Other regions of the brain that have been associated with manic states include lesions related to the anterior cerebral artery, with associated frontal lobe deficits, and lesions of the basal ganglia, which may manifest with symptoms such as chorea, athetosis, parkinsonism, or hemiballismus.

Although the evaluation of mania is based on a clinical assessment, rating scales can track the severity of symptoms. A well-accepted scale often used in clinical trials is the 11-item Young Mania Rating Scale (YMRS; Young et al. 1978).

Etiology and Differential Diagnosis

Secondary mania has been ascribed to numerous conditions (Table 10–4). Many are reported as cases, linked tem-

TABLE 10–4. Selected causes of secondary mania

Neurological conditions

Tumors (gliomas, meningiomas, thalamic metastasis)
Cerebrovascular lesions (right hemispheric)
Multiple sclerosis
Traumatic brain injury
Complex partial seizures
Viral encephalitis (acute and postinfectious)
Human immunodeficiency virus infection
Cryptococcal meningoencephalitis
Neurosyphilis
Huntington's disease
Parkinson's disease (including treatment with deep brain stimulation)
Frontotemporal dementia
Wilson's disease
Fahr's disease
Klinefelter's syndrome
Kleine-Levin syndrome

Systemic conditions

Cushing's disease
Vitamin B₁₂ deficiency
Niacin deficiency
Antiphospholipid antibody syndrome
Hyponatremia
Carcinoid syndrome
Hyperthyroidism

Medications and substances of abuse

Amantadine
Amphetamines
Anabolic steroids
Antidepressants
Baclofen (administration and withdrawal)
Buspirone
Captopril
Cimetidine
Clonidine withdrawal
Cocaine
Corticosteroids/corticosteroid withdrawal
Didanosine
Hallucinogens
Isoniazid
L-Dopa
Methylphenidate
Phencyclidine
Procainamide
Thyroxine
Zidovudine

porally to the development of mania, but some have proven to be more consistently associated with the development of manic syndromes and are discussed in more detail below.

Mania Secondary to Neurological Diseases

Cerebrovascular injury. Poststroke mania occurs in about 1% of strokes (Jorge et al. 1993; Starkstein et al. 1989). Manic syndromes have been reported following cerebrovascular lesions in multiple areas, including following a right middle cerebral artery territory stroke with ischemic lesions involving the medial and basal temporal lobes (Bornke et al. 1998), right thalamic infarcts and hemorrhage (Leibson 2000; Vuilleumier et al. 1998), and isolated strokes of the right caudate nuclei (Mendez et al. 1989). Berthier et al. (1996) reported a case series of nine patients with development of poststroke bipolar illness, with predominant involvement of subcortical structures of the right hemispheres, including the lentiform nucleus, internal capsule, caudate nucleus, thalamus, periventricular white matter, and brain stem. Most cases in the literature attribute the development of vascular-associated mania to right-sided infarcts, but left-sided lesions also have been described (Berthier et al. 1990; Fenn and George 1999).

Traumatic brain injury (TBI). Up to 50% of all patients with TBI may develop posttraumatic depression (Mendez 2000), whereas mania tends to be relatively infrequent. In a study of 66 patients with a head injury, 41% had symptoms of depression, 9% developed mania, and one patient was diagnosed with bipolar disorder within 1 year of the injury (Jorge et al. 1993). Post-TBI manic patients were typically less euphoric and less likely to have depressive episodes, with 85% of patients being irritable and 70% being more aggressive (Jorge et al. 1993; Shukla et al. 1987).

Neurodegenerative processes. Dementing processes also have been associated with the development of mania. Although mania tends to be rare in Alzheimer's disease, it has been reported to occur in greater frequency in patients with frontotemporal dementia (FTD) (Arciniegas 2006; Galvez-Andres et al. 2007; Woolley et al. 2007). Emotional changes (such as depression, mania, irritability, lability, and anger) are common in patients with FTD, as are obsessive symptoms. Neurodegenerative movement disorders also have been associated with mania. Manic episodes have been shown to occur in 2%–12% of patients with Huntington's disease, and often the mood change may precede the appearance of a movement disorder (Folstein 1989; Mendez 1994). Symptoms of mania also have been described in Fahr's disease (idiopathic basal ganglia calcification), Wilson's disease, and postencephalitic Parkinson's disease, along with a case report of mania following treatment of

Parkinson's symptoms with subthalamic nucleus stimulation (Krauthammer and Klerman 1978; Raucher-Chene et al. 2008; Rosenblatt and Leroi 2000).

Epilepsy. Although depression is more common in those with epilepsy, mania also may arise. Investigators have reported a frequency of bipolar illness of 3%–22% (Robertson 1992) in depressed patients with epilepsy, and these disorders occasionally can be clinically difficult to distinguish from primary bipolar disorder (Himmelhoch 1984). Mania may follow right temporal lobe epileptiform discharges (Hurwitz et al. 1985) and tends to occur with an increase in seizures or intermittent epileptiform activity (Barczak et al. 1988; Ramchandani and Riggio 1992). Mania associated with epilepsy also may present with compulsive behavior and elements of psychosis (such as thought insertion and hallucinations) (Himmelhoch 1984). In one retrospective review of patients seen by psychiatric consultants, two of four manic epileptic patients had peri-ictal mania and poor seizure control (Lyketsos et al. 1993b). In addition, patients in the immediate postictal state may show intermixed epileptiform activity without clinical signs of seizures (Mendez and Grau 1991). Patients may experience postictal psychosis with features of mania 12–48 hours after a burst of seizures, which may continue for weeks or even months, but this is rare (Chakrabarti et al. 1999; Mendez and Grau 1991).

Mania Secondary to Infectious Diseases

Several infections involving the CNS may produce manic syndromes. Mania may be the first manifestation of neurosyphilis, cryptococcal meningoencephalitis, or viral encephalitis, including herpes simplex encephalitis (Mendez 2000). Mania also may occur as a postencephalitic process following recovery from the acute stage of illness.

In a study conducted in the Department of Veterans Affairs (VA) health care system, 4% of HIV-infected patients were reported by their providers to have mania or bipolar disorder; however, the prevalence of mania directly as a result of HIV is not known (Kilbourne et al. 2001). In some settings, the prevalence of secondary mania might be quite high. In a study of mania in Uganda (a country with a high prevalence of HIV infection), 61 of 141 (43%) patients admitted to a psychiatric ward for mania were judged to have HIV-related secondary mania (Nakimuli-Mpungu et al. 2006). In this cohort, patients with secondary mania had more manic symptoms (including irritability and aggression) and showed more cognitive impairment compared with the patients admitted with primary mania. Almost all patients with secondary mania experienced psychosis (including visual hallucinations in 67% of patients). This recent cohort confirms earlier clinical descriptions of in-

creased irritability and pressured speech with neurocognitive changes in patients with advanced HIV disease who developed mania (Lyketsos et al. 1997). Compared with patients with primary bipolar disorder, patients with secondary mania are less likely to have a personal or family history of mood disorder. Secondary mania is associated with evidence of structural brain changes (as seen on CT or MRI scans) (Boccellari et al. 1988; Kiebertz et al. 1991; Lyketsos et al. 1993a). Certain antiretroviral medications have been implicated in medication-induced mania, including zidovudine (Maxwell et al. 1988; Wright et al. 1989), didanosine (Brouillette et al. 1994), abacavir (Brouillette and Routy 2007), and efavirenz (Shah and Balderson 2003). In addition, both ethambutol and clarithromycin have been reported to be associated with manic symptoms in the setting of treatment for *Mycobacterium avium* complex in individuals with AIDS (Nightingale et al. 1995; Pickles and Spelman 1996).

Mania Secondary to Endocrine Diseases

Several endocrine diseases have been associated with the development of manic states, including Cushing's disease and diseases of the thyroid. Typically, mania has been associated with hyperthyroidism (Clower 1984; C.S. Lee and Hutto 2008; Villani and Weitzel 1979), whereas hypothyroidism has been linked with depression and severe hypothyroidism with psychosis (Clower 1984). However, reports also have noted depression associated with hyperthyroidism (Thomsen et al. 2005) and mania associated with hypothyroidism (Balldin et al. 1987; Levitte 1993; Stowell and Barnhill 2005).

Treatment with corticosteroids is likely the most common cause of secondary mania (Rundell and Wise 1989). In a prospective study by Naber et al. (1996), of 50 patients with ophthalmic conditions being administered high-dose corticosteroids for 8 days, 13 patients (26%) developed symptoms of (mild) mania, and 5 patients (10%) developed depression. Most mood-related symptoms developed early in the course of treatment, typically within 3 days of starting corticosteroids.

Effects of Mania on Medical Disorders

Like patients with psychotic disorders, patients with bipolar disorder have medical comorbidity (Kilbourne et al. 2004) that can complicate treatment of the psychiatric disorder. Because of its unpredictable nature, bipolar illness may cause significant periods in which the patient has little or no contact with providers, especially during a manic episode (Keck et al. 1997). This lack of contact may lead to poor adherence, social instability, and increased medical comorbidity. Manic and hypomanic episodes can increase the risk of infectious diseases (e.g., cervical cancer, hepati-

tis C, HIV infection) through sexual indiscretions or drug use (el-Serag et al. 2002).

During an inpatient hospitalization, the development of mania may cause refusal of care proposed by medical-surgical teams. If secondary hypomania or mania is not suspected, the medical team may attribute the patient's behavior to personality traits or to being "difficult," often causing a schism between the patient and his or her providers, potentially jeopardizing the necessary medical evaluation and care.

Treatment of Secondary Mania

General Principles of Management

Similar to the management of psychotic patients, ensuring the safety of the patient and staff is of paramount importance and is the initial goal of care for the acutely manic patient. Patients with mania are unpredictable, disinhibited, and easily agitated, especially in an unknown medical environment with an overabundance of stimuli (e.g., ancillary staff, frequent vital sign checks, laboratory blood draws, medical procedures). The psychiatry consultant can assess the patient's medical and neuropsychiatric condition and help to minimize any unnecessary interventions (including medications with CNS effects that may contribute to or exacerbate the patient's symptoms). Once safety has been addressed, the focus should be helping to elucidate the underlying etiology of secondary mania.

Psychopharmacology

Medications used for the treatment of secondary mania are generally the same as those used in primary bipolar illness. The choice of medication is based on the severity of mania, the patient's willingness or ability to receive oral medications, the etiology of the mania, and the patient's comorbid medical illnesses. For example, lithium may be difficult to administer safely in patients with fluid shifts, electrolyte abnormalities, acute or chronic renal dysfunction, or already established thyroid dysfunction. Valproate may be relatively contraindicated in patients with hepatic disease or a history of pancreatitis. Carbamazepine also may pose difficulties in patients with hepatic disease and is associated with potential hematological toxicity (e.g., leukopenia or aplastic anemia), antidiuretic actions, and quinidine-like effects on cardiac conduction. In addition, carbamazepine is a potent inducer of cytochrome P450 3A4, and a review of current active medications is necessary to help prevent drug-drug interactions. Although benzodiazepines may provide rapid symptom reduction, they may also potentiate CNS depression by decreasing respiratory drive, and their use is relatively contraindicated in patients with chronic obstructive pulmonary disease

who are at risk for carbon dioxide retention. In addition, paradoxical disinhibition with worsening behavior may occur, especially in patients with a TBI. First- and second-generation antipsychotics are often used for the treatment of secondary mania, particularly in agitated patients. Second-generation antipsychotics are generally preferred for the short-term treatment of secondary mania because of lower propensity to cause EPS. Nevertheless, monitoring for neuroleptic-induced catatonia is still warranted. If long-term use of antipsychotics for the management of secondary mania is contemplated, potential morbidity and mortality risks associated with antipsychotics should be considered (e.g., risk for metabolic syndrome or TD).

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) has been used in the management of acute mania and may be especially helpful to treat mania and marked physical activity that is poorly responsive to pharmacological interventions. Delirious mania, a syndrome of acute onset characterized by excitement, psychosis, and delirium, has been described and treated successfully with ECT and benzodiazepines, with administration of lithium and/or antipsychotics possibly worsening the underlying condition (Fink 1999). If ECT is used, lithium should be avoided because this may prolong the neuromuscular blockade induced before ECT administration (Rudorfer et al. 1987). ECT may present higher risk in some medically ill patients (see Chapter 40, "Electroconvulsive Therapy").

Catatonia in the Medically Ill

Initially described in Kahlbaum's 1874 monograph, catatonia has long been associated with psychiatric, neurological, and medical disorders (Kahlbaum 1973). Modern theorists view catatonia as a syndrome of motor signs in association with disorders of affect, thought, and behavior. Some motor features are classic but infrequent (e.g., echopraxia and waxy flexibility), whereas others are common in psychiatric patients (e.g., agitation and withdrawal) but denoted as catatonic because of their duration and severity. The sometimes subtle presentation of catatonia may go undetected, which could account for the impression of a declining incidence. For example, in one study, clinicians diagnosed catatonia in only 2% of 139 patients, whereas a research team identified it in 18% (van der Heijden et al. 2005).

Epidemiology and Risk Factors

The rate of catatonia in the psychiatric population varies according to study design and diagnostic criteria. In a series

of prospective studies of patients hospitalized with acute psychotic episodes, the incidence of catatonia was within the 7%–17% range (Caroff et al. 2004a). When mood disorders were the focus, rates ranged from 13% to 31%. Catatonia secondary to medical illness with a variety of "organic" etiologies accounts for 4%–46% of cases in various series, underscoring the need for a thorough medical evaluation when catatonic signs are present. In pediatric settings, catatonia is sometimes reported in patients with mental retardation and autistic spectrum disorders (Wing and Shah 2006).

Certain conditions may increase the risk of developing neuroleptic malignant syndrome (NMS)—an important iatrogenic form of catatonia (Mann et al. 1994). A history of simple catatonia is a major risk factor for the progression to NMS (White and Robins 1991). Other risk factors include schizophrenia, mood disorders, neurological disorders (e.g., basal ganglia disorders), alcoholism, and substance abuse disorders. Alcohol or sedative-hypnotic withdrawal may increase the risk of NMS as a result of altered thermoregulation and autonomic dysfunction. Agitation, dehydration, and exhaustion also may increase the risk for NMS. Up to one-third of patients who have had NMS will have a subsequent episode when rechallenged with neuroleptics.

Clinical Features

Stupor, mutism, negativism, motoric immobility, catalepsy, posturing, but also excitement are considered the core clinical features of catatonia. These features are the same regardless of whether the condition occurs in the context of a mood, psychotic, or medical state. Catatonia may have rapid or insidious onset and may be associated with high morbidity and mortality. It may be described in a variety of ways by clinicians on medical, surgical, and neurological wards—as a stupor, as a fever of unknown origin, as an acute encephalopathic syndrome, or falsely as "schizophrenic" or "conversion disorder."

The clinician must be cognizant of the fact that diametrically opposed subtypes of catatonia have been described. Catatonic withdrawal, with posturing, rigidity, mutism, and repetitive actions, is the most commonly recognized form, and the term *catatonia* is sometimes used as shorthand for this retarded motor state, occasionally referred to as "Kahlbaum's syndrome" (Fink and Taylor 2009). Patients with severe catatonia will be stuporous and may even present with low Glasgow Coma Scale scores. However, patients also can present with hyperactivity, hyperproductive pressured speech, and restless, agitated behavior accompanied by catatonic features (bizarre stereotypies, mannerisms, grimacings, echo phenomena, perseverations) and an acute confusional state. Catatonic

excitement has at times been called “delirious mania” or “Bell’s mania” (Bell 1849; Fink 1999).

In 1934, Stauder described a syndrome of “lethal catatonia.” It was marked by the acute onset of a manic delirium, high fever, and catatonic stupor and a mortality rate of greater than 50%. Because not all cases are lethal, Philbrick and Rummans (1994) suggested the term *malignant catatonia* to describe critically ill cases marked by autonomic instability or hyperthermia, in contrast to cases of “simple, nonmalignant catatonia.”

NMS is a form of malignant catatonia (Caroff et al. 2004b; Fink and Taylor 2003). It is characterized by fever, autonomic dysfunction with tachycardia and elevated blood pressure, rigidity (sometimes “lead pipe” in nature), mutism, and stupor. NMS usually develops over the course of a few days (Caroff 1980; Mann and Caroff 1990). It commonly begins with rigidity and mental status changes followed by signs of a hypermetabolic state. Hyperthermia, which can climb to higher than 42°C, is reported in 98% of the cases. The patient with NMS may be alert, delirious, stuporous, or comatose. Once neuroleptics are stopped and supportive measures are begun, the course is usually self-limited, lasting 2 days to 1 month. Persistent cases are usually secondary to use of depot neuroleptics, and ECT is highly effective in these cases. Although the mortality rate has been reduced through better recognition and management, a 10% risk of death remains.

The prognosis in catatonia reflects the nature and severity of the underlying etiology of the catatonia, which largely accounts for the severity and chronicity of the catatonic state itself (Levenson and Pandurangi 2004). Those with catatonia secondary to a mood disorder often do better than do those with underlying schizophrenia; and those with catatonia secondary to toxic-metabolic disorders often have better prognoses than do those with catatonia secondary to brain lesions. When the catatonia becomes chronic, as it does in certain cases of catatonic schizophrenia, the prognosis is poorer.

Diagnosis and Assessment

The signs and symptoms of the catatonic syndrome based on the Modified Bush-Francis Catatonia Rating Scale (BFCRS) are outlined in Table 10–5 (Bush et al. 1996a).

The BFCRS 23-item rating scale operationally defines each catatonic sign, rates its severity, and provides a standardized schema for clinical examination (see Table 10–6), leading to reliable ratings that are sensitive to change (Bush et al. 1996b).

With the BFCRS, a case is defined by the presence of at least 2 of the first 14 items from this scale. However, the number of signs and symptoms required to make a diagnosis of catatonia is controversial. DSM-IV-TR stipulates

the presence of only one catatonic motor sign to make a diagnosis of catatonic disorder due to a general medical condition if evidence confirms a medical etiology. A nosological difficulty with DSM-IV-TR is that this diagnosis is prevented for an episode that occurs “exclusively during the course of a delirium,” an issue currently under debate for DSM-V.

A general evaluation to exclude secondary catatonia is provided in Table 10–1. Other entities to consider in the differential diagnosis that are not secondary catatonia but may be mistaken for it include stiff-person syndrome (Lockman and Burns 2007), malignant hyperthermia (Ali et al. 2003), locked-in syndrome (Smith and Delargy 2005), and other hyperkinetic and hypokinetic states (Fink and Taylor 2003). Akinetic Parkinson’s disease can produce a catatonia-like state (i.e., mute, immobilized), but it occurs well after the diagnosis of Parkinson’s disease. Selective mutism and conversion disorder are psychiatric conditions that can be confused with catatonia.

Diffuse, nonspecific changes on the EEG will be found most often in patients with secondary catatonias. An EEG read as normal would be most consistent with primary catatonia, although psychiatric patients may have abnormal EEG findings. Generalized slowing that is consistent with encephalopathy is found in approximately half of NMS cases. Occasionally, EEG evidence of nonconvulsive status epilepticus is found in catatonic patients (Louis and Pflaster 1995). Neuroimaging, especially MRI of the brain, should be obtained, although a negative result does not rule out an “organic” etiology. Brain imaging is important because strokes, hematomas, and space-occupying lesions can all present with new-onset catatonia, and these conditions may worsen with prolonged benzodiazepine treatment (Carroll and Goforth 2004). Head CT and cerebrospinal fluid studies are normal in 95% of NMS cases. Creatine kinase levels are often elevated in malignant catatonias but also can be high in simple catatonias.

Etiology and Differential Diagnosis

Catatonia erroneously became exclusively associated with schizophrenia through the influence of Kraepelin and Bleuler, and this nosological error continued into DSM, despite long-standing linkage of catatonia to affective disorders and to organic conditions (Abrams and Taylor 1976; Gelenberg 1976; Wilcox and Nasrallah 1986). Some now advocate a separate nosology for catatonia based on the syndromic nature of the diagnosis and its unique treatment with lorazepam and ECT (Taylor and Fink 2003). Clinically, the catatonic syndrome is perhaps best divided into primary (psychiatric) and secondary (“organic”) varieties on the basis of etiologies as well as into simple and malignant types on the basis of severity (see Table 10–7).

TABLE 10-5. Catatonic symptoms (based on the Modified Bush-Francis Catatonia Rating Scale)

Catatonia can be diagnosed by the presence of 2 or more of the first 14 signs listed below.

1. Excitement	Severe hyperactivity and constant motor unrest, which is manifestly purposeless (not to be attributed to akathisia or goal-directed agitation)
2. Immobility/stupor	Severe hypoactivity, immobility, and minimal response to stimuli
3. Mutism	Verbal unresponsiveness or minimal responsiveness
4. Staring	Fixed gaze, little or no visual scanning of environment, and decreased eye blink
5. Posturing/cataplexy	Spontaneous maintenance of posture(s), including everyday ones (e.g., sitting/standing for long periods without reacting)
6. Grimacing	Maintenance of bizarre facial expressions
7. Echolalia/echopraxia	Mimicking of an examiner's speech and/or movements
8. Stereotypy	Perseverative, non-goal-directed, not inherently abnormal motor activity (e.g., playing with fingers, or repetitively touching, patting, or rubbing oneself)
9. Mannerisms	Bizarre, inherently abnormal movements (e.g., hopping or walking on tiptoe, saluting those passing by, or exaggerating caricatures of mundane movements)
10. Verbigeration	Repetition of phrases (like a scratched record)
11. Rigidity	Maintenance of a rigid posture despite efforts to be moved; exclude if cogwheeling or tremor present
12. Negativism	Seemingly motiveless resistance to instructions or attempts to move or examine the patient; patient does the exact opposite of the instruction
13. Waxy flexibility	During repositioning, patient first offers resistance before allowing repositioning (similar to that of a bending candle)
14. Withdrawal	Refusal to eat, drink, do activities of daily living, or make eye contact
15. Impulsivity	Sudden inappropriate behaviors (e.g., running down a hallway, screaming, or taking off clothes) without provocation and without appropriate explanation
16. Automatic obedience	Exaggerated cooperation with the examiner's request or spontaneous continuation of the movement requested
17. <i>Mitgehen</i>	Exaggerated arm raising in response to light pressure of finger, despite instructions to the contrary; like an "Anglepoise lamp"
18. <i>Gegenhalten</i>	Resistance to passive movement that is proportional to strength of the stimulus; appears automatic rather than willful
19. Ambitendency	Appearance of being "stuck" in indecisive, hesitant movement
20. Grasp reflex	As in the neurological examination
21. Perseveration	Repeatedly returns to the same topic or persistence with movement
22. Combativeness	Aggressive in an undirected manner, with no or only inadequate or inappropriate explanation afterward
23. Fever and autonomic abnormality	Abnormal temperature, blood pressure, pulse, or respiratory rate, and diaphoresis

Note. The full 23-item Bush-Francis Catatonia Rating Scale (BFCRS) measures the severity of 23 signs on a 0–3 continuum for each sign. The first 14 signs combine to form the Bush-Francis Catatonia Screening Instrument (BFCSI). The BFCSI measures only the presence or absence of the first 14 signs, and it is used for case detection. Item definitions on the two scales are the same.

Source. Modified from the BFCRS (Bush et al. 1996a; Fricchione et al. 2004).

TABLE 10-6. Bedside examination for catatonia

This standardized method is used to complete the 23-item Bush-Francis Catatonia Rating Scale (BFCRS) and the 14-item Bush-Francis Catatonia Screening Instrument (BFSCI). Item definitions on the two scales are the same. The BFCSI measures only the presence or absence of the first 14 signs.

Ratings are based on observed behaviors during the examination, with the exception of completing the items for “withdrawal” and “autonomic abnormality,” which may be based on directly observed behavior or chart documentation.

Generally, only those items that are clearly present should be rated. If uncertain about the presence of an item, it should be rated as “0.”

Procedure

1. Observe the patient while attempting to involve in conversation.
2. The examiner should scratch his or her head in an exaggerated manner.
3. The arm should be examined for cogwheeling. Attempt to reposition, and instruct the patient to “keep your arm loose.” Move the arm with alternating lighter and heavier force.
4. Ask the patient to extend his or her arm. Place one finger under his or her hand and state, “Do *not* let me raise your arm,” and try to raise the arm slowly.
5. Extend the hand stating, “Do *not* shake my hand.”
6. Reach into your pocket and state, “Stick out your tongue. I want to stick a pin in it.”
7. Evaluate for grasp reflex.
8. Evaluate the chart for reports from the previous 24-hour period. Check for oral intake, vital signs, and any incidents.
9. Evaluate the patient indirectly, at least for a brief period each day, regarding the following:
 - ♦ Activity level
 - ♦ Abnormal movements
 - ♦ Abnormal speech
 - ♦ Echopraxia
 - ♦ Rigidity
 - ♦ Negativism
 - ♦ Waxy flexibility
 - ♦ *Gegenhalten*
 - ♦ *Mitgehen*
 - ♦ Ambitendency
 - ♦ Automatic obedience
 - ♦ Grasp reflex

TABLE 10-7. Clinical classification of catatonia

Based on etiology

Primary catatonia

- Due to mood disorder
- Due to psychotic disorder
- Due to other psychiatric disorder

Secondary catatonias

- Due to neurological condition
- Due to medical condition
- Due to substance toxicity^a

Based on severity

Simple (nonmalignant) catatonia^b

Malignant (“lethal”^c) catatonia

^aNeuroleptic malignant syndrome is an iatrogenic cause of a secondary malignant catatonia (i.e., antipsychotic-induced malignant catatonia).

^bKahlbaum’s syndrome is a hypokinetic form of nonmalignant catatonia.

^cNot all cases of “lethal” catatonia are deadly.

Source. Based on Philbrick and Rummans 1994; Taylor and Fink 2003.

The numerous causes of catatonia are summarized in Table 10-8 (Carroll et al. 1994; Fricchione et al. 2004; Philbrick and Rummans 1994).

When catatonic stupor occurs in the setting of delirium, limbic encephalitis should be considered in the differential diagnosis (Ali et al. 2008). Limbic encephalitis can present acutely or subacutely with confusion, cognitive impairment, seizures, and catatonia. Infectious, autoimmune, paraneoplastic, and idiopathic etiologies of limbic encephalitis should be ruled out (Eker et al. 2008; Foster and Caplan 2009; Tüzün and Dalmau 2007).

Effects of Catatonia on Medical Disorders

Major medical complications that frequently will be manifested in patients with persistent catatonic stupor need close monitoring and management if the patient is to escape morbidity and mortality (Levenson and Pandurangi 2004). Some of this risk stems from the clinical challenge of diagnosing medical conditions in patients who are mute, rigid, and unable to cooperate. But the risk is sometimes compounded by “therapeutic nihilism” when catatonic patients are viewed as hopeless or demented. In addition, those in chronic catatonic states often wind up in long-term care centers such as nursing homes or state facilities without the proper medical resources to adequately address their conditions.

Pulmonary Complications

Aspiration is the most common pulmonary complication of catatonia. It can result in pneumonitis or pneumonia.

TABLE 10-8. Selected causes of catatonia**Primary**

Acute psychoses
 Conversion disorder
 Dissociative disorders
 Mood disorders
 Obsessive-compulsive disorder
 Personality disorders
 Schizophrenia

Secondary*Cerebrovascular causes*

Arterial aneurysms
 Arteriovenous malformations
 Arterial and venous thrombosis
 Bilateral parietal infarcts
 Temporal lobe infarct
 Subarachnoid hemorrhage
 Subdural hematoma
 Third ventricle hemorrhage
 Hemorrhagic infarcts
 CNS vasculitis (e.g., systemic lupus erythematosus)

Other CNS disorders

Akinetic mutism
 Alcoholic degeneration and Wernicke's encephalopathy
 Cerebellar degeneration
 Cerebral anoxia
 Cerebromacular degeneration
 Traumatic brain injury
 Frontal lobe atrophy
 Multiple sclerosis and acute disseminated encephalomyelitis
 Hydrocephalus
 Lesions of thalamus and globus pallidus
 Narcolepsy
 Parkinsonism
 Postencephalitic states
 Seizure disorders^a
 Tuberous sclerosis

Tumors

Angioma
 Frontal lobe tumors
 Gliomas
 Langerhans' carcinoma
 Paraneoplastic encephalopathy (e.g., oat cell carcinoma, teratomas)
 Periventricular diffuse pinealoma

Toxins

Coal gas
 Organic fluorides
 Tetraethyl lead poisoning

TABLE 10-8. Selected causes of catatonia (continued)*Infections^a*

Bacterial meningoenzephalitis
 Bacterial sepsis
 Hepatic amoebiasis
 HIV/AIDS
 Cerebral malaria
 Subacute sclerosing panencephalitis
 Tertiary syphilis
 Typhoid fever
 Viral encephalitis (especially herpes)

Metabolic causes^a

Acute intermittent porphyria
 Addison's disease
 Cushing's disease
 Diabetic ketoacidosis
 Hepatic encephalopathy
 Hereditary coproporphyrin
 Homocystinuria
 Hyperparathyroidism
 Pellagra
 Uremia

Drug-associated causes

Antipsychotics^a (both typical and atypical have been associated)
 Antidepressants (tricyclics, monoamine oxidase inhibitors, and others)
 Anticonvulsants (e.g., carbamazepine, primidone)
 Disulfiram^a
 Efavirenz
 Metoclopramide
 Dopamine depleters (e.g., tetrabenazine)
 Dopamine withdrawal (e.g., abrupt discontinuation of L-dopa)
 Hallucinogens (e.g., mescaline, phencyclidine,^a and lysergic acid diethylamide)
 Lithium carbonate
 Sedative-hypnotic withdrawal
 Corticosteroids^a
 Stimulants (e.g., amphetamines, methylphenidate, and possibly cocaine)

Note. CNS = central nervous system.

^aSignifies most common medical conditions associated with catatonic disorder from literature review done by Carroll et al. 1994.

Source. Adapted from Fricchione et al. 2004; Philbrick and Rummans 1994.

Risk factors for pneumonia include atelectasis, malnutrition, poor respiratory effort, and institutional settings, which also make nosocomial infections with antibiotic-resistant organisms more likely. Prophylactic antibiotics are not beneficial in patients who are considered at high

risk for aspiration. Prophylactic administration of antacids, H₂ blockers, or proton pump inhibitors is also not recommended; although they would neutralize gastric acidity and therefore would be expected to reduce pneumonitis, gastric acidity normally keeps stomach contents sterile. Hence neutralization may promote colonization by pathogenic organisms, making aspiration pneumonia more likely (Levenson and Pandurangi 2004). Respiratory failure may result when respiratory effort is severely inadequate (Boyarsky et al. 1999). Catatonic patients are also more susceptible to pulmonary emboli. Immobility increases the likelihood of venous stasis, which can then promote thrombosis, which can lead to pulmonary embolism (Lachner and Sandson 2003; McCall et al. 1995; Woo 2007). Prophylactic measures such as hydration, physical therapy, support hose, and anticoagulation can be helpful.

Dehydration, Malnutrition, and Gastrointestinal Complications

Catatonia leads to dehydration and malnutrition. Infection, skin breakdown, constipation, and ileus may be sequelae (Kaufmann et al. 2006; Thomas 2001). Persistent catatonia may necessitate the use of enteral feeding, which can result in complications from the feeding tubes.

Oral and Cutaneous Complications

Dental caries, oral infections, and gum disease are common in chronic catatonia. Skin breakdown and decubitus ulcers are very common as a result of immobility and pressure (Thomas 2001).

Genitourinary Tract Complications

Urinary retention, urinary incontinence, and urinary tract and vaginal infections are frequent complications in the persistently catatonic patient.

Neuromuscular Complications

The immobility of catatonia can result in flexion contractures and nerve palsies. Mobilization through physical therapy can help prevent these complications. Muscle breakdown as a result of immobilization may lead to rhabdomyolysis, particularly in malignant catatonias.

Treatment of Catatonia

Catatonia when properly treated typically resolves completely, but an underlying psychosis will often remain. Benzodiazepines and ECT are the most frequently recommended treatments. Bush et al. (1996b) in an open trial with 13 acute catatonic patients reported that 2 mg of intravenous lorazepam reduced catatonia scores on the BFCRS by 60% within 10 minutes. Although no published random-

ized controlled trials for acute catatonia are available, many case series and prospective open trials over the past 20 years with parenteral or oral benzodiazepines (such as lorazepam) showed a response rate of 60%–80% within hours or days (Rosebush and Mazurek 2004). Given the consistent benefit with low risk in these studies along with extensive clinical experience, a benzodiazepine given parenterally has been advocated as appropriate initial treatment for catatonia (Bush et al. 1996b; Rosebush and Mazurek 2004). Arguments favoring benzodiazepines include familiarity in contemporary psychiatric practice, a favorable therapeutic index, and the availability of flumazenil, a specific antagonist for benzodiazepines. It is of interest that flumazenil reversed the benefit of lorazepam in a case of catatonia (Wetzel et al. 1987). Initial dosages of 2–6 mg/day of lorazepam by any route of administration are recommended, but some patients may require higher doses.

Benzodiazepines are effective for both simple and malignant catatonia attributed to primary psychiatric illness, neuroleptic toxicity, and a variety of other secondary conditions. Treatment response is not predicted by age, sex, or severity of catatonia, but underlying chronic schizophrenia may predict a poorer response (Bush et al. 1996b; J.W.Y. Lee et al. 2000; Rosebush et al. 1990; Ungvari et al. 1999). Because underlying psychiatric disorders are difficult to assess in mute catatonic patients, specific treatment may be delayed until resolution of the catatonic state.

Since the 1930s, ECT has had a well-deserved reputation as the most effective treatment for catatonia. Clinical experience and case series have determined that ECT produces remission of catatonia even when other treatments such as lorazepam have failed. An added benefit of ECT is its effectiveness for the mood or psychotic disorders frequently associated with the catatonic syndrome. A synergism between ECT and lorazepam has been reported in the treatment of catatonia; therefore, embarking on an ECT course does not preclude continued lorazepam use (Petrides et al. 1997). (See also Chapter 40, “Electroconvulsive Therapy.”)

One damaging consequence of the nosological error linking catatonia prominently to schizophrenia was the reflexive use of neuroleptic medication in catatonic patients. Many patients likely have been pushed into NMS as a result. The use of antipsychotics for catatonia requires caution because of this risk of changing a simple catatonia into a malignant one. Several reports indicated that both the older high-potency agents, such as haloperidol, and the second-generation antipsychotics failed to improve catatonia, induced or worsened catatonia, or led to progression from catatonia to NMS (Lopez-Canino and Francis 2004; Rosebush and Mazurek 2004; White and Robins 1991). Nevertheless, second-generation antipsychotics

may have a role in the treatment of catatonia (Van Den Eede et al. 2005). In one double-blind study, 14 of 68 patients with nonaffective disorder and catatonia who had failed to respond to lorazepam were randomly assigned to receive risperidone plus sham ECT ($n=6$) or bilateral ECT plus placebo ($n=8$). After 3 weeks, scores on the BFCRS declined more than 90% with ECT and approximately 50% with risperidone (Girish and Gill 2003).

Unfortunately, ECT may not be available or permitted, and the clinician may be motivated to consider use of second-generation antipsychotics. Use of antipsychotic agents in the treatment of malignant catatonia is contraindicated because of the risk of exacerbation. In this setting, prompt use of ECT is advocated (Mann et al. 2004). In a review of 18 cases of malignant catatonia, 11 of 13 patients who received ECT survived, whereas only 1 of 5 who did not receive ECT lived (Mann et al. 2004). In another series, 16 of 19 patients who had received ECT within 5 days of symptom onset survived, whereas none of the 14 patients who had received ECT after 5 days did (Philbrick and Rummans 1994). Thus, when a patient presents with malignant catatonia of any type, ECT should be used expeditiously (i.e., within 5 days if possible) if a medication trial is unsuccessful.

Conclusion

Secondary psychosis, mania, and catatonia can occur in a wide range of medical diseases and toxic states. Prompt recognition of these neuropsychiatric complications allows for specific syndromal treatments that can lead to a complete resolution of the psychiatric symptoms, even if the underlying illness cannot be cured. If the neuropsychiatric symptoms are not recognized or poorly treated, substantial morbidity or even death can result.

ANXIETY IS AN EXTREMELY common problem in primary care and specialty medical settings. Because the 1-year prevalence rate of any anxiety disorder in the general population is approximately 18% (Kessler et al. 2005), many medically ill patients will have concurrent anxiety unrelated to the experience of medical illness. The profound physical and psychological stressors of medical illness often precipitate anxiety, particularly in individuals with preexisting vulnerability. Therefore, when evaluating a medically ill patient, the psychosomatic medicine psychiatrist should always determine whether anxiety symptoms are present. Although the presence of anxiety may reflect a mood disorder or other psychiatric disorder, formal assessment for the presence of an anxiety disorder should be considered in all patients. Unfortunately, medical professionals often neglect to screen for these highly treatable disorders. Even when they recognize anxiety, some practitioners minimize its significance by considering it to be a “normal” response to the uncertainty and adversity associated with having a disease.

Once the psychiatrist has determined that a patient has anxiety, the more complex task of ascertaining etiology must be undertaken. Although it is advisable to use a biopsychosocial approach to formulation, surprisingly few data are available regarding medical and pharmacological causes of anxiety. Nonetheless, the psychiatrist must carefully assess their potential etiological roles. Finally, it is important to consider medical comorbidity when designing pharmacological and psychotherapeutic treatment plans. In this chapter, we discuss each of these topics. For detailed reviews of anxiety among individuals with specific medical comorbidities, the reader is referred to the corresponding chapters in this text.

General Features and Diagnostic Considerations

Anxiety may reflect the presence of an anxiety disorder but also may be a symptom of another psychiatric disorder such as depression. In the medical setting, it is also important to remember that anxiety may be a symptom of delirium, dementia, or a somatoform disorder such as hypochondriasis. Anxiety also may be the result of a medical disorder (e.g., hyperthyroidism) or a medication side effect. Furthermore, some symptoms and signs of medical disorders (e.g., tachycardia, dyspnea, and diaphoresis) may be mistaken for anxiety.

An interview during which DSM-IV-TR (American Psychiatric Association 2000) criteria are used is the gold standard for diagnosis of an anxiety disorder. In primary care settings, it is often useful to ask brief screening questions to determine whether a full diagnostic assessment is necessary. A 7-item anxiety screen, the Generalized Anxiety Disorder (GAD)-7 scale, has been reported to be an effective screen for GAD, panic, posttraumatic stress disorder (PTSD), and social phobia (Kroenke et al. 2007). The Hospital Anxiety and Depression Scale (HADS), a 14-item scale, also has been shown to be a valid screening instrument for both anxiety and depression (Bjelland et al. 2002).

Many patients with anxiety do not present to mental health providers. Of all anxiety disorder visits in the National Ambulatory Medical Care Survey in 1998, 48% were to primary care physicians (Harman et al. 2002). Among a sample of 3,000 adult primary care patients, 11% were diagnosed with an anxiety disorder (Spitzer et al. 1999). Individuals with chronic medical conditions such as arthritis,

heart disease, gastrointestinal disease, and hypertension are more likely to have anxiety disorders (Sareen et al. 2006). Unfortunately, many individuals treated in primary care settings do not receive appropriate care for anxiety (Roy-Byrne et al. 1999; Young et al. 2001). Some physicians lack the skill or time to treat anxiety. In addition, some primary care patients are reluctant to consider either psychosocial or pharmacological treatment for their conditions (Hazlett-Stevens et al. 2002).

Anxiety disorders have clearly been shown to impair functioning and well-being among individuals with chronic medical conditions (Kessler et al. 2003; Sherbourne et al. 1996). Anxiety may be a risk factor for the development of medical illness and may physiologically exacerbate some conditions (e.g., angina, arrhythmias, movement disorders, labile hypertension, and irritable bowel syndrome). Some evidence indicates that phobic anxiety is a risk factor for fatal coronary artery disease (Albert et al. 2005; Kawachi et al. 1994), but some studies have shown no relation between anxiety and mortality (e.g., Herrmann et al. 2000; Lane et al. 2001). Anxiety also may lead to increased risk of developing hypertension (Jonas et al. 1997) and cardiovascular morbidity (Smoller et al. 2007). In a recent analysis of National Comorbidity Survey data, lifetime PTSD was associated with a higher prevalence of hypertension (Kibler et al. 2009). For an excellent recent review of anxiety disorders and their relation to medical illnesses, see Roy-Byrne et al. (2008).

Although depression is more clearly a predictor of poor adherence to medical treatment (DiMatteo et al. 2000), excessive anxiety might reduce adherence to medical treatment in some individuals (Martín-Santos et al. 2008). Anxiety may lead some individuals to refuse diagnostic procedures or surgery and even to sign out of the hospital against medical advice.

Specific Anxiety Disorders

Panic Disorder

Primary care patients with panic attacks (see Table 11-1 for diagnostic criteria) are high utilizers of medical care (Roy-Byrne et al. 1999). In particular, many patients who present with chest pain are found to have panic disorder. For example, in one study, panic disorder was found in approximately 25% of 441 patients presenting to an emergency department with chest pain (Fleet et al. 1996). Researchers estimate that at least one-third of individuals with chest pain and normal coronary arteries have panic disorder (e.g., Bringager et al. 2008; Fleet et al. 1998; Mad-dock et al. 1998). These rates contrast with 12-month prevalence rates of 2.7% found in the National Comorbidity

TABLE 11-1. DSM-IV-TR criteria for panic attack

Note: A panic attack is not a codable disorder. Code the specific diagnosis in which the panic attack occurs (e.g., 300.21 panic disorder with agoraphobia).

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 minutes:

- (1) palpitations, pounding heart, or accelerated heart rate
- (2) sweating
- (3) trembling or shaking
- (4) sensations of shortness of breath or smothering
- (5) feeling of choking
- (6) chest pain or discomfort
- (7) nausea or abdominal distress
- (8) feeling dizzy, unsteady, lightheaded, or faint
- (9) derealization (feelings of unreality) or depersonalization (being detached from oneself)
- (10) fear of losing control or going crazy
- (11) fear of dying
- (12) paresthesias (numbness or tingling sensations)
- (13) chills or hot flushes

Source. American Psychiatric Association 2000.

Survey Replication (Kessler et al. 2005). A meta-analysis identified five variables that correlate with higher rates of panic disorder among individuals seeking treatment for chest pain in emergency departments or cardiology clinics: 1) absence of coronary artery disease; 2) atypical quality of chest pain; 3) female gender; 4) younger age; and 5) high level of self-reported anxiety (Huffman and Pollack 2003).

Patients with benign palpitations have high rates of panic disorder (Barsky et al. 1994; Ehlers et al. 2000). One explanation for such high rates is that individuals with panic disorder may have heightened cardiac sensitivity to symptoms such as chest pain and palpitations (Barsky 2001; Mayou 1998). Panic symptoms also may be linked to physiological changes in peripheral organ systems. Panic attacks may be difficult to distinguish symptomatically from paroxysmal atrial tachycardia; both occur frequently in young, otherwise healthy women, and they are frequently comorbid. Before palpitations are attributed to anxiety, it is important for patients to undergo cardiac evaluation (e.g., ambulatory electrocardiographic monitoring) to rule out arrhythmias. There have been many reports of comorbidity of panic disorder and mitral valve prolapse, but data are not sufficiently strong to support a clear association (Filho et al. 2008). (See also Chapter 18, "Heart Disease.")

Panic disorder also leads patients to present to other medical specialists. For example, patients who present for

evaluation of dizziness have elevated rates of this disorder (N.M. Simon et al. 1998; Wiltink et al. 2009; Yardley et al. 2001). Panic disorder also has significant comorbidity with irritable bowel syndrome (Kumano et al. 2004; Sugaya et al. 2008). In patients with irritable bowel syndrome, anxiety may be due to locus coeruleus activation by afferent signals from the bowel. Thus, with irritable bowel syndrome and other medical disorders such as asthma, anxiety symptoms may be due to central nervous system responses to afferent information from the viscera (Zaubler and Katon 1998). Finally, many patients with negative evaluations for pheochromocytoma are found to have anxiety disorders, including panic disorder (Eisenhofer et al. 2008).

Collaborative care interventions can improve outcomes for primary care patients with panic disorder. In one model, collaborative care consisted of patient education, treatment with paroxetine, two visits with an on-site consulting psychiatrist, and follow-up telephone calls. Patients who received this intervention, compared with those receiving usual primary care, had significant reductions in anxiety (Katon et al. 2002; Roy-Byrne et al. 2005).

(For further discussion of panic disorder in cardiac patients, see Chapter 18, "Heart Disease.")

Posttraumatic Stress Disorder

The National Comorbidity Survey estimated the 12-month prevalence of DSM-IV-TR PTSD in the general population to be 3.5% (Kessler et al. 2005). Prevalence in medical settings appears to be higher. For example, in one primary care sample, the current prevalence of PTSD was approximately 12% (M.B. Stein et al. 2000). Trauma victims and individuals with PTSD are frequent users of health care (Seng et al. 2006). PTSD also has been linked to adverse medical outcomes. For example, in a study of Vietnam veterans, PTSD was associated prospectively with heart disease mortality (Boscarino 2006). In a large study of former prisoners of war from World War II, risk of cardiovascular disease was associated with PTSD (Kang et al. 2006).

It is not surprising that PTSD symptoms are common among individuals who experience acute physical traumas. For example, burn victims have been reported to have PTSD at rates ranging from 20% to 45% (Difede et al. 2002; McKibben et al. 2008; Yu and Dimsdale 1999). In one study, 30%–40% of survivors of a motor vehicle crash or an assault reported PTSD symptoms for months after the trauma. Higher symptom levels were associated with female gender, stimulant intoxication, and greater prior trauma (Zatzick et al. 2002). PTSD also has been reported among individuals with automatic implantable cardioverter defibrillators (Hamner et al. 1999). In one recent study of patients with an implanted cardioverter defibrillator, high levels of PTSD symptoms were associated with

increased mortality over an average of 5 years of follow-up (Ladwig et al. 2008).

Intensive care unit experiences can result in PTSD symptoms. In one study, recall of "delusional memories" (paranoia, hallucinations, or nightmares presumably due to delirium) from an intensive care unit hospitalization was shown to be associated with the development of PTSD symptoms (C. Jones et al. 2001). PTSD symptoms may occur after many other medical conditions or treatments, including myocardial infarction (Gander and von Kanel 2006) and the diagnosis of HIV infection. For reviews, see the articles by Tedstone and Tarrier (2003) and Davydow et al. (2008).

Acute stress disorder also may occur after life-threatening illnesses or injuries. In one study, 19% of 83 hospitalized adult burn patients developed acute stress disorder within 2 weeks of injury. The presence of acute stress disorder strongly predicted the presence of PTSD at least 6 months later (Difede et al. 2002; McKibben et al. 2008). Similarly, the degree of fright experienced at the time of myocardial infarction was associated with PTSD symptoms 3 months later (Bennett et al. 2001).

Life-threatening illness such as cancer is a stressor that can precipitate PTSD (Kangas et al. 2002; Smith et al. 1999). However, this trauma is different from more usual PTSD stressors such as rape in two principal ways: 1) the threat arises from one's own body; and 2) once the patient has been treated, the ongoing stressor is often not the memory of past events but the fear of recurrence (Green et al. 1997). Some researchers have speculated that the trauma associated with the diagnosis and treatment of serious medical illness might be sufficient to cause PTSD even in the absence of a catastrophic event. The rate of current PTSD in cancer survivors is approximately 3%–5%, but many more patients experience some symptoms of PTSD (Alter et al. 1996; Andrykowski and Cordova 1998; Green et al. 1998). The likelihood of developing PTSD symptoms after cancer treatment has been shown to be increased among individuals with past trauma, prior psychiatric diagnoses, lower levels of social support, and recent life stressors (Green et al. 2000; Jacobsen et al. 2002). As is the case with other medical illnesses, severity of cancer is not a strong predictor of the development of PTSD.

Other Anxiety Disorders

There are relatively few studies regarding the characteristics and significance of other anxiety disorders in medical settings. Although the 12-month prevalence rate of GAD in community samples is approximately 3% (Kessler et al. 2005), an international study found the 1-month prevalence rate in primary care to be 7.9%. In that study, GAD was usually comorbid with other psychiatric conditions

(Maier et al. 2000). GAD also may lead to excess health care use (G.N. Jones et al. 2001). GAD symptoms such as fatigue, muscle tension, and insomnia often lead the patient to present initially to a primary care physician. As is the case with depression, it is important for physicians to consider GAD in the differential diagnosis for such patients. A simple screening question can be extremely useful in helping the physician to determine whether GAD may be present; for example, "In the past 4 weeks, how often have you been bothered by feeling nervous, anxious, on edge, or worrying a lot about different things?" (Spitzer et al. 1999).

Although specific phobias are quite common, they rarely come to the attention of medical professionals. Exceptions include blood-injection-injury phobias and claustrophobia. Blood-injection-injury phobias may lead to fainting during medical procedures or to avoidance of injections and blood tests. In the Baltimore Epidemiologic Catchment Area study, approximately 3% of the sample was found to have one of these phobias. Of that sample of 60 individuals, 23% reported fear of blood; 47%, fear of injections; and 78%, fear of dentists. Although this condition may have serious implications for an affected individual, little is known about its public health significance (Bienvenu and Eaton 1998). Syncope or presyncope in individuals with health care phobias may be due to an underlying predisposition toward neurally mediated syncope (Accurso et al. 2001). Claustrophobia comes to medical attention most commonly when individuals need a magnetic resonance imaging (MRI) procedure. The procedure commonly causes anxiety that is severe enough to require sedation (e.g., with a short-acting benzodiazepine such as midazolam or lorazepam). Behavioral techniques such as relaxation exercises also may be helpful.

Compulsive skin picking or scratching may be a manifestation of obsessive-compulsive disorder (OCD). In a recent study of 60 individuals with skin picking, 15% were found to have OCD (Odlaug and Grant 2008). Among 31 individuals with psychogenic excoriation seen in a dermatology clinic, 45% had OCD (Calikusu et al. 2003). However, in another study of 34 patients with psychogenic excoriation, OCD was not a common disorder (Arnold et al. 1998). (For further discussion, see Chapter 29, "Dermatology.")

Causes of Anxiety in the Medically Ill

In evaluating an anxious patient who is also medically ill, it is essential for the psychiatrist to consider the full range of potential causes of anxiety. In addition to the possibility of a preexisting primary anxiety disorder, three categories of causes of anxiety should be considered for every patient. First, is the patient having a psychological reaction to the

experience of medical illness? Second, is the patient's anxiety directly due to the biological effects of a substance? Third, is the patient's anxiety directly due to the biological effects of a medical illness? As is the case for many medically ill patients, the etiology of anxiety is often multifactorial and may vary with the course of illness.

Anxiety as a Psychological Reaction to the Experience of Illness

The importance of one's health added to the often unavoidable uncertainty associated with medical illness leads many medically ill patients to feel anxious. Particularly for individuals with a predisposition to anxiety, the psychosocial stress of illness may be sufficient to induce an anxiety disorder. Just as when evaluating a depressed patient, psychiatrists should never make assumptions regarding the cause of anxiety in an individual patient. For example, it is easy to assume that the patient who is awaiting cardiac surgery is afraid of dying, when in fact the patient might actually be more concerned about potential disability. When approaching the anxious patient, the psychiatrist should consider all potential psychological causes of anxiety. The following discussion reviews the major causes among medically ill populations. For seminal reviews of this topic, the reader is referred to the work of Strain and Grossman (1975) and Kahana and Bibring (1964) (see also Chapter 4, "Psychological Responses to Illness").

Uncertainty Regarding Medical Diagnosis

Some individuals worry excessively that they might have a serious illness. Routine evaluations may cause anxiety, especially in those with a personal or family history of illness. For example, an individual with a family history of breast cancer might become quite anxious in the period preceding routine mammography. Anxiety also may occur during the period between initial evaluation and receipt of the definitive result—for example, after the physician tells the patient, "It's probably nothing, but let's perform a brain MRI just to be sure." Prolonged uncertainty regarding diagnosis is even more anxiety-provoking, such as when the patient is told, "Your PSA [prostate-specific antigen] is slightly elevated, but at this point we should simply wait and reevaluate your level in a few months." Although physicians are acutely aware that there is significant uncertainty inherent in medical diagnoses, patients are generally not reassured by this fact.

Uncertainty Regarding Medical Prognosis

For most medical illnesses and medical procedures, prognosis is uncertain. Many patients will experience ongoing fears of recurrence, especially when they have illnesses that fre-

quently do recur (e.g., arrhythmias, cancer, and multiple sclerosis). Similarly, many fear that their treatments will fail, even if they are initially successful. Examples include fear of rejection of a transplanted organ and development of graft-versus-host disease. Physicians often realize that the potential for a poor prognosis—for example, in cases of relatively advanced cancer—often leads to anxiety. However, it is important to keep in mind that patients who have favorable prognoses often experience anxiety. For example, a 95% cure rate is reassuring to many patients, but some will have difficulty coping with the prospect of a 5% recurrence rate. Complicating the problem is the fact that prognoses may be inaccurate when they are derived from aggregate data, which may have been based on treatments that are now outmoded. For patients who learn about their prognoses through personal medical searches, physicians may be able to provide reassurance by reminding the anxious patients of this information: “You are not a statistic; those data were published before the newest treatments became available.”

Anxiety About One's Body

Many individuals experience anxiety about the future effects of illness on their bodies (see Strain and Grossman 1975). Patients may fear that they will lose body parts (e.g., due to amputation). Ongoing fears of amputation are particularly problematic for some patient populations (e.g., those with diabetes mellitus and peripheral vascular disease). Others may fear that they will lose functional capacities or that they will become overly dependent on others. For example, individuals with diabetes mellitus may fear eventual blindness, patients with chronic obstructive pulmonary disease may fear “being hooked to a breathing machine,” and men with prostate cancer may fear impotence. Others are afraid of the experience of pain. For example, individuals with metastatic cancer are often afraid that they will have unremitting, severe pain. Knowledge of these fears can help the physician to provide appropriate reassurances (e.g., that pain will be aggressively treated).

Fear of Death

All individuals, regardless of their physical health, fear death at some time in their lives. The experience of physical illness often heightens that fear because everyone either has faced life-threatening illness or has known someone who has died from a physical illness. Physicians must be comfortable assessing fears of death in both patients and their families. This assessment must include an exploration of specific reasons for fear of death (e.g., a patient may fear death from childbirth because that occurred many years earlier to a close relative). Exploration of the reasons for an irrationally high estimate of risk of death may lead to straightforward reassurance. Assessment of death anxiety

also should include the opportunity for individuals to discuss existential thoughts about dying (e.g., reflections about the meaning of one's life [Adelbratt and Strang 2000]). When interviewing the patient with a fear of dying, the physician should assess for particular dying-related fears (e.g., a patient may actually be at peace with dying but may be afraid that her family will not be able to survive without her). In that case, involvement of the family may lead to reassurance and a more peaceful dying process (see also Chapter 41, “Palliative Care”).

Anxiety About the Effect of Illness on Identity and Livelihood

Even if illness alone is not sufficient to cause anxiety, patients may be concerned about the potential effect of illness on their ability to work, to perform essential household functions, or to maintain income. Uncertainties about medical reimbursements may make insured individuals justifiably concerned. The uninsured are often so anxious about how they would pay for medical procedures that they avoid medical visits altogether. Patients may be anxious that the costs of medical treatment might cause financial burdens for their families, and they may decline treatment for this reason. In these situations, meetings with family members and health care financial counselors may help to assuage unjustifiable fears that treatments will cause more harm than good.

Anxiety About Strangers and Being Alone in the Hospital

Individuals with medical illnesses become anxious even when their own personal physician performs a medical procedure. Thus, it is not unusual for an acutely ill patient to become intensely anxious when asked to trust his or her life to the new physician he or she has just met in the emergency department or the intensive care unit. Patients who are so anxious that they refuse a medical procedure may be labeled as noncompliant when, in fact, fear is the underlying explanation. As noted by Muskin (1995), acceptance of the involvement of unfamiliar clinicians may be particularly difficult for individuals with preexisting problems with trust (e.g., those with paranoia or borderline personality disorder). Similarly, it is often difficult for some patients to tolerate being alone in the hospital. Because many individuals regress while hospitalized, it is not surprising that patients with dependency needs might become unduly anxious when left alone in an unfamiliar environment.

Anxiety About Negative Reactions From Physicians

Many individuals with medical illness worry about their physician's opinion of them. Excessive concern may lead to reluctance to seek health care. Persons who feel guilty for

not following their physician's recommendations might cancel appointments for fear of being scolded (e.g., for failure to lose weight, stop smoking, or check blood sugar levels more reliably). Similarly, some individuals' anxiety might lead them to deny or fail to disclose important information (e.g., regarding sexual risk factors or level of alcohol intake). Anxiety may be particularly prominent among patients who have caused or aggravated their own illness. It is important for the physician to be vigilant for clues that a patient might have excessive anxiety. Awareness of negative countertransference is essential; it is appropriate to provide consistent, firm reminders of the need for proper medical care, but harsh criticism is unwarranted and may contribute to poor adherence.

Substance-Induced Anxiety

In evaluating the anxious medical patient, it is important to consider whether medications or medication withdrawal might be contributory. Because they can be obtained without prescriptions, caffeine and over-the-counter sympathomimetics are common causes of anxiety in the general population. Caffeine is widely used and commonly causes anxiety. It may be present in significant quantities in coffee, tea, caffeinated soda, caffeinated water, and coffee ice cream, as well as in over-the-counter preparations for alertness (e.g., NoDoz), weight loss, and headache (e.g., Excedrin). Even at low doses, caffeine may induce anxiety in susceptible individuals (Childs et al. 2008). In individuals with anxiety disorders, reduction of caffeine intake often reduces anxiety symptoms. Over-the-counter sympathomimetics used as decongestants (e.g., pseudoephedrine) frequently cause anxiety, and tachyphylaxis develops rapidly. Some individuals may use large quantities in the form of nasal spray. Similarly, the widely used herbal preparation ephedra also may cause anxiety.

The most important medication classes that are associated with anxiety are summarized in Table 11-2, which includes examples of specific medications in each class. Where appropriate, notes have been added for further clarification. General references in this area are *The Medical Letter on Drugs and Therapeutics* ("Drugs That May Cause Psychiatric Symptoms" 2008) and the *Physicians' Desk Reference* (2009).

Anxiety Secondary to General Medical Conditions

Many medical problems have been reported to cause anxiety, but data are limited to case reports for many associations. Nonetheless, it is important for the psychosomatic medicine physician to consider medical causes of anxiety when evaluating an anxious patient. It is particularly important to evaluate medical causes when the history is not

typical for a primary anxiety disorder (e.g., lack of personal or family history, lack of psychosocial stressors) and when the onset of anxiety is at a later age. In addition, it is important to evaluate medical causes when the anxiety is accompanied by disproportionate physical symptoms (e.g., marked dyspnea, tachycardia, or tremor) or atypical physical symptoms (e.g., syncope, confusion, or focal neurological symptoms).

It is important for the clinician to keep in mind the distinction between anxiety that is physiologically secondary to a general medical condition and anxiety that is comorbid with, or a psychological reaction to, a general medical condition. (For example, hyperthyroidism appears to biologically cause anxiety, whereas diabetes mellitus usually does not.) The DSM-IV-TR diagnosis of anxiety due to a general medical condition refers to the former, not the latter. This difference has not been clearly articulated in some reviews in this area, and it can also be confusing for patients. One source of confusion results from the assumption of causality when there is an epidemiological association between anxiety and a specific medical condition. For example, anxiety disorders are common among individuals with migraine (Torelli and D'Amico 2004), but the onset of anxiety disorders generally precedes that of migraine (Merikangas and Stevens 1997).

Components of the medical evaluation of the anxious patient should be determined by the patient's specific medical symptoms. For example, it may be necessary to obtain electroencephalograms and a neurological consultation for a patient with seizurelike episodes. The general evaluation of all anxious patients should include the following elements (Colon and Popkin 2002):

- ♦ History and physical examination, including neurological examination
- ♦ Evaluation of the potential role of medications and substances (see Table 11-2)
- ♦ Screening diagnostic studies (e.g., routine blood chemistries, complete blood cell count, calcium concentration, thyroid hormone levels, electrocardiogram)

In the following subsections, we discuss common medical conditions that are associated with anxiety for which data are strongly supportive of a causal relation.

Thyroid Disease

Anxiety symptoms commonly occur among individuals with thyroid disease. Patients with subclinical and clinical hyperthyroidism have been shown to have elevated anxiety levels (Gulseren et al. 2006; Sait Gonen et al. 2004) (see also Chapter 22, "Endocrine and Metabolic Disorders"). Hyperthyroidism may be difficult to distinguish from a primary

TABLE 11–2. Substances that may cause anxiety

Class	Example(s)	Notes
Androgens	Methyltestosterone, nandrolone	Most problems occur when abused.
Angiotensin-converting enzyme inhibitors	Captopril, lisinopril	They are often stimulating.
Anticholinergics	Atropine, benztropine, dicyclomine, hyoscyamine	
Anticatatpexy agent	Sodium oxybate	
Antidepressants	Bupropion, serotonin reuptake inhibitors, tricyclics	
Antiemetics	Droperidol, prochlorperazine, promethazine	Anxiety may actually be akathisia.
Antiepileptics	Pregabalin, zonisamide	
Antimalarial agents	Mefloquine	
Antimycobacterial agents	Isoniazid	
Antineoplastic agents	Ifosfamide, vinblastine	
Antipsychotics	Haloperidol, thiothixene	Anxiety may actually be akathisia.
Antiviral agents	Acyclovir, efavirenz, ganciclovir, valganciclovir	
Beta-adrenergic agonists	Albuterol, metaproterenol	
Cannabinoids	Dronabinol	
Class I antiarrhythmics	Lidocaine, procainamide, quinidine	
Corticosteroids	Methylprednisolone, prednisone	
Dopaminergic agents	Amantadine, carbidopa-levodopa	
Estrogens	Conjugated estrogens, ethinyl estradiol, levonorgestrel implant	They may cause panic attacks and depression.
Gonadotropin-releasing hormone active agents	Leuprolide	
Histamine H ₂ receptor antagonists	Cimetidine, famotidine, nizatidine	
Interferons	Interferon-alpha, interferon-beta	
Methylxanthines	Caffeine, theophylline	
Sympathomimetics	Ephedrine, epinephrine, phenylephrine nasal, pseudoephedrine	
Nonsteroidal anti-inflammatory drugs	Indomethacin, naproxen, salicylates	
Opiates	Meperidine	Anxiety may be a symptom of delirium.
Opioid antagonists	Naltrexone	Observe patient for opiate withdrawal.
Progestins	Medroxyprogesterone acetate, norethindrone	
Prokinetic agents	Metoclopramide	Anxiety may be due to akathisia.
Psychostimulants	Dextroamphetamine, methylphenidate	
Sedative-hypnotics	Alcohol, barbiturates, benzodiazepines	Anxiety occurs with drug withdrawal.

anxiety disorder. Signs that may be suggestive of thyrotoxicosis include persistent tachycardia, palms that are warm and dry (not cold and clammy), and fatigue accompanied by the desire to be active (Colon and Popkin 2002). However, data differentiating the two are not definitive in this regard (see Iacovides et al. 2000), and much of the research in this area is not current. Some individuals with hyperthyroidism also may have cognitive impairment. Improvement in anxiety usually parallels successful treatment of the hyperthyroidism. Therefore, specific antianxiety treatment may not be necessary. Nonetheless, antianxiety treatment should be considered during normalization of thyroid hormone levels, particularly for individuals with moderate to severe symptoms. Beta-blockers, which are used routinely for acute treatment of hyperthyroidism, will relieve peripheral manifestations of anxiety.

Because thyroid dysfunction is so common among individuals with anxiety, a screening thyroid stimulating hormone (TSH) assay should be considered for patients with new-onset anxiety disorders and treatment-resistant anxiety, particularly when the anxiety is generalized and accompanied by prominent physical symptoms. If the TSH level is abnormal, further evaluation of the thyroid axis is recommended (e.g., free thyroxine index or free thyroxine measurement).

There are several putative mechanisms for the association between abnormalities of the thyroid axis and mood or anxiety symptoms. A blunted TSH response to thyrotropin-releasing hormone stimulation had been reported to occur in some depressed patients, but little recent research is available, and the test does not have clinical utility. The adrenergic overreactivity that accompanies hyperthyroidism provides a ready explanation for its association with anxiety. Finally, thyroid hormones interact with brain neurotransmitters (e.g., the serotonergic and noradrenergic systems; Altshuler et al. 2001). Nonetheless, the association between the thyroid axis and anxiety is not well understood.

Anxiety also has been reported to be a symptom of hypothyroidism (Hall and Hall 1999; Sait Gönen et al. 2004). Its association may be better explained by the association between depression and hypothyroidism, in which anxiety is conceptualized as a symptom of depression as opposed to a direct biological result of a hypothyroid state.

Pulmonary Disease

Patients with pulmonary disease often experience symptoms of anxiety. Rates of anxiety disorders among individuals with asthma and chronic obstructive pulmonary disease are higher than among the general population (e.g., Goodwin and Pine 2002; Goodwin et al. 2003; Hasler et al. 2005; Rockhill et al. 2007). The psychological stress and un-

certainty of living with asthma certainly make important contributions to this association. In addition, it is essential to consider physiological factors intrinsic to asthma. For example, both hypercapnia and hyperventilation may lead to symptoms of a panic attack; in one model, hypercapnia may lead to increased locus coeruleus activity, which could cause panic and hyperventilation (Zaubler and Katon 1998). Furthermore, carbon dioxide inhalation has been shown to precipitate panic attacks among individuals with panic disorder. Asthma also may be associated with panic attacks through a process of classical conditioning. In this paradigm, because a severe asthma attack is so terrifying, a future sensation of mild dyspnea might precipitate a full-blown panic episode (Carr 1998). In addition, anxiety may worsen asthma, thereby contributing to a vicious circle in which pulmonary and anxiety symptoms exacerbate each other (Carr 1998; Deshmukh et al. 2008). Several asthma medications may cause anxiety (see Table 11-2). Pulmonary emboli also may lead to symptoms of anxiety (Tapson 2007); this diagnosis is more easily missed when the emboli are small (see also Chapter 19, "Lung Disease").

Parkinson's Disease

Anxiety is often seen in individuals with Parkinson's disease (Richard 2005; Walsh and Bennett 2001). Most studies of the prevalence of anxiety disorders among patients with Parkinson's disease involve small samples, but they indicate that these disorders are much more common among Parkinson's disease patients than in the general population (Richard 2005). Anxiety often appears after the manifestations of symptoms of Parkinson's disease. For example, some individuals may develop social anxiety disorder symptoms because they are embarrassed about manifestations of the Parkinson's disease (e.g., tremor) (American Psychiatric Association 2000). Anxiety also may be due to the uncertainty associated with Parkinson's disease, with respect to both day-to-day functioning and long-term prognosis. Anxiety in some patients may be worse during "off" periods compared with "on" periods, but in others, anxiety symptoms do not correlate with motor fluctuations (Richard 2005; Richard et al. 2004). Depression and anxiety symptoms often coexist among individuals with Parkinson's disease (Richard 2005).

The neurobiology of anxiety in Parkinson's disease has not been clearly delineated, but limited evidence supports the roles of neurotransmitter abnormalities, particularly in central noradrenergic systems (Richard 2005). The dopaminergic neural circuits implicated in Parkinson's disease have intimate connections with systems involved with anxiety (e.g., serotonin). Anxiety also may be due to medications used to treat Parkinson's disease, such as L-dopa (see Table 11-2). Deep brain stimulation of the

subthalamic nucleus was shown to reduce anxiety in one recent study (Witt et al. 2008).

Poststroke Anxiety

Although poststroke depression has been more widely described, many individuals also have anxiety after a stroke (Angelelli et al. 2004; De Wit et al. 2008). It may appear alone or comorbid with depression (Barker-Collo 2007; Kimura et al. 2003; Wise and Rundell 1999). When they appear after a stroke, anxiety symptoms have been shown to persist in many individuals. For example, in one large study, 40% of the patients with initial anxiety remained anxious at 6 months (De Wit et al. 2008). Stroke also has been reported to result in PTSD (Bruggimann et al. 2006). Limited literature has found anxiety to be associated with right-hemisphere lesions, whereas depression and mixed depression and anxiety are more commonly associated with left-hemisphere lesions (Aström 1996; Castillo et al. 1993).

Seizures

Anxiety symptoms may be caused by seizures. For example, complex partial seizures may be accompanied by symptoms of panic disorder, including fear, depersonalization, derealization, dizziness, and paresthesias (Kim et al. 2007; S.A. Thompson et al. 2000). One group used ambulatory electroencephalographic monitoring with sphenoidal electrodes to study patients with atypical panic attacks (i.e., panic attacks with concomitant neurological symptoms such as change in level of consciousness, aphasia, and focal paresthesias). Focal paroxysmal electroencephalographic changes were found in 5 of 11 patients who had panic attacks during monitoring (Weilburg et al. 1995).

For further discussion of neurophysiological and neuroanatomical aspects of anxiety disorders, the reader is referred to Chapter 32, "Neurology and Neurosurgery," and D.J. Stein and Hugo (2002).

Other Conditions

In addition to the disorders discussed earlier, anxiety has reportedly been caused by many other medical conditions. For example, anxiety may be associated with hypocalcemia and hypomagnesemia. Relatively rare conditions for which there are only limited data supporting a causal relation include carcinoid syndrome, hyperparathyroidism, and pheochromocytoma (Colon and Popkin 2002). In the absence of other findings suggestive of one of these rare disorders, it is not advisable to screen for them (e.g., serotonin metabolites to rule out carcinoid, parathyroid hormone levels to rule out hyperparathyroidism, or catecholamine metabolites to rule out pheochromocytoma).

Treatment of Anxiety in the Medically Ill

Treatment of anxiety disorders has been shown to be safe and effective. Treatment of anxiety associated with medical illness can also improve physical symptoms, decrease disability, lower high rates of frequent medical use, and improve quality of life (Roy-Byrne et al. 2008). Most people with anxiety disorders seek care from their primary care physicians, complaining of the physical symptoms of anxiety such as pain, insomnia, or gastrointestinal symptoms, and often not recognizing the underlying emotional disorder. In a study of three academic primary care outpatient clinics (M.B. Stein et al. 2004), fewer than one-third of identified patients with anxiety disorders received adequate treatment with psychotherapy or medication. Collaboration between psychiatrists and primary care providers is important to ensure effective treatment. Several current models of collaborative care and stepped care interventions in primary care treatment of anxiety and depression show cost-effective outcomes and improved patient satisfaction (Katon et al. 2002; G.E. Simon et al. 2004; Veer-Tazelaar et al. 2009).

Psychotherapy

An overemphasis on psychopharmacology in the care of medically ill patients sometimes results in overlooking the value of psychotherapy. The first step in treatment is to spend time listening to and talking with the patient. Just as in psychotherapy with any patient, empathic listening is a powerful tool to relieve distress. With medically ill patients, the goal is to help patients understand and discuss their emotional reactions to their illness so that they can then manage these feelings by using their own coping mechanisms. Psychotherapeutic approaches include supportive, cognitive-behavioral, and psychodynamic therapies.

Supportive Therapy

Supportive therapy involves listening and providing reassurance, sympathy, education about the medical process and the underlying illness, advice, and suggestions. The process includes listening for fears and misperceptions about illness or its treatment and giving patients appropriate information so that they can be as prepared as possible (House and Stark 2002). Effective communication, using language the patient and family can understand, can lead to a great decrease in anxiety. It is also helpful to give patients as much choice in their treatment decisions as possible so that they feel they have some control over the course of their treatment.

Reassurance is an important skill that all physicians use in treating patients. In some highly anxious patients, however, simple reassurance can actually cause increased anxiety and lead to a cycle of maladaptive behavior. For example, if a patient who has been told that a procedure is simple or painless subsequently experiences pain or untoward results, the resulting anxiety can lead to more reassurance-seeking behavior, mistrust, and decreased cooperation. Many anxious patients tend to interpret bodily symptoms as evidence of serious disease, and as a result, they may seek multiple consultations for reassurance. Understanding the patient's beliefs, concerns, and perceptions can be helpful in challenging misperceptions, educating the patient about his or her illness, and devising a realistic plan to monitor symptoms. Having a realistic plan to help patients differentiate minor symptoms from those that may need medical attention will reduce anxiety and decrease the excessive need for reassurance (Stark and House 2000). It is also important that the physician not assume that a patient's anxiety is due to fear of dying. When reassurance is directed at the wrong fear, it may accentuate anxiety and lead patients to believe that their physician does not understand them.

The consultant can serve as a liaison between the patient and the health care team. For example, the psychiatrist might help the primary physician understand the importance of clarifying the risks and benefits of treatment and of informing the anxious patient when delays in scheduling arise. It also may be helpful for the treatment team to consult directly with the psychiatrist about how to care for the anxious patient. Facilitating communication among the patient and members of the treatment team can help avoid misperceptions or mistrust that will only serve to heighten anxiety.

Another important aspect of supportive therapy is the involvement of the patient's support system of family, friends, and spiritual/religious community. Some patients may need assistance in expanding their support network (e.g., to reach out to friends with whom they may have lost contact). Some family members may need supportive psychotherapy to reduce their anxieties about the patient's medical condition. Hospital staff such as nurses and chaplains can be instrumental in reducing patient's fears.

Patients confronting life-threatening or terminal illnesses such as cancer may experience death anxiety (Yalom 1980). Open discussions with patients about death help to reduce anxiety and distress (Spiegel et al. 1981), and psychological interventions alone can help patients manage their death anxiety (Payne and Massie 2000). Maintaining hope is an important aspect of minimizing anxiety, although goals can change from full recovery to having more time to accomplish specific short-term goals. Help-

ing patients find meaning and value in their lives, despite their illness and suffering, helps to relieve emotional distress (Frankl 1987). For example, anxiety can be reduced when patients see that they are still important to their families or that they still have unfinished business to address. Dignity-oriented therapy has extended this approach to the care of terminally ill patients (G.N. Thompson and Chochinov 2008). The hospice movement has been instrumental in helping provide relief for many patients (Byock 1997). Despite recent improvements in physician education, some caregivers need more training to be able to overcome their own death anxiety so that they can provide comfort to end-of-life patients (Adelbratt and Strang 2000) (see Chapter 41, "Palliative Care").

Supportive group interventions have been shown to be effective in reducing anxiety and distress in medically ill patients, and support groups for HIV, cancer, cardiac, and other medical illnesses have proliferated in recent years (Wallis 2004). They can be quite helpful in providing emotional support, improving coping skills, and providing information about health promotion and wellness (Sherman et al. 2007).

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy has been proven to be as effective as medication in treating many anxiety disorders, including GAD, PTSD, and panic disorder ("Generalized anxiety disorder: toxic worry" 2003; Stanley et al. 2009). Cognitive techniques are used to uncover and correct misinterpretations and irrational thoughts that lead to increased anxiety and distress. Behavioral techniques, such as systematic desensitization, can be used to help overcome fears that can interfere with effective treatment, such as claustrophobia during MRI (Goldberg and Posner 2000). A brief course of cognitive-behavioral therapy can have long-lasting effects, but occasional "booster" sessions may be needed.

A variety of therapies that involve teaching self-awareness and self-regulation of body functions have been found effective in reducing anxiety and physical symptoms in medically ill patients. These include muscle relaxation techniques (such as Jacobson's progressive muscle relaxation), autogenic training (such as biofeedback, which uses technology to control internal processes), and relaxation techniques (such as meditation, breathing exercises, and self-hypnosis). Stress management interventions may improve quality of life (e.g., by decreasing anxiety in the course of medical treatments; Antoni et al. 2006). Relaxation techniques may help to wean patients from the ventilator as well as to reduce dyspnea and anxiety in patients with chronic obstructive pulmonary disease (Smoller et al. 1999). A review of studies that have examined efficacy of

meditation and relaxation techniques indicates that they are safe and may have some benefit in reducing anxiety in medically ill patients (Arias et al. 2006).

Psychodynamic Therapy

For patients who are not too ill and who have sufficient emotional resilience, brief dynamic psychotherapy can be useful in uncovering the conscious and unconscious meaning of the illness to the patient. Understanding patients' developmental history, interpersonal dynamics, and defense mechanisms can help the psychiatrist to assist them in finding healthier ways to cope with medical illness (Viederman 2000). What coping strategies have helped in the past? When did the individual feel most fulfilled in his or her life? How can those memories and skills be used now, even in the presence of significant medical illness? Psychotherapy can uncover areas leading to increased distress, such as real or imagined guilt, unhealthy coping strategies such as avoidance and denial, and recognition of past conflicted relationships that may be repeated in the current doctor-patient relationship. An understanding of the patient's underlying dynamics can help identify and resolve conflicts with the treatment team that may be interfering with recovery. An understanding of psychodynamic principles can also help psychiatrists in working with the primary treatment team that is caring for the anxious patient.

Countertransference reactions can cause problems for providers of anxious patients. For example, physicians may overidentify with their patients, leading to frustration because of lack of progress or poor prognosis. As a result, they may then overcompensate by offering excessive reassurance, or they may minimize or overlook symptoms in an unconscious attempt to reduce their own anxiety. Caregivers also may become withdrawn and distant, providing care mechanically with little empathy or awareness of the emotional needs of the patient. Psychiatrists can play a role in helping the health care team to be cognizant of these defenses so that they do not interfere with the provision of optimal patient care. (See Chapter 39, "Psychotherapy," for further discussion of psychotherapy for the medically ill.)

Pharmacotherapy

Psychotherapeutic techniques are often not sufficient to manage anxiety in the medically ill. An increasingly broad range of psychopharmacological agents can be used safely with this population. (For further details, see Chapter 38, "Psychopharmacology," as well as specific discussions in Chapters 18–37 of Part III, "Specialties and Subspecialties.")

Benzodiazepines and Hypnotics

For acute anxiety symptoms, the most immediately effective and frequently used agents are the benzodiazepines

(Table 11–3). Diazepam and chlordiazepoxide were among the first of these to be used. They also have established efficacy for other conditions—diazepam as an anticonvulsant and muscle relaxant and chlordiazepoxide for alcohol detoxification. Newer benzodiazepines have better safety profiles and shorter half-lives, so they tend to be used more frequently.

Alprazolam works rapidly and is eliminated quickly, but as a result there may be rebound anxiety and withdrawal symptoms. Because lorazepam can be given orally, intravenously, or intramuscularly and does not have an active metabolite, it is often a preferred medication in hospitalized patients. Lorazepam can be given in an intravenous bolus or drip, but as doses increase to provide sedation and treat delirium tremens, respiratory status must be watched closely. Lorazepam and oxazepam are metabolized through conjugation, and temazepam is metabolized almost exclusively through conjugation (Trevor and Way 2007). As a result, those benzodiazepines may be less problematic in patients with liver disease than are the other benzodiazepines, which are oxidatively metabolized (Crone et al. 2006). Midazolam, a benzodiazepine with a very short half-life that can only be given intravenously or intramuscularly, is used for short-term procedures such as bone marrow biopsies, endoscopies, and MRI scans in claustrophobic patients. For patients who need long-term benzodiazepines, it is often helpful to change to a medication with a longer half-life, such as clonazepam.

All benzodiazepines can cause excessive sedation. They may also cause motor and cognitive disturbances, especially in older persons and individuals with impaired brain functioning (e.g., due to dementia, head injury, or mental retardation). Therefore, they should be used with caution, if at all, in these patients. Anxiety in delirious patients is usually better treated with antipsychotics than with benzodiazepines (Breitbart et al. 1996). Benzodiazepines can cause respiratory suppression, so they should be used cautiously in persons with pulmonary disease who retain carbon dioxide, or in patients with sleep apnea. Because of potential teratogenicity, benzodiazepines should be avoided in the first trimester of pregnancy. They should also be avoided at the very end of pregnancy because there are reports of sedation and withdrawal symptoms in the fetus (McGee and Pies 2002). All benzodiazepines can lead to tolerance and dependence, so they should be avoided or used judiciously (i.e., for detoxification) in persons with a substance abuse history. However, compared with barbiturates and earlier sedative-hypnotics such as meprobamate, they are much safer in overdose and have fewer side effects. In persons who are conscientious and do not have a history of chemical dependence, benzodiazepines often can be used safely for years without causing problems or tolerance. As an individual

TABLE 11-3. Selected benzodiazepines used for anxiety in the medically ill

Medication	Route of administration	Dosage	Elimination half-life (hours)	Comments
Alprazolam	Oral	0.25–1.0 mg tid	9–20	Rapid onset. Interdose withdrawal a problem, but new extended-release form is available.
Chlordiazepoxide	Oral, intramuscular	5–25 mg qid	28–100 (including metabolites)	Useful for alcohol withdrawal.
Clonazepam	Oral	0.25–1 mg bid–tid	19–60	Also used for absence seizures, periodic leg movements, and neuropathic pain.
Diazepam	Oral, intravenous	2–10 mg qid	30–200 (including metabolites)	Also used as an anticonvulsant and muscle relaxant.
Lorazepam	Oral, intramuscular, intravenous	0.5–2.0 mg up to qid	8–24	Intravenous availability is an advantage. Metabolized by conjugation. Also approved for chemotherapy-related nausea and vomiting.
Midazolam	Intramuscular, intravenous	Intramuscular: 5 mg single dose Intravenous: 0.02–0.10 mg/kg/h	1–20 (including metabolites)	Used for preoperative sedation and intravenous induction.
Oxazepam	Oral	10–30 mg qid	3–25	Metabolized by conjugation. May also be useful for alcohol withdrawal.

Note. bid = twice a day; qid = four times a day; tid = three times a day.

ages, use should be reevaluated. Similarly, long-term benzodiazepine use may need to be reduced or discontinued among patients who develop specific medical conditions (e.g., end-stage liver disease, dementia, chronic obstructive pulmonary disease, and cerebellar dysfunction).

Hypnotics are commonly used in medically ill patients who are kept awake by their anxiety. Newer agents such as zolpidem, zaleplon, and eszopiclone are nonbenzodiazepines that act on the benzodiazepine receptor. They are preferred for short-term use because they have very short half-lives and generally cause less daytime sedation, impaired coordination, and cognitive disturbance than do the benzodiazepines. Ramelteon is a melatonin receptor agonist that is thought to act on the suprachiasmatic nucleus to help with sleep induction (Roth and Culpepper 2008). Generally all of the hypnotics are best used for short intervals to decrease the chance of side effects, to maintain effectiveness (i.e., prevent tolerance), and to prevent dependence (National Institutes of Health 2005).

Antidepressants

The pharmacological treatment of choice for GAD, panic disorder, PTSD, OCD, and social anxiety disorder is a medication that can increase serotonin, such as the selective serotonin reuptake inhibitors (SSRIs): fluoxetine, sertraline, paroxetine, citalopram, escitalopram, and fluvoxamine. All antidepressants now have a black-box warning to monitor for increased suicidality, especially in children through young adults. These medications have few side effects and therefore are generally quite safe for the medically ill; they do not result in cardiac conduction problems, orthostatic hypotension, or physical dependence. Because antidepressants may take 2–6 weeks to relieve anxiety, the patient may need initial treatment with benzodiazepines. Once the patient has been stabilized on the antidepressant medication, the benzodiazepines usually can be gradually withdrawn without recurrence of anxiety. The antidepressant should be used for at least 3–6 months before stopping it, and it should be tapered to avoid discontinuation symptoms.

Antidepressants can be used safely on a long-term basis if anxiety returns.

One of the main side effects of the SSRIs is a relatively high incidence of sexual dysfunction in both men and women. This side effect may be particularly problematic for persons with medical problems already associated with sexual dysfunction, such as diabetes or vascular disease (see Chapter 16, "Sexual Dysfunction"). In addition, psychiatrists must be concerned about the potential for drug interactions—for example, with fluoxetine and paroxetine (cytochrome P450 2D6 inhibitors) and fluvoxamine (a cytochrome P450 3A4 inhibitor; see Chapter 38, "Psychopharmacology"). Serotonin reuptake inhibitors may cause initial gastrointestinal distress and nausea, so they are generally given with food. It is important to reassure the patient with gastrointestinal disease that these side effects are almost always transient. SSRIs are also associated with the syndrome of inappropriate secretion of antidiuretic hormone, especially in older patients. Caution is advised when using serotonin medications with the antibiotic linezolid because of the potential for hypertensive crisis and serotonin syndrome, although they are thought to occur rarely (Sola et al. 2006). SSRIs may help decrease frequency of migraine headaches, but they can also exacerbate headaches. Caution is advised in using triptans with SSRIs because of the potential for serotonin syndrome. It has been reported that SSRIs can exacerbate parkinsonism in individuals with Parkinson's disease; however, this appears to be an uncommon side effect (Dell'Agnello et al. 2001; Hedenmalm et al. 2006). Because all SSRIs are equally efficacious, medication choice is often based on side-effect profile. For example, the more sedating SSRIs (e.g., fluvoxamine and paroxetine) may be advantageous for the highly anxious patient with insomnia, whereas fluoxetine may be more stimulating. For medically ill patients taking multiple medications, agents with the fewest drug interactions are preferred: sertraline, citalopram, and escitalopram.

Serotonin–norepinephrine reuptake inhibitors (SNRIs), including venlafaxine, duloxetine, and desvenlafaxine, also may be useful for anxiety (Katzman 2009). Venlafaxine and duloxetine have been approved for treatment of some anxiety disorders and, based on their mechanism of action, are probably effective agents for treating all anxiety disorders. Blood pressure should be monitored when these drugs are being initiated and with each dosage increase. If diastolic blood pressure increases, the dosage should be reduced or the drug stopped. These medications also can cause sexual dysfunction and should be given with food to decrease gastrointestinal side effects.

Mirtazapine—an alpha-adrenergic receptor antagonist and an antagonist at serotonin 5-HT_{2A}, 5-HT_{2C}, and 5-HT₃ receptors—may be helpful in reducing anxiety. Its use in

medically ill patients has increased recently for two reasons: 1) it has few drug interactions, and 2) the side effects of sedation and increased appetite may be helpful in patients who have insomnia and anorexia with weight loss (Cankurtaran et al. 2008). Trazodone is a weak antidepressant; it is most commonly used as a hypnotic because of its sedative properties and lack of tolerance or dependence. In some cases, it has been used for anxiety and agitation in patients, mainly because of its sedative properties.

Tricyclic antidepressants and monoamine oxidase inhibitors are well established as effective treatments for anxiety disorders and for depression. Tricyclics can be efficacious for the treatment of anxiety in the medically ill (e.g., in patients with chronic pain or diarrhea-predominant irritable bowel syndrome). The main reasons these medications are currently not used frequently as first-line treatment are their numerous side effects and their toxicity in overdose. Tricyclics often cause dry mouth, weight gain, constipation, sedation, orthostatic hypotension, urinary retention, and falls, especially in elderly patients. In addition, because of their quinidine-like effects, they can cause heart block and arrhythmias. Because the margin of safety between efficacy and toxicity is relatively small, overdose can be dangerous and even fatal. Persons with liver and kidney disease may develop toxicity as a result of impaired metabolism and excretion. Monoamine oxidase inhibitors can cause dizziness, orthostatic hypotension, and weight gain. These side effects, as well as the potential for serious hypertensive crises, limit their usefulness in medically ill patients. Selegiline recently has been introduced as a transdermal patch, which offers the advantage of fewer food restrictions than with oral monoamine oxidase inhibitors at the lower dose. However, the risks of hypertensive crisis with many medications remain, so it probably will not be used widely in medically ill persons.

Antipsychotics

Antipsychotic medications are not approved for the treatment of anxiety, although limited data support their efficacy (Gao et al. 2006). Psychosomatic medicine psychiatrists often find them to be efficacious and safe to use in selected medical populations. Long-term use may lead to adverse side effects such as metabolic syndrome. Because antipsychotics do not cause confusion or respiratory compromise, they may be preferable to benzodiazepines for the more severe anxiety associated with agitation or delirium or in patients with respiratory compromise. For example, antipsychotics may be helpful in assisting the anxious patient who is being weaned from a ventilator (Rosenthal et al. 2007). The antipsychotic agent used most often in medically ill patients is haloperidol, which can be given orally, intramuscularly, or intravenously. In acutely agitated pa-

tients who may be violent or psychotic, 5–10 mg of haloperidol is often given orally or intramuscularly, usually in conjunction with a benzodiazepine such as lorazepam, and sometimes with benztropine to prevent a dystonic reaction. For mild agitation, 0.5–2.0 mg might be given, but much higher doses can be used. If a high-potency typical antipsychotic such as haloperidol is used in treating anxiety, it is important to monitor for akathisia because it can be mistaken for worsening anxiety.

Newer atypical antipsychotics such as olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole are also used selectively in the management of anxiety, especially in lower doses. Ziprasidone, olanzapine, and aripiprazole are now available in intramuscular formulation. The intramuscular formulations may be helpful in those with severe anxiety or agitation, especially if they are unable to take oral medications. Olanzapine, risperidone, and aripiprazole are available as orally disintegrating tablets, which may be useful for patients who cannot swallow pills. Current data suggest that ziprasidone and aripiprazole may have less propensity to cause weight gain and metabolic syndrome than do the other atypical antipsychotics.

Buspirone

Buspirone is a partial serotonin agonist that may be effective in the treatment of anxiety (Lee et al. 2005). It may be useful in treating anxiety in medically ill patients because it has few drug interactions and does not cause respiratory depression. It can be used safely in substance abusers because it does not cause dependence, and its metabolism is not greatly affected by liver disease (Stahl 2004). The main drawbacks with buspirone are that it may take 2–4 weeks to become effective, and its benefits seem modest. Because of its short half-life, it needs to be given two to three times a day. Some patients complain of dizziness and excessive sedation when first beginning the medication, but it is usually well tolerated.

Beta-Blockers

Beta-adrenergic blockers produce anxiolytic effects by blocking autonomic hyperarousal (elevated pulse, elevated blood pressure, sweating, tremors) associated with anxiety responses. They work best for specific anxiety-producing situations, such as performance anxiety and public speaking, and are less efficacious for panic disorder and social phobias. All beta-blockers are contraindicated in persons with asthma or chronic obstructive lung disease, and they can worsen peripheral vascular disease (Barnes 2005). Patients with type 1 diabetes should not be prescribed nonselective beta-blockers; those medications block the sympathetic nervous system response to hypoglycemia, resulting in lack of

awareness of symptoms (Kaplan 2007). The reported association between beta-blockers and depression has not been supported by data from clinical trials (Ko et al. 2002).

Antihistamines

Sedating histamine H₁ receptor blockers are sometimes used to treat anxiety and insomnia. Hydroxyzine has been shown to be as effective and safe as benzodiazepines in treating anxiety (Llorca et al. 2002) in a general study population. Diphenhydramine, which is often used to treat insomnia, is available in over-the-counter preparations. Because these medications are not addicting, many physicians consider them to be benign. However, they can cause dizziness, excessive sedation, incoordination, and confusion, especially when used with alcohol or other central nervous system depressants. Elderly patients and those with brain disease or injury are more sensitive to these medications and may become delirious even with low doses. Despite these risks, these medications are still an option when benzodiazepines must be avoided because of concerns about dependence or respiratory depression.

Anticonvulsants

Anticonvulsants are primarily prescribed by psychiatrists for patients with bipolar disorder who cannot tolerate or do not respond to lithium, but they can also be helpful for some individuals with anxiety (Mula et al. 2007). Divalproex sodium may be helpful in calming agitated, anxious patients, especially those with brain injury, mental retardation, or dementia. Newer anticonvulsants such as lamotrigine and pregabalin have shown some promise in treating mood and anxiety symptoms and may prove to have some role in treating anxiety in medically ill patients.

Conclusion

The experience of medical illness often leads to clinically significant anxiety symptoms. Although many individuals with medical illnesses have anxiety disorders, these disorders are often underrecognized and undertreated. Both psychotherapy and pharmacotherapy can significantly ameliorate anxiety symptoms, even among patients with severe medical problems. Thus, careful assessment and treatment of anxiety disorders are important components of the psychiatric care of the medically ill.

Somatization and Somatoform Disorders

Susan E. Abbey, M.D., F.R.C.P.C.

Lawson Wulsin, M.D.

James L. Levenson, M.D.

SOMATIZATION IS A POORLY understood “blind spot” of medicine (Quill 1985). Somatoform disorders remain neglected by psychiatrists and primary care clinicians despite their associated significant functional impairments and economic burden (Bass et al. 2001). Important conceptual and clinical questions exist about the validity and utility of the concepts, particularly in primary care settings, where they appear most commonly, and new paradigms might lead to more effective management (Epstein et al. 1999; Mayou et al. 2003; Sharpe and Carson 2001). Recent proposals for major revisions in the definitions of somatoform disorders are likely to guide these new paradigms (Dimsdale and Creed 2009; Fink et al. 2005; Kroenke et al. 2007; Oken 2007).

Somatization and somatoform disorders challenge consulting psychiatrists, who often wade into emotionally charged clinical situations in which diagnosis is difficult, both the referring physician and the patient are frustrated and angry, and the involvement of a psychiatrist may be stigmatizing. The complex set of emotions that patients with somatoform disorders engender has resulted in the application of disparaging names both to these patients (e.g., “crocks”) (Lipsitt 1970) and to the discipline (e.g., “psychoceramic medicine”). The DSM diagnostic terms themselves may offend patients and are often not used (Stone et al. 2002b). The evidence base for diagnosing and treating these patients remains suboptimal, but there is a strong clinical literature that can help psychiatrists to work effectively with these patients, produce substantial im-

provements in the patients’ and their families’ well-being, and decrease direct and indirect costs of their illness. The medical training of psychosomatic medicine psychiatrists facilitates management of difficult cases, such as patients who somatize or have a somatoform disorder and have a concurrent general medical condition with overlapping symptoms.

We begin this chapter with a discussion of the process of somatization, followed by a review of the DSM-IV-TR (American Psychiatric Association 2000) somatoform disorders. The sections for each disorder include diagnostic dilemmas to be addressed in DSM-V and key treatment approaches for that disorder. The chapter concludes with principles of management and treatment. Our focus in this chapter is on adults; somatization and somatoform disorders in children are discussed in Chapter 34, “Pediatrics,” and in several reviews (Garraalda 1999; Silber and Pao 2003). Conversion disorder is also discussed in Chapter 32, “Neurology and Neurosurgery.”

Somatization as a Process

Somatization can be conceptualized in a variety of different ways, but fundamentally it appears to be a way of responding to stress. It is a ubiquitous human phenomenon that at times becomes problematic and warrants clinical attention. Somatization is extremely common in medical settings and among the patients referred to psychosomatic medicine psychiatrists. Not all somatizing patients have a

somatoform disorder. Many have another Axis I disorder or transiently somatize in the context of significant life stress.

Definitions and Clinically Useful Theoretical Concepts

The area of somatization is complicated by a lack of uniformity in the use of terminology. Theoretical concepts that are clinically useful in management are described below.

Somatization as a Dimension of Distress

Historically, *somatization* was defined by Steckel as a deep-seated neurosis that produced bodily symptoms (Lipowski 1988). In the past 20 years, the term *somatization* has been used to describe the tendency of certain patients to experience and communicate psychological and interpersonal problems in the form of somatic distress and medically unexplained symptoms for which they seek medical help (Katon et al. 1984; Kleinman 1986; Lipowski 1988). Although it has become a widely used term, Sharpe (2002) cautioned that its use should be restricted to cases in which the somatic symptoms are an expression of an identifiable emotional disorder. In essence, somatization is a culturally sanctioned idiom of psychosocial distress (Katon et al. 1984; Kleinman 1986). Kirmayer and Young (1998) noted that depending on circumstances, somatization “can be seen as an index of disease or disorder, an indication of psychopathology, a symbolic condensation of intrapsychic conflict, a culturally coded expression of distress, a medium for expressing social discontent, and a mechanism through which patients attempt to reposition themselves within their local worlds” (p. 420).

Because severity of somatic symptoms, when related to either psychiatric or medical illness, is associated with increasing functional impairment, disability days, and use of health care services (Kroenke et al. 2002), some experts have proposed considering somatization as a dimension in all illnesses and measuring somatic symptom number and severity, regardless of whether the symptom can be medically explained.

Three components of somatization described by Lipowski (1988) can offer targets for intervention: experiential, cognitive, and behavioral (Table 12-1).

Medically Unexplained Symptoms

Somatization is frequently implicated in medically unexplained symptoms (MUS), defined as symptoms that are not attributable to or are out of proportion to identifiable physical disease (Sharpe 2002). Medically unexplained symptoms are discussed in other chapters in this volume, including noncardiac chest pain (see Chapter 18, “Heart Disease”), hyperventilation syndrome (see Chapter 19,

“Lung Disease”), irritable bowel and functional upper gastrointestinal tract disorders (see Chapter 20, “Gastrointestinal Disorders”), chronic fatigue syndrome and fibromyalgia (see Chapter 26, “Chronic Fatigue and Fibromyalgia Syndromes”), idiopathic pruritus (see Chapter 29, “Dermatology”), chronic pelvic pain and vulvodynia (see Chapter 33, “Obstetrics and Gynecology”), pain syndromes (see Chapter 36, “Pain”), and multiple chemical sensitivity (see Chapter 37, “Medical Toxicology”).

Clinicians and cultures vary widely in how they explain symptoms (i.e., causes) and what they consider a sufficient medical explanation for a symptom. Recent proposals to discard “medically unexplained symptoms” as a diagnostic criterion note the following disadvantages: 1) it is not clear what counts as a medical explanation, 2) it is a negative explanation that can feel dismissive to patients, 3) MUS foster mind-body dualism, 4) the concept is difficult to operationalize into reliable measures, and 5) the evidence for causality is often sketchy (Dimsdale and Creed 2009).

Somatosensory Amplification

Symptoms are the result of bodily sensations and their subsequent cortical interpretation. *Somatosensory amplification* refers to the tendency to experience somatic sensations as intense, noxious, or disturbing (Barsky et al. 1988b). It is composed of three elements: 1) hypervigilance to bodily sensations, 2) predisposition to select out and concentrate on weak or infrequent bodily sensations, and 3) reaction to sensations with cognitions and affect that intensify them and make them more alarming (Duddu et al. 2006; Nakao and Barsky 2007). It has both trait and state components.

Illness Versus Disease

The distinction between illness and disease (Eisenberg 1977) is useful for psychosomatic medicine psychiatrists. *Illness* is the response of the individual and his or her family to symptoms; this contrasts with *disease*, which is defined by physicians and is associated with pathophysiological processes and documentable lesions. Mismatches between illness and disease are common and are at the root of many management problems. Hypertensive patients may not perceive themselves as ill and therefore might not comply with treatment regimens. Patients with somatoform disorders view themselves as very ill despite not having a disease. In somatizing patients with some disease component, their subjective illness experience is assessed to be disproportionate to the degree of disease.

Illness Behavior and Abnormal Illness Behavior

Illness behavior refers to “the manner in which individuals monitor their bodies, define and interpret their symptoms,

TABLE 12-1. Clinical implications of the components of somatization

Component	Potential intervention
Experiential	Techniques to decrease somatic sensations (e.g., biofeedback, pharmacotherapy for concomitant psychiatric disorder)
Cognitive	Reattribution of sensation from sinister to benign cause Distraction techniques
Behavioral	Operant techniques to reduce medication consumption Contract to “save” symptoms for regular visit with primary care physician rather than visiting emergency room

take remedial action, and utilize sources of help as well as the more formal health care system. It also is concerned with how people monitor and respond to symptoms and symptom change over the course of an illness and how this affects behavior, remedial actions taken, and response to treatment” (Mechanic 1986, p. 1). Illness behavior may be regarded as a syndrome, as a symptom, as a dimension, or as an explanation of behavior (Mayou 1989). Illness behavior is affected by a wide variety of social, psychiatric, and cultural factors and can be used “to achieve a variety of social and personal objectives having little to do with biological systems of the pathogenesis of disease” (Mechanic 1986, p. 3).

Abnormal illness behavior is identified by a physician when there is an “inappropriate or maladaptive mode of perceiving, evaluating or acting in relation to one’s own health status, which persists despite the fact that a doctor (or other appropriate social agent) has offered an accurate and reasonably lucid explanation of the nature of the illness and the appropriate course of management to be followed, based on a thorough examination of all parameters of functioning, and taking into account the individual’s age, educational and sociocultural background” (Pilowsky 1987, p. 89). The behavior may be somatically or psychologically focused and may be either illness affirming or illness denying. The construct has been criticized as dangerous in that it places physicians in the position of defining what is normal and what is abnormal. It has been counterargued that a corresponding physician behavioral pattern of “abnormal treatment behavior” might also be proposed.

Somatization as a Clinical Problem

Somatization becomes clinically significant when it is associated with significant occupational and social dysfunction or with excessive health care use. The relation between acute and persistent forms of somatization is unclear; they may form a continuum or may be discrete conditions. Although individual somatic symptoms are notoriously unstable, clusters of somatic symptoms tend to persist. A literature review concluded that patients with at least three bothersome somatic symptoms typically continue to have

multiple somatoform symptoms at 1 year (86%) and at 5 years (67%) (Rief and Rojas 2007). Somatization and somatoform disorders pose a significant economic burden (Bass et al. 2001). In addition to the higher-than-average inpatient, ambulatory, and physician service costs of care of such patients, there are social costs, including decreased occupational productivity. Many patients with somatization also have severe distress, particularly depression and anxiety. In addition, somatizing patients are at increased risk of iatrogenic disease and injury. For example, in pseudoseizures, the most frequent cause of morbidity and death is the misdiagnosis of epilepsy and resulting aggressive treatment with anticonvulsants (Kanner 2003).

Relation Among Psychiatric Disorders, Somatization, and Medically Unexplained Symptoms

Strong interrelations exist among somatization, psychiatric disorders, and health care utilization. Four models (Figure 12-1) have been advanced to explain these interrelationships (Simon 1991). Different models may apply to different patients.

Somatization as Cause and Consequence of Psychiatric Illness

Physical symptoms are an integral part of most psychiatric disorders, at times triggering their onset, at others complicating their course (Lieb et al. 2007). Somatizing patients may focus on their physical symptoms to the exclusion of psychological symptoms. They may then attribute the psychological symptoms to the distress resulting from the physical symptoms (e.g., “Yes, doctor, I am sad, but you would be too if you couldn’t sleep or eat and had no energy!”). This “masking” of the psychiatric syndrome is important, because major depressive disorder and anxiety disorders are significantly underrecognized in patients presenting with somatic complaints (Kirmayer et al. 1993). Somatization does not appear to be a defense against acknowledging the presence of a psychiatric disorder (Hotopf et al. 2001). On the contrary, more than half of primary care patients with significant somatization ac-

FIGURE 12-1. Four models of the relation between psychiatric symptomatology and psychiatric disorder.

knowledge significant anxiety and/or depression (Lowe et al. 2008). Although depression and anxiety frequently overlap with somatization, they also occur independently (see Figure 12-2). Furthermore, depression and anxiety often amplify the perception and the distress of somatic symptoms in the presence of common chronic illnesses like diabetes, arthritis, and pulmonary disease (Katon et al. 2007). Ironically, the physical symptom burden in depression and anxiety, as measured by the number and severity of physical symptoms, may exceed that in many common chronic illnesses that are relatively asymptomatic or limited to a single bothersome symptom (e.g., hypertension, diabetes, coronary artery disease, arthritis, asthma).

Depression and somatization. Physical symptoms are common in major depressive disorder (Simon et al. 1999; see also Chapter 8, "Depression"). The mechanism by which they are produced is unclear and may be related to 1) psychophysiological concomitants of depression, 2) somatosensory amplification, and 3) a depressive attributional style in which symptoms are perceived as indicating poor health. Primary care patients with depression have higher health care utilization and report more somatic symptoms than do patients without depression (Kroenke 2003). It is estimated that 50% or more of the patients presenting in primary care with major depressive disorder do so with predominantly somatic complaints rather than with cognitive or affective symptoms of depression (Lowe et al. 2008; Simon and Gureje 1999). These somatic presentations of depression have been referred to as *masked depression* or *depressive equivalents*. Somatic symptoms in depression are related to concomitant anxiety, the tendency to amplify somatic distress, and difficulty identifying and communicating emotional distress (Sayar et al. 2003). Comorbidity among depression, somatization, and somatoform disorders is high (G.R. Smith 1992). Consequently, it has been argued that medically unexplained symptoms are a manifestation of an affective-spectrum disorder (Hudson et al. 2003).

Anxiety and somatization. Anxiety disorders (especially panic disorder) are also accompanied by prominent physical symptoms and are frequently mistaken for or associated with somatization in patients presenting in primary care and medical subspecialty settings (Lowe et al. 2008; Sullivan et al. 1993; see also Chapter 11, "Anxiety Disorders"). Somatization and hypochondriacal fears and beliefs are common among patients with panic disorder, particularly those who also have agoraphobia and focus more on seeking an explanation for, than on treatment of, their symptoms (Starcevic et al. 1992). In addition, posttraumatic stress disorder (PTSD) often presents with somatic complaints (Andreski et al. 1998; Moreau and Zisook 2002).

Other Axis I diagnoses. Substance abuse is associated with somatization (Mehrabian 2001) and is reported in subsets of patients with substance abuse. Finally, somatization is also prevalent in patients with schizophrenia and is associated with emotional distress, medication side effects, and expressed emotion within families. One study found that more than a quarter of patients with schizophrenia had five or more unexplained medical symptoms, both at admission and 12 months later (Ritsner 2003). Psychotic somatic symptoms (somatic delusions, hallucinations, and misperceptions) are common in schizophrenia and in somatic delusional disorders such as delusions of parasitosis (see Chapter 29, "Dermatology").

Somatization as an Amplifying Personal Perceptual Style

An amplifying personal perceptual style may be a stable personality trait or a consequence of abnormal neuropsychological information processing (Barsky et al. 1988a). Some somatizing patients show a lowered threshold for reporting physical symptoms (Barsky et al. 1988b; Pennebaker and Watson 1991).

Somatization as a Tendency to Seek Care for Common Symptoms

This model posits that emotional distress prompts people to seek care for common symptoms for which they would not seek care in the absence of emotional distress. It is sup-

ported by research in patients with a variety of medically unexplained symptoms in whom medical help seeking is associated with higher levels of emotional distress rather than physical symptoms (Drossman 1999; McBeth and Silman 2001).

Somatization as a Response to the Incentives of the Health Care System

The health care system tends to reinforce illness behavior and symptom reporting and may produce “iatrogenic somatization” (Henningesen et al. 2007; Simon 1991).

Etiological Factors in Somatization and Somatoform Disorders

Pathophysiological Mechanisms

Understanding and acknowledging the physiological as well as the psychological mechanisms associated with somatization helps both patient and physician to avoid dualistic “mind versus body” thinking—which often devolves into stigmatized notions of “imaginary” versus “real” symptoms—and to develop a therapeutic alliance (Sharpe and Bass 1992). Some of the proposed pathophysiological mechanisms of somatization are summarized in Table 12–2. Occasionally, what appears to be a pattern of somatization is subsequently found to be a medical syndrome or disorder, such as multiple sclerosis, obstructive sleep apnea, or celiac disease; however, rates of misdiagnosis of patients with somatoform disorders have been in the range of 2%–10%—not high, though not negligible (Rief and Rojas 2007; Stone et al. 2005).

Genetic Factors

Somatization and somatization disorder appear to have a genetic component (Guze 1993; Kendler et al. 1995). Adoption studies of Swedish men suggested that the psychiatric processes associated with somatization in men and women may be qualitatively different (Cloninger et al. 1986). There have been no recent studies of genetic factors in somatization disorder, but recent twin studies illustrate complex relationships between genetic factors and the co-occurrence of functional somatic syndromes, anxiety, and depression (Kato et al. 2006, 2009).

Developmental Factors

The cognitive appraisals patients make of somatic symptoms often have some of their roots in early family experiences. Physical symptoms are a major form of interpersonal communication in some families (Stuart and Noyes 1999). Childhood exposure to parental chronic illness or abnormal illness behavior appears to increase the risk of somatization in later life (Bass and Murphy 1995; Craig et

al. 1993; Gilleland et al. 2009). Negative parenting styles are associated with somatization in irritable bowel syndrome patients (Lackner et al. 2004). Children with poor awareness of emotional experiences are more likely to experience impairing, unexplained somatic complaints (Gilleland et al. 2009). Anxious attachment behavior arising from early life experiences may also be the basis for persistent care-seeking behavior that frustrates both health care professionals and family members (Noyes et al. 2003; Stuart and Noyes 1999).

Cognitive Theories

Cognitive distortions and preferential memory bias for disorder-congruent information have been demonstrated in patients with somatoform disorders (Brown et al. 1999; Pauli and Alpers 2002). For a recent review, see Escobar et al. 2007 and Woolfolk et al. 2007.

Personality Characteristics

A variety of psychological traits or personality factors have been linked with somatization, although it is unclear whether they primarily influence symptom production and help-seeking behavior or are a consequence of living with chronic symptoms. Introspectiveness (i.e., the tendency to think about oneself) is associated with increased symptom reporting, greater physical and psychological

distress, and more medical help seeking (Mechanic 1986). Negative affectivity, a construct based on negative mood, poor self-concept, and pessimism, is also considered an important contributor to somatization (De Gucht et al. 2004) and was found to be a prospective predictor of somatization among victims of acute trauma (Elklit and Christiansen 2009).

Psychodynamic Factors

Bodily symptoms have been interpreted as metaphors through which a patient expresses emotional distress or psychic conflict (McDougall 1989). Self psychologists argue that bodily preoccupation develops in response to a fragmented sense of self and can be best understood as an attempt to restore a sense of integration (Rodin 1984). *Alexithymia* refers to impairment in the ability to verbalize affect and elaborate fantasies that results from deficits in the cognitive processing and regulation of emotions (Taylor 2000). It has been implicated as a mechanism of some forms of somatization. Although repressed anger or aggression was thought by classical psychodynamic theorists to be important, Kellner et al. (1985) found no evidence that anger or hostility plays a specific etiological role in somatization and hypochondriasis.

Sexual and Physical Abuse

Sexual and physical abuse, in both childhood and adulthood, has been linked with somatization, medically unexplained symptoms, and somatoform disorders in numerous studies since the late 1980s. The development of insight into the relation of the abuse to subsequent somatization is helpful for some patients and may decrease subsequent health care use (Walling et al. 1994). The mechanisms by which physical and sexual trauma is associated with somatization are poorly understood. Sexual abuse negatively affects "embodiment" (i.e., the experience of the self in and through the body) (Young 1992). Abuse also causes a tendency to dissociate, and dissociation is associated with a tendency to report increased physical symptoms (Salmon et al. 2003). Higher hypnotic susceptibility, a marker of the capacity to self-evoke dissociative experiences, has been found to partially mediate the relationship between abuse and conversion symptoms in patients with conversion disorder (Roelofs et al. 2002).

Sociocultural Factors

Somatization was originally thought to be more common among non-Western cultures, but recent work suggests that somatization is ubiquitous, although prevalence and specific features vary across cultures (Kirmayer and Young 1998). The World Health Organization Cross-National

Study of Mental Disorders in Primary Care found that all sites (14 countries) reported high rates of somatization (Gureje et al. 1997) and correlation of somatic symptoms and emotional distress (Simon et al. 1996). The stigmatization of psychiatric distress may be a powerful factor promoting somatization. "Organic" or physical illnesses are seen as more real and less blameworthy than psychiatric disorders, which are seen as being under voluntary control and are often associated with connotations of malingering and weak moral fiber (Kirmayer and Robbins 1991). Somatization may be the only form of communication permissible for the socially powerless.

Gender

The relation between gender and somatization is complex and poorly understood. Although it has traditionally been believed that women somatize more than men, the literature is problematic (Barsky et al. 2001b). An international study of somatization in primary care found few sex differences (Piccinelli and Simon 1997). A longitudinal study of primary care attendees found that somatizers were more likely to be men (Kirmayer and Robbins 1996), whereas data from the Epidemiologic Catchment Area study found that women report more unexplained symptoms overall (Liu et al. 1997).

Iatrogenesis

The health care insurance and disability systems may foster somatization by providing reinforcement (Ford 1983; Henningsen et al. 2007; Simon 1991). Insurance policies with better coverage and fewer barriers for nonpsychiatric medical care than mental health care also provide incentives to somatize (Ford 1992). Well-intentioned but uninformed actions by physicians may also contribute, through unnecessary diagnostic testing and treatments (and their adverse effects) and reinforcement of the sick role (Page and Wesley 2003).

Assessment and Diagnosis of Somatization

Assessment for somatization or somatoform disorders is often difficult and requires special interviewing skills (Creed and Guthrie 1993; Sharpe et al. 1992).

Building an Alliance With the Patient

Early in the interview, the patient's ambivalence about seeing a psychiatrist must be addressed, as well as what the patient has been told about the consultation process. The specific approach to the examination will vary according to the patient. For very resistant patients, the initial interview is often dominated by gaining sufficient cooperation to allow a more detailed assessment to take place at a later

time. The initial phase of the assessment should focus on the history of physical symptoms. Allowing the patient to report a detailed history of his or her physical symptoms provides reassurance that the symptoms are being taken seriously, which aids immeasurably in later phases of the assessment and treatment process. The psychiatrist's use of empathic comments such as "You have had a terrible time" or "The symptoms sound very difficult" help to build an alliance and may lead the patient to volunteer information (Creed and Guthrie 1993). The question "How has this illness or symptom affected your life?" may go a long way toward answering the question "How has your life affected this illness?" Making interpretive or linking statements that bring together the patient's physical and emotional states may encourage the patient to be more forthcoming with regard to emotional distress and may further the sense of engagement (Creed and Guthrie 1993). However, caution must be exercised because premature or maladroit interpretations can be detrimental to the developing trust between patient and physician. For especially skeptical patients, the psychiatrist can emphasize his or her expertise in helping people develop the skills they need to cope with symptoms, regardless of the "cause."

Collaborating With the Referral Source

Collaboration with the referral source is essential for a clear understanding of the reason for referral and of what the patient has been told about it. Psychiatrists can provide guidance about how to explain the psychiatric referral to the patient to make it more acceptable.

Reviewing the Medical Records

Medical records should be reviewed before the consultation to help the psychiatrist devise an approach to the patient. Familiarity with the history fosters an alliance. The type, number, and frequency of the patient's symptoms, as well as comments about the patient's prior attitude toward symptoms and behavior, should be documented (Creed and Guthrie 1993). The importance of a thorough chart review cannot be overestimated, because the psychosomatic medicine psychiatrist may be the first person to thoroughly review the typically thick chart and thus may be in a better position than any other member of the medical team to reach a diagnosis of either a general medical condition or a psychiatric disorder.

Gathering Collateral Information From Family and Friends

Collateral information can be invaluable to the accurate assessment of current and past functional capacity and current and past psychosocial stressors.

Performing a Psychiatric and Mental Status Examination

In addition to routine psychiatric observations, the examination of the patient with somatic symptoms should include observations about abnormal illness behavior, symptom amplification, and the quality of the patient's description of his or her symptoms. It is essential to evaluate the individual's ideas about the meaning, cause, implications, and significance of his or her symptoms and the individual's emotional response to his or her situation (Barsky 1998; Creed and Guthrie 1993; Sharpe et al. 1992). If it is performed after taking a history of the physical complaints (but not before), a mental status examination is usually acceptable to the patient.

Assessing the severity of somatic distress by self-report measures adds clarity and consistency to the assessment process. The 15-item somatic symptom Patient Health Questionnaire (PHQ-15; Kroenke et al. 2002) is perhaps the most useful measure for screening and monitoring somatic symptom severity. It is brief, easy to complete, easy to score, and available through public access. The PHQ-15 assesses the number and severity of symptoms that account for 90% of physical complaints in the outpatient setting (aside from upper respiratory tract symptoms). Patients who reported that three or more somatic symptoms "bothered [me] a lot" during the previous 4 weeks reported significantly more functional impairment, number of sick days, and health care utilization. In a primary care sample of more than 900 men and women in which a cutoff of three or more severe somatic symptoms during the past 4 weeks was used, the PHQ-15 detected somatoform disorders with a sensitivity of 78% and a specificity of 71% (van Ravesteijn et al. 2009). Although not a diagnostic instrument for somatoform disorders, the PHQ-15 is useful as a measure of somatic symptom severity.

Performing a Physical Examination

A physical examination of the patient is a prerequisite for accurate diagnosis and treatment for several reasons. In some cases, elements of the physical examination should be performed by the psychiatrist (see Chapter 1, "Psychiatric Assessment and Consultation"), who may be in the best position to diagnose a general medical condition because "something about the patient (personality, behavior, affect, odd cognition) has effectively distracted the primary physician and other consultants from the diagnosis" (Cassem and Barsky 1991, p. 132). A case vignette follows.

Case Vignette

Ms. P, a 42-year-old woman who had had a renal transplant 2 months earlier, was referred for psychiatric evalu-

ation of "suspected conversion disorder in a patient with history of obsessive-compulsive disorder" after she developed "constant rocking movement that she can voluntarily stop." The psychiatrist found on examination that the patient had an obvious resting rhythmic truncal tremor. The psychiatrist's examination revealed subtle choreiform movements in the patient's tongue and fingers. Noting that metoclopramide had been started at the time of the transplant, the psychiatrist diagnosed a movement disorder, which resolved after drug discontinuation.

The physician who is managing a persistently somatizing patient must also tolerate the patient's perpetual concern about symptoms with some degree of equanimity. A medical education that repeatedly emphasizes the danger of "missed diagnoses" and the current medicolegal climate mean that the physician must be confident that a thorough medical evaluation has been completed.

The physical examination may also help to establish a positive diagnosis of somatization disorder. For example, awareness of physical signs associated with stress (e.g., tender anterior chest wall, tender abdomen, spurious breathing, short breath-holding time) leads to a more confident diagnosis rather than a diagnosis of exclusion, the latter of which always has an implication of doubt associated with it (Sharpe and Bass 1992). A variety of physical signs may be useful, but some are controversial in making a diagnosis of a somatoform disorder (see Fishbain et al. 2003). A somatoform disorder should be diagnosed (as the sole diagnosis) only if the examination also confirms normal functioning of the system being tested (Newman 1993).

Somatoform Disorders

The DSM-IV-TR somatoform disorders are somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified (American Psychiatric Association 2000). The feature they have in common is the presence of unexplained physical symptoms that are not intentionally produced. In DSM-IV-TR, it is emphasized that these disorders are grouped together because of the need to exclude medical and substance-induced etiologies (American Psychiatric Association 2000).

Somatoform disorders are more common in ambulatory than in inpatient settings. They have been diagnosed in 3%–4% of psychiatric consultations in general hospitals in Australia (G.C. Smith et al. 2000) and the Netherlands (Thomassen et al. 2003). In the latter study the somatoform diagnoses were conversion disorder, 40%; hypochondriasis, 24%; somatoform pain disorder, 20%; and somatization disorder, 17%. Studies of the general population

have reported more variable rates. One study of German adolescents and young adults found a lifetime rate for somatoform disorders of 3%; a further 11% of subjects had subsyndromal conditions (Lieb et al. 2000).

There are a number of difficulties in the clinical application of the somatoform diagnoses as defined in DSM. First, excluding a medical cause for symptoms is problematic, particularly for those with comorbid medical diseases. The focus on exclusion promotes dualistic thinking, but failure to demonstrate a medical cause for symptoms does not necessarily mean the patient has a psychiatric disorder (Kirmayer and Young 1998). Second, the question of intentionality or consciousness in symptom production is a vexing one. Distinguishing somatoform disorders from the factitious disorders and malingering is discussed in Chapter 13 ("Deception Syndromes: Factitious Disorders and Malingering"), but these disorders can overlap. Third, dimensional rather than categorical approaches may be more helpful in describing hypochondriacal preoccupation, medically unexplained symptoms, and help seeking. Fourth, the clinical descriptions of specific disorders are largely derived from tertiary care or psychiatric hospital samples and emphasize chronicity. Diagnostic dilemmas specific to each disorder are described below.

Finally, the separate existence of a discrete category of somatoform disorders reinforces the mind-body dualism of Western medicine and implies a separation of affective, anxiety, dissociative, and somatic symptoms (Kirmayer and Young 1998). In fact, somatic symptoms and somatization cut across DSM-IV-TR diagnostic categories. Although somatization is commonly observed in primary care settings, somatoform disorder diagnoses are relatively rarely used by either primary care clinicians or mental health specialists. It may be that the DSM-IV-TR somatoform disorders are too numerous and are too narrowly defined, separated by distinctions for which there is only limited evidence. Some recent critics have suggested extensive reformulation, reclassification, and even abolition of the somatoform disorders (Fink et al. 2005; Kroenke et al. 2007; Oken 2007).

Somatization Disorder

Definition

Somatization disorder is based on the earlier diagnosis of Briquet's syndrome, which required 25 of 59 physical symptoms, an illness onset before age 30 years, and a pattern of recurrent physical complaints and was shown to have validity, reliability, and internal consistency (Feighner et al. 1972). The long-term stability of the diagnosis was documented by the finding that 80%–90% of patients continued to meet diagnostic criteria at 6- to 8-year follow-

up (Guze et al. 1986). DSM-III (American Psychiatric Association 1980) criteria for somatization disorder were a modification of Feighner's criteria, with a total symptom count of 14 symptoms in women and 12 symptoms in men from a total list of 36 physical symptoms. In DSM-III-R (American Psychiatric Association 1987), the criteria were further modified by simplifying the requirement to 13 of 35 physical symptoms and specifically excluding symptoms occurring only during a panic attack. The diagnostic criteria were again simplified in DSM-IV (American Psychiatric Association 1994), and they have been found to be concordant with prior criteria (Yutzy et al. 1995).

Diagnostic Dilemmas

Critics have argued that complexity of the criteria for somatization disorder (i.e., four sets of symptoms across different body sites/functions: four pain, two gastrointestinal, one sexual, and one pseudoneurological) defy memory or reliable application in all but the most rigorous research settings (Creed 2006; Kroenke et al. 2007). Can a simpler definition be devised that captures the more common patterns of somatization and its distress and impaired functioning and thus proves more useful to clinicians? Several less restrictive alternatives have been proposed and are described under "Undifferentiated Somatoform Disorder" later in this chapter.

Epidemiology

The lifetime prevalence of somatization disorder has varied widely across studies, ranging from 0.2% to 2.0% among women and less than 0.2% in men (American Psychiatric Association 2000), reflecting variations in research methodology and study samples. Because patients with somatization disorder actively seek medical help, their prevalence in medical settings is higher than in the general population. Somatization disorder has been diagnosed in 1%–5% of primary care patients (Simon and Gureje 1999). Changes in practice patterns have likely led to fewer somatization disorder patients being admitted to hospitals. Patients with somatization disorder accounted for 0.7% of Dutch psychiatric consultations (Thomassen et al. 2003) and 0.2% of Australian consultations to medical and surgical inpatients (G.C. Smith et al. 2000). Recent work has emphasized the instability of recall of somatic symptoms, with implications for underdiagnosing somatization disorder (Simon and Gureje 1999). By definition, the syndrome must begin before age 30, but most often symptoms begin in the teens, often with menarche, or less commonly in the early 20s. The risk for depression, alcohol abuse, and antisocial personality disorder is increased in the first-degree relatives of individuals with somatization disorder (Golding et al. 1992).

Specific Culture and Gender Factors

There is cultural variability in the presentation of somatization disorder. Symptoms used in DSM-IV-TR are those that have been found to be most diagnostic in the United States (American Psychiatric Association 2000). The disorder is uncommon in American men (Golding et al. 1991), although in an American sample women and men with somatization disorder had similar clinical characteristics, including comorbid psychopathology (Golding et al. 1991). Women with somatization disorder are more likely to have a history of sexual abuse than are women with primary mood disorders (Morrison 1989).

Case Vignette

Ms. L is a 28-year-old woman referred for psychiatric assessment based on 25 primary care visits, 18 emergency room visits, and 2 hospitalizations in the past 12 months for a variety of symptoms, including unexplained headaches, pelvic pain, dysmenorrhea, back pain, nausea, dysphagia, and irregular menses. She has been "sickly" since childhood; is unemployed as a result of her multiple medical problems; and is socially isolated, having had difficulties in interpersonal relationships for many years.

Clinical Features

The classic patient with somatization disorder is a woman who subjectively is "sickly" and who began to experience medically unexplained symptoms in early adolescence. Her condition has shown a waxing and waning course over the years, with a medical history that documents repeated, unexplained physical complaints. Patients with somatization disorder are often difficult historians who provide dramatic and colorful but vague descriptions of their medical history (Cassem and Barsky 1991) and may present as odd or anxious (Rost et al. 1992). There is often more to be learned in a review of their medical records.

Associated features. Patients with somatization disorder have high rates of psychiatric comorbidity. As many as 75% of patients with somatization disorder have comorbid Axis I diagnoses (Katon et al. 1991), of which the most common are major depressive disorder, dysthymia, panic disorder, simple phobia, and substance abuse. Because patients with somatization disorder have a low threshold for endorsing symptoms, in some cases comorbid diagnoses may reflect an amplifying response tendency rather than significant symptomatology. However, many patients do have bona fide comorbid Axis I disorders with significant negative impact on functioning. Personality disorders appear to be especially common in patients with somatization disorder. The most common comorbid Axis II diagnoses in psychiatric settings are Cluster B diagnoses, whereas in primary care settings Cluster C and paranoid personality diagnoses are

more frequent (Rost et al. 1992). The association between personality disorder and somatization disorder may result from a common biological substrate or social-environmental factors such as childhood abuse (G.R. Smith 1991). Patients with somatization disorder often have multiple social problems and chaotic lifestyles characterized by poor interpersonal relationships, disruptive or difficult behavior, and substance abuse (Cassem and Barsky 1991) and show significant occupational and social impairment.

Clinical course and prognosis. Somatization disorder is “a chronic but fluctuating disorder that rarely remits completely. A year seldom passes without the individual’s seeking some medical attention prompted by unexplained somatic complaints” (American Psychiatric Association 2000, p. 488). Patients may experience iatrogenic disease or injury secondary to unnecessary diagnostic investigations, polypharmacy, and polysurgery. They are particularly at risk for abuse and dependence on drugs prescribed for symptom control (e.g., analgesics, sedative-hypnotics).

Differential Diagnosis

Occult medical diseases affecting multiple organ systems and manifesting with vague or nonspecific symptoms (e.g., systemic lupus erythematosus, sarcoidosis, lymphoma) should be excluded. Patients with these diagnoses, in contrast to somatization disorder, look chronically ill and usually have abnormal physical examinations or laboratory tests. *Panic disorder* may be mistakenly diagnosed as somatization disorder, given a history of many physicians and extensive diagnostic investigations, although symptom patterns differ, with panic disorder patients describing acute symptoms occurring simultaneously, in contrast to the chronic, protean, and fluctuating symptoms of somatization disorder. Chronic physical symptoms may be a part of a *depressive disorder* but occur in the context of the mood disturbance without the long duration and dramatic symptom fluctuations seen in somatization disorder. Some patients with *schizophrenia* or *delusional disorder* develop multiple somatic delusions, distinguished from somatization disorder by their bizarre content. By definition, somatization disorder includes symptoms compatible with other *somatoform disorders*, and diagnostic overlap is common. Somatization disorder differs from *factitious disorder* and *malinger*ing by the lack of intentional symptom production.

Specific Treatments

The most effective treatments for somatization disorder (discussed in greater detail later in this chapter under “Management of Somatization and Somatoform Disorders”) include cognitive-behavioral therapy (CBT), short-

term group therapy, and a psychiatric consultation letter to the primary care physician about strategies for managing the somatizing patient.

Undifferentiated Somatoform Disorder

Definition

Undifferentiated somatoform disorder is a residual category for individuals who do not meet the full criteria for somatization disorder or another somatoform disorder. The diagnosis requires one or more physical complaints persisting for more than 6 months that cannot be accounted for by a general medical condition, direct effects of a substance, or another psychiatric disorder.

Epidemiology

No studies of undifferentiated somatoform disorder per se have been conducted, but investigators have studied variously defined subsyndromal somatization syndromes. *Abridged somatization disorder*, defined by a cutoff score of four DSM-III-R somatization symptoms for men and six symptoms for women, identified patients whose characteristics, including increased medical utilization, resembled those of patients meeting the full criteria for somatization disorder (Escobar et al. 1987, 1989). Studies of distressed high utilizers of medical care documented significant increased health care utilization by patients endorsing functional somatic symptoms falling below the DSM-III-R cutoff score of 13 symptoms (Katon et al. 1991). It is estimated that 4%–11% of the population have multiple medically unexplained symptoms that are consistent with a subsyndromal form of somatization disorder (Escobar et al. 1987, 1989).

Other diagnoses have been proposed as being more clinically useful than undifferentiated somatoform disorder. *Multisomatoform disorder* is characterized by three or more medically unexplained, currently bothersome physical symptoms in addition to a greater than 2-year history of somatization (Kroenke et al. 1997). Criteria for multisomatoform disorder were met in 8% of primary care patients, and the diagnosis was associated with worse functional status, and higher health care utilization (Jackson and Kroenke 2008). *Specific somatoform disorder* requires at least one unexplained physical impairment and a substantial impairment in more than one life domain (Rief and Hiller 1998, 1999) and identifies a more impaired group than does the DSM-IV-TR diagnosis of undifferentiated somatoform disorder (Grabe et al. 2003).

Clinical Course, Prognosis, and Differential Diagnosis

It is likely that the course of this heterogeneous disorder is variable, although there has been little systematic study

(American Psychiatric Association 2000). The differential diagnosis is similar to that of somatization disorder.

Specific Treatments

There are no good studies of the effectiveness of specific treatments for undifferentiated somatoform disorder per se. Beneficial effects have been shown in two small randomized controlled trials (RCTs) of antidepressants in multisomatoform disorder (Kroenke et al. 2006; Muller et al. 2008) and one RCT of a care recommendation letter to primary care physicians (Dickinson et al. 2003). There is an ongoing trial of CBT for abridged somatization disorder (Magallon et al. 2008).

Conversion Disorder

Definition

Conversion symptoms have been described since antiquity (Mace 1992). DSM-IV-TR diagnostic criteria for conversion disorder include neurological (voluntary motor or sensory) symptoms or deficits that are associated with psychological factors (American Psychiatric Association 2000). Conversion presentations can be quite dramatic and can include paralysis, pseudoseizures, amnesia, ataxia, or blindness (see Chapter 32, "Neurology and Neurosurgery").

Controversies surrounding the diagnosis of conversion disorder include whether 1) it is a symptom rather than a disorder, because it has not been validated on the basis of longitudinal or family studies (Martin 1992); 2) it is better classified with the dissociative disorders as in ICD-10 (Phillips et al. 2003; Toone 1990); and 3) the determination that the symptom is unconsciously produced can be a valid and reliable judgment. Critics have also questioned what constitutes "relevant psychological conflict," how malingering is excluded, and the extent to which organic disorders can and should be excluded (Halligan et al. 2000).

Diagnostic Dilemmas

Some have argued for moving conversion disorder to the dissociative disorders category, given that the conversion experience, as in pseudoseizures, usually includes features of dissociation. In most cases the clinician can at best only speculate about the psychological factors whose presence is required by criterion B—the patient is often unaware of or unwilling to divulge such factors, and the psychological factors may not emerge for a long time or even at all. Because the psychological factors are not usually measurable, there is little research to support the value of this criterion. The requirement in criterion C that the symptoms not be intentionally produced or feigned is untestable and unfairly suggests that patients with conversion symptoms are more likely to be dishonest. Because neurologists tend to arrive at

the diagnosis of conversion disorder in a manner that differs from the methods of the psychiatrist, future diagnostic revisions may attempt to reduce these differences.

Epidemiology

The reported prevalence of conversion disorder has varied and is likely influenced by several factors. Toone's 1990 review noted rates of 0.3% in the general population, 1%–3% in medical outpatients, and 1%–4.5% in hospitalized neurological and medical patients. Settings such as combat, in which substantial secondary gain may be involved, have increased rates of conversion. Studies of associations of conversion disorder with social class and urban versus rural distribution have yielded equivocal findings (Murphy 1990). A large prospective cohort study found that one-third of new referrals to general neurology clinics had symptoms that were poorly explained by identifiable organic disease (Carson et al. 2000).

Onset is typically in adolescence or early adulthood, but cases have been described in children as well as in older adults. An often-quoted early study cautioned that many patients given a conversion disorder diagnosis subsequently received a diagnosis of a neurological or medical condition that explained the symptom (Slater and Glithero 1965). Later studies have found lower (5%–12%) rates of explanatory neurological diagnoses (Crimlisk et al. 1998; Moene et al. 2000), and the most recent systematic review found an overall rate of misdiagnosis of conversion disorder of only 4% (Stone et al. 2005). These more recent findings may be partially explained by increasing caution on the part of clinicians in making a diagnosis of conversion disorder and by modern neuroimaging and electrophysiological tests. The relationship between childhood traumatization, particularly physical and sexual abuse, and the subsequent development of conversion disorder was first described by Freud and is supported by empirical research (e.g., Roelofs et al. 2002), although this association has not been found in all samples (Binzer and Eisemann 1998). Clinically, this association appears especially frequently among patients with pseudoseizures, with trauma reported by 84%, which included sexual abuse by 67%, physical abuse by 67%, and other traumas by 73% in one study (Bowman and Markand 1996).

Specific Culture and Gender Factors

Much higher prevalence rates have been described in developing countries (Murphy 1990) and in isolated rural American settings (Ford 1983). Women outnumber men with the disorder in a ratio varying from 2:1 to 10:1 (Murphy 1990). Men are more likely to present with conversion symptoms related to military service and industrial accidents (Ford 1983).

Case Vignette

Mr. T is a 36-year-old male payroll officer presenting with frequent seizures despite a 10-year history of excellent anticonvulsant control after originally developing seizures following a severe head injury sustained in a motor vehicle accident. There is a strong family history of epilepsy and a history of childhood febrile seizures. Anti-convulsant levels remained therapeutic, and there were no changes in his neurological examination. Detailed history taking revealed markedly increased workplace stress with little chance of changing jobs and a precarious marital relationship. His wife noted that the first seizure occurred on the morning after he had been reprimanded at work.

Clinical Features

Conversion symptoms typically begin abruptly and dramatically. Common conversion symptoms include motor symptoms (e.g., paralysis, disturbances in coordination or balance, localized weakness, akinesia, dyskinesia, aphonia, urinary retention, and dysphagia), sensory symptoms (e.g., blindness, double vision, anesthesia, paresthesias, deafness), and seizures or convulsions that may have voluntary motor or sensory components. Unilateral symptoms may be more likely to occur on the left side of the body, as may be true for other somatoform disorders, although the neurophysiological basis for this finding is unclear (Toone 1990) and not all data support it (Roelofs et al. 2000; Stone et al. 2002a). Some patients with conversion symptoms also have or had the same symptoms from a neurological disease (e.g., conversion pseudoseizures in a patient with epilepsy, as in the case vignette above; Iriarte et al. 2003). In many patients with conversion disorder there is a discrepancy between the presumably frightening symptoms and the patient's bland, even cheerful emotional response (*la belle indifférence*), but this is not a pathognomonic sign and if present does not have prognostic value (Toone 1990). In fact, a review of 11 studies found the frequency of *la belle indifférence* to be 21% in patients with conversion disorder and 29% in patients with organic disease (Stone et al. 2006). The authors recommended abandoning *la belle indifférence* as a clinical sign since it failed to discriminate between conversion symptoms and symptoms of organic disease.

Psychological factors are associated with symptom onset or exacerbation. Psychodynamic views of conversion focus on the etiological role of *primary gain*, which refers to "the effectiveness of the conversion symptom in providing a satisfactory symbolic expression for the repressed wishes" (Engel 1970, p. 660). For example, a conflict about aggression might be symbolically expressed through a paralyzed arm. *Secondary gain* refers to the potential tangible benefits accruing from the sick role, which may include alterations in the behavior of significant others that are deemed posi-

tive by the patient (e.g., increased attentiveness) and permission to withdraw from disliked responsibilities. Secondary gain is believed to occur, but not to be consciously sought, in patients with conversion disorder. This contrasts with malingering, in which symptoms are produced intentionally and are motivated by external incentives, or factitious disorders, in which symptoms are produced intentionally from the unconscious motivation of assuming the sick role. Caution must be exercised in making judgments about secondary gain because it is intrinsic to the sick role and may be found in patients with any medical or psychiatric illness.

Associated features. Although there has been little systematic study of comorbid Axis I diagnoses, conversion disorder frequently co-occurs with PTSD and other somatoform, dissociative, and mood disorders. The literature on associated personality features suggests that "hysterical personality may be seen, but only in a minority of conversion cases; other forms of personality disorder of immature, dependent type are more usual" (Toone 1990, p. 229). Protracted conversion reactions may be associated with secondary physical changes (e.g., disuse atrophy).

Clinical course and prognosis. The course of conversion disorder is difficult to predict. Individual episodes of conversion are usually of short duration with sudden onset and resolution, although recurrence of symptoms over time is common (American Psychiatric Association 2000; Murphy 1990). In some cases, conversion symptoms may last years. Factors reported to predispose to conversion disorder are antecedent physical disorders in the individual or a close contact, which provides a model for the symptoms occurring, and severe social stressors, including bereavement, rape, incest, warfare, and other forms of psychosocial trauma (Toone 1990). The prognosis depends on a number of factors, including acuity of onset, presence of major stressors, duration of symptoms before treatment, symptom pattern, personality, and sociocultural context within which the illness developed. Most patients show a rapid response to treatment, but some do not. Patients with pseudoseizures, tremor, and amnesia are particularly likely to have a poor outcome (Toone 1990). In the Scottish Neurological Symptom Study (Sharpe et al. 2010), two-thirds of the patients reported poor outcome (symptom worsening) at 1 year, with the best predictors of poor outcome being patients' illness beliefs (expectation of nonrecovery) and receipt of financial benefits.

Differential Diagnosis

The differential diagnosis of conversion disorder includes *neurological conditions* that present with evanescent signs

and symptoms (e.g., multiple sclerosis, complex partial seizures, myasthenia gravis). *Pain disorder* is diagnosed in DSM-IV-TR if pain is the only conversion symptom. Conversion symptoms may occur in *other psychiatric disorders* (e.g., pseudoseizures as a manifestation of panic disorder or PTSD [Bowman and Coons 2000]) or during *bereavement*. Psychogenic amnesia, fugue, or stupor may represent conversion or *dissociative disorders*, although this appears to be an arbitrary semantic distinction. As with other somatoform disorders, symptoms are generated unconsciously, whereas they are intentional in *factitious disorder* and *malingering*, although in practice the distinction may be blurry.

Specific Treatments

The most effective treatments for conversion disorder (discussed in detail later in this chapter under “Management of Somatization and Somatoform Disorders”) include supportive therapy, physical therapy, and hypnosis. Clinical trials of pharmacotherapy for conversion disorder have reported inconclusive results (Kroenke 2007).

Pain Disorder

Pain disorder in DSM-IV-TR is the latest incarnation of somatoform pain disorder (DSM-III-R) and psychogenic pain disorder (DSM-III) (see Chapter 36, “Pain”).

Hypochondriasis

Definition

Hypochondriasis is characterized by persistent fears of having a disease or the belief that one has a serious disease based on the misinterpretation of one or more bodily symptoms that persist despite medical reassurance (American Psychiatric Association 2000). The validity of the construct in medical outpatients has been documented (Barsky et al. 1986b; Noyes et al. 1993). Secondary hypochondriasis (i.e., hypochondriasis developing in the context of another Axis I psychiatric disorder, a major life stress, or a medical disorder) has been described (Barsky et al. 1992), although it is not recognized in DSM-IV-TR.

Diagnostic Dilemmas

The obsessional preoccupation and phobic distress of hypochondriasis have led some to propose reclassifying it as an anxiety disorder, perhaps under the less stigmatizing name of “health anxiety” (Olatunji et al. 2009). Although hypochondriasis includes some features of obsessive-compulsive disorder (OCD), only 10% of patients with hypochondriasis also have OCD.

Epidemiology

No large-scale epidemiological studies of hypochondriasis have been conducted. Prevalence rates for primary and secondary forms of hypochondriasis of 3%–13% have been reported for study samples from medical and psychiatric settings (Kellner 1986) and 4%–6% of general medical outpatients (Barsky 2001). The prevalence in the general population is thought to be 1%–5% (American Psychiatric Association 2000), but the diagnosis has not been included in large psychiatric epidemiological studies. The disorder can begin at any age, but onset is most commonly in early adulthood (American Psychiatric Association 2000).

Specific Culture and Gender Factors

The reported data on ethnic and cultural differences are equivocal (Barsky et al. 1986a; Kellner 1986), and these factors may be most important when an individual’s concerns are reinforced by a traditional or alternative healer who disagrees with the medical reassurance provided (American Psychiatric Association 2000). Gender has received little attention, but there does not seem to be a female predominance (Creed and Barsky 2004).

Case Vignette

Mr. J, a 44-year-old sales manager, was referred for assessment of anxiety by an infectious disease doctor who felt that the patient did not have chronic fatigue syndrome. Mr. J was reluctant to speak with a psychiatrist but was grateful to have someone listen in detail to his various medical concerns. On the second assessment interview, he confided that he was convinced that he had multiple sclerosis or amyotrophic lateral sclerosis and that he repeatedly measured the muscle mass in his legs, tested for changes in strength, and watched for “muscle twitches.” His preoccupation with his health had negatively affected his work, because he spent much of the day searching the Internet for information, and he reported feeling distant from his wife and children as he “prepared to go downhill and die.”

Clinical Features

The core feature of hypochondriasis is fear of disease or a conviction that one has or is at risk for a disease despite normal physical examination results and investigations and physician reassurance. Bodily preoccupation (i.e., increased observation of and vigilance toward bodily sensations) is common. The preoccupation may be with a particular bodily function or experience (e.g., heartbeat); a trivial abnormal physical state that is taken as evidence of disease (e.g., cough); a vague physical sensation; or a particular organ (e.g., heart) or diagnosis (e.g., cancer). Patients with hypochondriasis believe that good health is a relatively symptom-free state, and compared with control

patients, they are more likely to consider symptoms to be indicative of disease (Barsky et al. 1993). They also have an exaggerated appraisal of their risk of developing disease (Barsky et al. 2001a). The concern about the feared illness “often becomes a central feature of the individual’s self-image, a topic of social discourse, and a response to life stresses” (American Psychiatric Association 2000, p. 504).

Associated features. Patients with hypochondriasis have a high rate of psychiatric comorbidity, with the most common comorbid diagnoses being generalized anxiety disorder, dysthymia, major depressive disorder, somatization disorder, and panic disorder (Barsky et al. 1992). Personality disorders as assessed by questionnaire were three times more likely to be diagnosed in hypochondriacal patients compared with a control group (Barsky et al. 1992). High medical utilization is common, and the potential exists for iatrogenic damage from repeated investigations. Involvement with complementary health care practices is common. Interpersonal relationships typically deteriorate because of the preoccupation with disease. Occupational functioning is often compromised, with increased time taken off from work and decreased performance when the individual is at work because of the preoccupation with disease.

Clinical course and prognosis. The clinical course and prognosis of hypochondriasis are poorly understood. There appear to be multiple pathways to the diagnosis. Primary hypochondriasis appears to be a chronic condition, and therefore some have argued that it might be better classified as a personality style or trait (Barsky and Klerman 1983; Fallon and Feinstein 2001; Mayou et al. 2003; Tyrer et al. 1990). In DSM-IV-TR the course is described as “usually chronic, with waxing and waning symptoms, but complete recovery sometimes occurs” (American Psychiatric Association 2000, p. 506). Positive prognostic features include an acute onset, brief duration, mild symptoms, absence of secondary gain, presence of a comorbid general medical condition, and absence of psychiatric comorbidity (American Psychiatric Association 2000). Secondary hypochondriasis may develop in the context of either current or past serious illness in the patient or family, bereavement, and psychosocial stressors or during the course of another Axis I disorder, principally a mood or anxiety disorder characterized by prominent somatic symptoms. Some forms of secondary hypochondriasis remit with resolution or treatment of the underlying condition (e.g., major life stressors, mood or anxiety disorders). A prospective study found that hypochondriacal patients had a considerable decline in symptoms and improvement in role functioning over 4–5 years, but two-thirds still met diagnostic criteria

(Barsky et al. 1998). A large international primary care study reported that at 1-year follow-up, of those with hypochondriasis at baseline, 18% still had it, and an additional 16% continued to report hypochondriacal worries. Forty-five percent of those with hypochondriasis at follow-up also met criteria for DSM-IV anxiety or depressive disorders (Simon et al. 2001).

Differential Diagnosis

The differential diagnosis of hypochondriasis includes *general medical conditions*, particularly the early stages of a variety of rheumatological, immunological, endocrine, and neurological diseases in which the patient may notice symptoms that may not be associated with signs detectable on physical examination or with abnormal laboratory investigation. Of course, hypochondriasis may coexist with medical pathology (Barsky et al. 1986a). Transient hypochondriacal preoccupations related to medical illness do not constitute hypochondriasis (American Psychiatric Association 2000). Hypochondriacal concerns may accompany *other psychiatric diagnoses* characterized by prominent somatic symptoms (e.g., *major depressive disorder, dysthymia, panic disorder, generalized anxiety disorder, obsessive-compulsive disorder*). *Psychotic disorders* are characterized by the fixed quality of the patient’s delusional belief, in contrast to the hypochondriacal patient, who is convinced of the veracity of his or her concerns but is able to consider the possibility that the feared disease is not present. In clinical practice sorting out delusional from non-delusional hypochondriasis is sometimes difficult.

Specific Treatments

The most effective treatments for hypochondriasis (discussed in detail later in this chapter under “Management of Somatization and Somatoform Disorders”) include CBT, exposure and response prevention, and systematic desensitization (Thomson and Page 2007). There is also evidence for the efficacy of selective serotonin reuptake inhibitors (SSRIs) (Fallon et al. 2008; Greeven et al. 2007).

Body Dysmorphic Disorder

Definition

The hallmark of body dysmorphic disorder (BDD) is the preoccupation with an imagined defect in appearance (if a slight physical anomaly is present, the individual’s concern with it is judged to be markedly excessive) that is accompanied by significant distress or impairment in social or occupational functioning (American Psychiatric Association 2000). Although BDD is classified in DSM-IV-TR as a somatoform disorder, it is increasingly seen as an obsessive-compulsive spectrum disorder (Chosak et al. 2008; Phillips and Stout 2006).

Diagnostic Dilemmas

Future revisions of DSM may reclassify BDD as a subtype of OCD, although there are some differences between the disorders (Chosak et al. 2008).

Epidemiology

The prevalence of BDD is greater than many clinicians recognize (Phillips 1998). BDD has been reported to occur in about 5% of patients seeking cosmetic surgery in the United Kingdom (Veale et al. 2003), 5% of female Turkish college students (Cansever et al. 2003), and 9% of Turkish patients presenting for acne treatment (Uzun et al. 2003). See also Chapter 29, "Dermatology." The prevalence of BDD in Dutch psychiatric outpatients who were referred for depressive, anxiety, or somatoform disorders was 0.8% (Vinkers et al. 2008). Otto et al. (2001) estimated a point prevalence of 0.7% in a community sample of women ages 36–44 years in Boston, Massachusetts. Structured interviewing is more likely to identify cases (Zimmerman and Mattia 1998), supporting the claim that it is an underrecognized disorder. Onset is typically in adolescence (Phillips 1998), although the disorder may begin in childhood (Albertini and Phillips 1999). Many years may pass before diagnosis because of the individual's reluctance to reveal symptoms (American Psychiatric Association 2000).

Specific Culture and Gender Factors

Cultural variation in BDD has received relatively little attention, although it is clear that concerns about physical appearance vary across cultures and likely color the presentation in different cultures. A comparative study of American and German college students concluded that body image concerns and preoccupation were significantly greater in American than in German students, although the prevalence of probable BDD was not (Bohne et al. 2002). The sex distribution of BDD varies across case series (Phillips 1998). Men and women describe differential preoccupations in line with cultural norms: women are more likely to be preoccupied with their hips and weight, and men with body build, genitals, and thinning hair (Phillips and Diaz 1997).

Case Vignette

Ms. Y is a 32-year-old woman who was referred to a psychiatrist for "support" by a plastic surgeon whom she had consulted regarding revisions of a rhinoplasty ("still not right") and breast augmentation ("I don't look balanced"). The breast augmentation had been complicated by infection, and there was an objective imbalance and excessive scarring, but her nose appeared aesthetically pleasing. She believed that plastic surgery would make her more attractive, thus "allowing" her to leave her married abusive boyfriend and find a new partner. Collateral

information from her mother revealed long-standing bodily preoccupation dating from early adolescence, difficulties in relationships with men, and poor occupational functioning and underemployment.

Clinical Features

Most patients with BDD have concerns about more than one body part (Phillips 1998). The intensity of the preoccupation with the bodily "defect" has been described as "torturing" and "tormenting," dominating the patients' lives and severely limiting social and occupational functioning. Many patients engage in compulsive "checking" behaviors, such as observing themselves in the mirror or measuring the body part of concern. Medical intervention, including surgery, is sought by many patients—75% in one study, with 66% receiving treatment (Phillips et al. 2001b). Delusional BDD—classified as delusional disorder, somatic type—may reflect a difference in insight rather than a distinct syndrome (Phillips et al. 1994).

Associated features. BDD has substantial comorbidity. Major depressive disorder is the most common comorbid disorder, with a current comorbidity rate of about 60% and a lifetime rate of more than 80% (Phillips and Diaz 1997). Other disorders with lifetime rates of more than 30% include social phobia, substance use disorders, and OCD. Some case series have lower rates of comorbidity (Veale et al. 1996). Social phobia usually begins before the onset of BDD, whereas depression and substance use disorders typically develop after the onset of BDD (Gunstad and Phillips 2003). Personality disorder is common (Phillips 2001), with the most common diagnosis being avoidant personality disorder (Veale et al. 1996). Psychosocial dysfunction is often profound, with social withdrawal and occupational functioning below capacity (Phillips 1998) as well as suicidal behavior (Phillips et al. 1993). BDD can profoundly reduce quality of life; BDD subjects' scores in all mental health domains of the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36) were worse than norms for patients with depression, diabetes, or a recent myocardial infarction (Phillips 2000).

Clinical course and prognosis. Case series suggest that BDD is usually chronic, with few symptom-free intervals. The one prospective study found that psychosocial functioning remained stably poor over 1–3 years follow-up (Phillips et al. 2008). The intensity of the symptoms may vary over time (American Psychiatric Association 2000). Patients with BDD often seek and obtain inappropriate medical and surgical treatment (Phillips et al. 2001b). Cosmetic surgeons have recognized the importance of identifying BDD, because it occurs in 7%–15% of those seeking

surgery, and operating on BDD patients may worsen the BDD, placing the surgeon at risk of litigation and physical harm (Sarwer et al. 2003).

Differential Diagnosis

A diagnosis of BDD is not made when another Axis I disorder (e.g., mood disorder, schizophrenia, anorexia nervosa) better accounts for the behavior. Distinguishing between BDD and delusional disorder, somatic type, can be difficult (Phillips 2001; Phillips et al. 1993), as can sorting out “normal body dissatisfaction” (Murphy 1990), because concerns about appearance are common and are reinforced by unrealistic media ideals.

Specific Treatments

The most effective treatments for BDD (discussed in detail later in this chapter under “Management of Somatization and Somatoform Disorders”) include CBT, SSRIs, and clomipramine (Ipser et al. 2009).

Management of Somatization and Somatoform Disorders

The key to clinical management of chronic somatization and somatoform disorders is to adopt caring rather than curing as a goal. Management is a much more realistic goal than cure in these patients (Bass and Benjamin 1993; Creed and Guthrie 1993; Epstein et al. 1999; Sharpe et al. 1992; G.C. Smith et al. 2000). Management must be tailored to the individual's somatic symptoms, thoughts and beliefs, behavior, and emotional state (Epstein et al. 1999). Three potential management approaches to the patient with somatization disorder have been described:

1. A *reattribution approach* emphasizes helping the patient to link his or her physical symptoms with psychological or stressful factors in his or her life. This is accomplished via a three-step process that links psychosocial stressors (e.g., marital strife) through physiological mechanisms (e.g., increased muscle tension) to physical symptoms (e.g., headache) (Goldberg et al. 1989).
2. A *psychotherapeutic approach* concentrates on developing a close and trusting relationship with the patient (Guthrie et al. 1991).
3. A *directive approach* treats the patient as though he or she has a physical problem, and interventions are framed in a medical model (Benjamin 1989).

The three management approaches vary in their suitability for different patients. The reattribution approach is particularly useful in primary care settings, in medical-sur-

gical inpatient settings with patients who have a fair degree of insight, and in psychiatric settings with patients who have less lengthy histories of somatization. The reattribution technique can be easily taught to primary care practitioners (Goldberg et al. 1989). The psychotherapeutic approach is most suitable for patients with persistent somatization who are willing to explore the effect of psychosocial factors on their symptoms. The directive approach is most useful for hostile patients who deny the importance of psychological or social factors in their symptoms.

A systematic review of 34 RCTs of treatments for somatoform disorders, almost all published in 1995–2007, concluded that CBT is the best-established treatment for a variety of somatoform disorders (Kroenke 2007). CBT was effective in 11 of 13 studies, and antidepressants were effective in 4 of 5 studies. For the treatment of somatization disorder, 3 of 4 studies found that a psychiatric consultation letter to the primary care physician about strategies for managing the somatizing patient was effective in improving patient functional status, though none found this intervention to reduce patient psychological distress.

Principles of Management

The fundamental principles of management are similar for patients with somatization and with somatoform disorders.

Providing a Positive Explanation of Symptoms

In order to engage in treatment, patients require a sense that their primary physician is taking them seriously, appreciates the magnitude of their distress, and has a rationale for the proposed management plan. Most somatizing patients hold explanatory models of their symptoms that are in conflict with their physician's model (Salmon et al. 1999). The clinical challenge is therefore to provide explanations that empower patients with tangible mechanisms, exculpation, and encouragement of self-management rather than explanations that reject or collude with the patient's model (Salmon et al. 1999). Reassurance is helpful to many patients (Page and Wessely 2003), but it must be carefully dosed and targeted. Facile or excessive reassurance may exacerbate disease fears or cause patients to redouble efforts to prove they are sick and may undermine the doctor-patient relationship (Warwick 1992). It is important to emphasize to patients that the psychiatrist is not dismissing their symptoms as being “all in their head” but rather sees the symptoms as being “real” and “in their body” and wants to explore all opportunities for symptom control. The use of metaphors and analogies is often helpful. The metaphor of a radio has been reported to be particularly useful (N.H. Cassem, personal communication,

July 1985). The radio channel playing is the symptom that is of concern, and given that it cannot be changed by medical or surgical interventions, the patient must gain greater control over the volume control knob (i.e., factors that exacerbate or relieve symptoms) or the sensitivity of the antenna (i.e., factors that amplify symptoms). Physiological mechanisms underlying symptoms may be usefully explained (see Table 12-2) (Sharpe and Bass 1992). Understanding the personal meaning of the symptoms to the patient and tailoring one's explanations and reassurance in light of this meaning may improve the doctor-patient relationship (Epstein et al. 1999; Priel et al. 1991).

Ensuring Regular Follow-Up

Regular follow-up is the key to effective management; it results in decreased health care utilization overall and is less stressful for both patients and physicians than symptom-driven visits. The best choice for most patients is management by their primary care practitioner in consultation with a psychiatrist. However, the psychiatrist may provide primary follow-up if significant comorbid Axis I or Axis II pathology is present or if the primary care physician cannot manage the symptoms.

Treating Mood or Anxiety Disorders

Mood or anxiety disorders have significant morbidity in their own right and interfere with participation in rehabilitation and psychotherapy. Their physiological concomitants may fuel the somatization process or heighten somatic amplification.

Minimizing Polypharmacy

Polypharmacy may produce iatrogenic complications. Unnecessary medications, especially those that are potentially addictive, should be tapered and withdrawn using a staged approach over time with small, realistically achievable steps.

Providing Specific Therapy When Indicated

A variety of specific therapies have been recommended for the somatoform disorders and are discussed below. For example, physiotherapy or massage may be helpful in diminishing musculoskeletal pain for patients with somatoform disorders.

Changing Social Dynamics That Reinforce Symptoms

Many patients' lives come to revolve around their symptoms and their use of the health care system. Regularly scheduled follow-up means that the patient no longer has to present a symptom as a "ticket of admission" to the physician's office. Important members of the patient's social support system may be persuaded to consistently reward

non-illness-related behaviors. Social skills building, life skills training, assertiveness training, and physical reactivation programs may be indicated. Group therapy may be useful because it provides social support, increases interpersonal skills, and provides a nonthreatening environment in which to learn to experience and express emotions and desires more directly.

Resolving Difficulties in the Doctor-Patient Relationship

Somatizing patients often have difficult relationships with their caregivers because of attention seeking, demands, and anger. These difficulties have multiple determinants, including problematic early attachment (Stuart and Noyes 1999), differences in expectations and beliefs about the meaning and management of symptoms, and prior frustrating experiences with the health care system (Page and Wessely 2003). Consequently, addressing shortcomings in doctor-patient interactions can be helpful (Page and Wessely 2003).

Recognizing and Controlling Negative Reactions or Countertransference

Somatizing patients can evoke powerful emotional responses in physicians, which may result in less than optimal clinical care (Hahn et al. 1994; Sharpe et al. 1994). The range of emotions experienced by physicians may include guilt for failing to help the patient, fear that the patient will make a complaint, and anger at the patient's entitlement. The physician may be dismissive of the patient or, alternatively, may collude with the patient in excessive investigations to exclude physical disease in "a suspension of professional judgment" (Bass and Murphy 1990). Excessive investigation might result from a conscious attempt to avoid a "painful, embarrassing and time-consuming confrontation" (Bass and Murphy 1990) or may represent an unconscious solution to the conflicts and emotions that the patient evokes in the physician. The treating physician should seek to identify something about the patient that is either likable or interesting that will help to sustain his or her involvement—in the most difficult patients, it may simply be a sense of amazement at the degree of somatization. A physician caring for these patients must also set clear limits as to his or her availability. If all else fails, the physician should transfer the care of the patient to a colleague, either temporarily or permanently.

Because many patients with somatoform disorders refuse mental health treatment, the psychiatrist's role is often that of a consultant developing a management plan that integrates multiple treatment modalities and different health care disciplines. Several reviews have discussed

psychosocial treatments for unexplained physical symptoms (Looper and Kirmayer 2002; Woolfolk et al. 2007). Cost-effective integrated programs have shown decreased health care utilization (Hiller et al. 2003). Treatment interventions can be tailored to the relevant underlying mechanisms in specific patients, as illustrated in Figure 12-3 (Looper and Kirmayer 2002).

Therapeutic Interventions

Approach to the Patient

Specific management strategies have been described for patients with conversion disorder that also apply to patients with other somatoform disorders. These include 1) explaining to the patient that his or her conversion (or somatic) symptoms are not caused by a serious disease, 2) refraining from confronting the patient, and 3) providing some form of “face-saving” mechanism for symptom resolution such as physical therapy or the suggestion that the patient will improve over a specified period. Eisendrath (1989) observed that “when dealing with behavior with prominent unconscious motivation such as conversion reactions...the therapist provides no benefit by revealing understanding of the psychological processes too early in the treatment” (p. 386). Although many clinicians feel uncomfortable about the risks inherent in “legitimizing” the illness, this approach seems justified based on considerable anecdotal experience of good outcome with treatment and prolonged disability without it. The consulting psychiatrist often must help the referring physician and other health care professionals manage their emotional responses to these patients, whom they may view as deceiving them. The choice of words in talking to patients is very important: terms such as *stress-related seizures* or *functional seizures* are much more acceptable, while remaining truthful, than *pseudoseizures* or *psychogenic seizures*, which may be seen as offensive or pejorative (Stone et al. 2003).

There has been little study of the treatment preferences of patients. Walker et al. (1999) studied 23 volunteers with a diagnosis of hypochondriasis and found that CBT was rated as more acceptable than medications and was perceived as more likely to be effective in the short and long term. CBT was the first choice of 74% of participants, in contrast to medication in 4% and equal preference in 22%. Of note, 48% reported they would accept only CBT. Stone et al. (2004) reported that the majority of neurology clinic patients, and not just those with medically unexplained symptoms, have largely negative beliefs about antidepressants.

Cognitive Therapy

In Kroenke's (2007) systematic review of the efficacy of treatments for somatoform disorders, cognitive therapy

proved effective in 11 of 13 RCTs. These trials spanned the range of somatoform disorders and drew from samples that included psychiatric outpatients, medical outpatients, and community respondents. Cognitive therapy has been shown to be beneficial for somatization disorder, hypochondriasis, BDD, and medically unexplained symptoms.

The use of cognitive therapy is predicated on cognitive models such as the one shown in Figure 12-4 for hypochondriasis. The cognitive model directs attention to factors that maintain preoccupation with worries about health, including attentional factors, avoidant behaviors, beliefs, and misinterpretation of symptoms, signs, and medical communications (Salkovskis 1989). Cognitive therapy has been helpful in decreasing health care visits and physical complaints in patients with multiple unexplained physical symptoms (Sumathipala et al. 2008). In a 15-month follow-up of a 10-week RCT of CBT, primary care patients with somatization disorder showed improvements in functioning, fewer somatic symptoms, and a decrease in health care costs (Allen et al. 2006). A controlled treatment study using both individual and group CBT demonstrated cost-effectiveness and decreased health care utilization in a mixed group of patients with somatoform disorders (Hiller et al. 2003).

Cognitive therapy programs for hypochondriasis have been described in considerable detail (Salkovskis 1989) and are based on a model of hypochondriasis as a disorder of perception and cognition in which somatic sensations are perceived as abnormally intense and are attributed to serious medical disease. Barsky et al. (1988a) described a 6-week group program for patients with hypochondriasis. At 12-month follow-up, a randomized usual-care control trial of a 6-session individual CBT intervention demonstrated significant, persistent reductions in hypochondriacal beliefs and attitudes; in health-related anxiety; and in impairment in social role functioning and activities of daily living, but no improvement in hypochondriacal somatic symptoms (Barsky and Ahern 2004). Cognitive therapy achieved a somewhat higher rate of response than paroxetine (45% vs. 30%) in a comparative RCT in psychiatric outpatients with hypochondriasis, and response rates for both treatments were significantly greater than the response rate for placebo (14%) (Greeven et al. 2007). Four of the five studies of CBT in patients with medically unexplained symptoms reported a positive response rate (Kroenke 2007), and two of three studies of CBT in BDD patients reported significant reduction in symptom severity (Ipser et al. 2009).

Pharmacotherapy

The evidence base for pharmacological treatment of somatoform disorders is limited to studies of small heteroge-

Mechanisms**Treatment interventions****FIGURE 12-3. Matching mechanisms and interventions in the management of somatoform disorders.**

neous samples, chart reviews, open-label trials, and a small number of RCTs. There is great interest in the potential role of antidepressants in ameliorating somatic symptoms associated with depression, as well as functional somatic symptoms in nondepressed patients (Stahl 2003). Norepinephrine and serotonin have important functions in mediating physical symptoms, and therefore their modulation with antidepressants may bring about changes in somatic experiences (Stahl 2003). An open-label trial of fluoxetine found moderate improvement in 61% of 29 patients with a variety of somatoform disorders (Noyes et al. 1998). In a European placebo-controlled trial, opipramol (a histamine H_1 , serotonin 5-HT $_2$, and dopamine D_2 blocker) demonstrated efficacy in a diverse group of somatoform patients

with high rates of depressive and anxiety comorbidity (Volz et al. 2000).

Pharmacotherapy has shown limited evidence of effectiveness in somatization disorder except for treatment of comorbid mood and anxiety disorders. Drugs that have been studied for hypochondriasis include high-dose fluoxetine (average dosage 51 mg/day), which improved the response rate to 63% versus 33% for placebo in one RCT (Fallon et al. 2008), and paroxetine, which proved better than placebo in another RCT (Greeven et al. 2007). Secondary hypochondriasis in patients with depression has been treated with amitriptyline (Kellner et al. 1986). A number of studies of BDD have reported success with SSRIs in about two-thirds of patients treated (Phillips 1998; Phillips

et al. 2001a, 2008). In one RCT, fluoxetine proved effective in reducing BDD beliefs and behaviors (Phillips et al. 2002). It has also been reported that augmentation strategies and changing antidepressants may be helpful in BDD patients who are nonresponsive to SSRIs (Phillips et al. 2001a). High relapse rates in BDD were reported with discontinuation of pharmacotherapy (Phillips et al. 2001a). Clomipramine (a potent serotonin reuptake inhibitor) was more effective than desipramine (a norepinephrine reuptake inhibitor) in treating BDD in a 16-week double-blind crossover trial (Hollander et al. 1999). The SSRIs appear to be effective even among patients with a delusional variant of BDD (Hollander et al. 1999; Phillips et al. 2001a). The time to response is longer than with major depression for at least one-third of patients.

Physical Reactivation and Physical Therapy

Physical reactivation via a gradually escalating program of exercise (e.g., walking, swimming) often improves the quality of life in patients with a variety of somatoform disorders. It may be difficult to engage patients in exercise, but once they become more active, they often find it pleasurable and report feelings of accomplishment, reduced stress, and greater confidence in their body. Physical reactivation should start at a level just below what the patient can do on his or her worst day, and the patient should then strive for consistency with activity at least 5 days a week. Physical therapy is invaluable for patients who have conversion disorder and may be the only treatment required to restore physical function in some cases (Delargy et al. 1986; Dvornich et al. 1991). In a recent report of 34 consecutive referrals for inpatient rehabilitation treatment of conversion disorder patients with motor paralysis, 9 had complete recovery, 10 had partial recovery, and 15 remained unchanged (Heruti et al. 2002).

Relaxation Therapies, Meditation, and Hypnotherapy

Various forms of relaxation therapies, biofeedback, meditation, and hypnotherapy have been used with somatoform disorder patients. Relaxation therapies modulate somatic sensations and may be used as part of a more comprehensive group treatment program for hypochondriasis (Barsky et al. 1988a). These therapies may be used either as a primary form of treatment based on a psychophysiological model or as an adjuvant to other forms of treatment. Hypnosis has been used diagnostically and therapeutically in patients with conversion disorder (see review by Van Dyck and Hoogduin 1989), and it showed sustained benefits for 6 months in an RCT (Moene et al. 2003). Hypnotherapy may be combined with intravenous sedation (Toone 1990) and eclectic behavioral treatment programs

(Moene et al. 2003). Although abreaction or catharsis under hypnosis or sedation has had dramatic anecdotal effects in some individuals in whom the conversion was precipitated by extreme trauma, such interventions are not helpful for most patients (Toone 1990).

Behavioral Treatment

Learning theory models have been proposed for the treatment of several somatoform disorders. Hypochondriasis has been treated with exposure and response prevention individually tailored to the patient's specific problem behaviors (Visser and Bouman 1992, 2001; Warwick and Marks 1988). Prevention of reassurance seeking was a key component of treatment because it is conceptualized as an anxiety-reducing ritual that is reinforced by the reassurance received (Warwick 1992). This program, which required a median of seven treatment sessions and 11 therapist hours, was associated with improvement that was maintained in half of the patients at follow-up (mean duration, 5 years; range, 1–8 years). Exposure therapy may decrease hypochondriacal fears and beliefs in agoraphobic patients (Fava et al. 1988). Exposure plus response prevention for hypochondriasis was found to be as effective as cognitive therapy, and both treatments demonstrated results that were superior to a wait-list control group (Visser and Bouman 2001). Behavioral stress management is helpful in treating hypochondriasis (Clark et al. 1998). In some patients, BDD has been successfully treated with behavioral techniques such as desensitization, live and fantasy exposure, and assertiveness training (Marks and Mishan 1988).

Suggestion and Reassurance

The use of suggestion or reassurance requires clinical acumen in framing the intervention and ensuring that one does not give an explanation that is heard as "It's all in your head." Explanations should empower patients, reframe the symptoms, and emphasize the possibility of improvement over time, particularly with active involvement from the patient. For example, the psychiatrist may tell the patient, "The sudden weakness in your legs really laid you up. The good news is that you don't have multiple sclerosis, a stroke, a tumor, or anything else like that. This sort of weakness typically disappears as mysteriously as it initially appears, but our experience is that you can speed up your recovery through physical therapy."

Dynamic Psychotherapy

Psychotherapy has a role in the management of some somatoform disorders. In general, psychoeducational and supportive techniques predominate, although insight-oriented therapy may be indicated in some patients. Explanatory therapy for hypochondriasis has been described

(Kellner 1986) and showed an impact superior to the waiting-list control condition (Fava et al. 2000). Explanatory therapy has been described as "providing accurate information, teaching the principles of selective perception (attention to one part of the body makes the patient more aware of sensations in that part of the body than in other parts), reassurance, clarification and repetition" (Fava et al. 2000). Unlike CBT, explanatory therapy is simpler, uses fewer therapeutic components, does not introduce specific behavioral techniques, and is not based on a specific theoretical framework (Fava et al. 2000). Insight-oriented psychotherapy for somatizing patients has been advocated (McDougall 1989; Rodin 1984), but there is no empirical evidence supporting it, and it will appeal to only a minority of patients.

Group Psychotherapy

Group therapy may be particularly useful in the management of somatoform disorders. When social and affiliative needs are gratified via the group, patients' need to somatize to establish or maintain relationships may be reduced (Ford 1984). Confrontation by fellow group members about secondary gain is usually better tolerated than that by an individual therapist or primary physician. Anger at physicians and family and dependence needs may be better tolerated in the group setting, which tends to diffuse intense affects. Group therapy also may be useful in increasing interpersonal skills and in enhancing more direct forms of communication regarding thoughts, feelings, and desires (Ford 1984). Helplessness has been identified as a central psychotherapeutic issue that can be effectively addressed in group therapy for patients with somatoform disorder (Levine et al. 1993). Various forms of group therapy have been reported for patients with somatoform disorder (see review by Levine et al. 1993). Short-term group therapy appears to be effective in primary care patients with somatization disorder (Kashner et al. 1995).

Marital and Family Therapy

Most families will benefit from information and psycho-educational approaches. More intensive forms of therapy are required when patients have significant marital or family pathology and when somatic symptoms are an important form of social communication within the family. It is important to identify the family's attitude and response because they may have a conscious or unconscious interest in maintaining a symptom in a patient.

Deception Syndromes

Factitious Disorders and Malingering

Charles V. Ford, M.D.

Disease has been simulated in every age, and by all classes of society. The monarch, the mendicant, the unhappy slave, the proud warrior, the lofty statesman, even the minister of religion as well as the condemned malefactor and boy “creeping like a snail unwillingly to school,” have sought to disguise their purposes, or obtain their desires, by feigning mental or bodily infirmities.

Gavin 1838, p. i

THE ABOVE INTRODUCTORY PARAGRAPH to Hector Gavin’s 1838 book *On the Feigned and Factitious Diseases of Soldiers and Seamen*, in which he described clinical features of factitious disorders and malingering, indicates the pervasiveness of simulated disease. Also noteworthy is that in the second century A.D., the Roman physician Galen devoted a chapter to simulated disease in one of his medical texts (Adams 1846).

In the current diagnostic classification, that of DSM-IV-TR (American Psychiatric Association 2000), simulated diseases such as somatization disorder are placed within the category of *somatoform disorders*. These disorders are considered to be of unconscious etiology. *Factitious disorders*, considered to be of conscious production but of unconscious motivation, are included among Axis I diagnoses in a separate category. *Malingering*, considered to be of both conscious production and motivation, is assigned a V code. Imprecise criteria (e.g., conscious vs. unconscious motivation) are bound to result in imprecise diagnoses, and in fact illness behavior is frequently motivated by a variety of conscious and unconscious objectives. Furthermore, a person may feign illness to achieve different goals at different times (Eisendrath 1996). Thus, an originally unconsciously moti-

vated symptom may evolve into a consciously driven symptom so that the patient may achieve secondary gains.

Anticipation of the development and publication of new diagnostic criteria and categories of DSM-V (work in progress) has generated debate within the medical community regarding factitious disorders. Some authors (Bass and Halligan 2007; Ford 2005; Turner 2006) have proposed that factitious disease production is a syndrome of misbehavior, while others (Hamilton et al. 2009; Krahn et al. 2008) note its similarities to somatization disorder and advocate maintaining factitious disorder as an Axis I diagnosis. The draft proposed DSM-V criteria for *factitious disorder on self* and *factitious disorder imposed on another* (previously, factitious disorder by proxy) places these disorders within a new category, Somatic Symptom Disorders. The proposed criteria for *factitious disorder on self* require “a pattern of falsification of physical or psychological signs or symptoms associated with identified deception” and state that “this pattern of presentation to others as ill or impaired is evident even in the absence of obvious external rewards.” Exclusion criteria are that the behavior is neither due to an acute psychosis or delusional belief system nor better accounted for by another mental disorder. The pro-

posed criteria for *factitious disorder imposed on another* are the same, except that there is the presentation of another person (the victim) to others as ill or impaired (Dimsdale and Creed 2009).

Illness behavior includes a wide continuum of symptoms and motivations. At one extreme are behaviors that might be considered normal in view of their commonality, such as using a complaint of a physical symptom (e.g., a headache) to avoid some undesired social obligation. In this chapter, I focus on the other extreme of consciously initiated illness behavior: factitious disorders and malingering. As noted earlier, the primary difference between these two forms of illness behavior is the perceived role of conscious versus unconscious motivation. Such a distinction is useful for textbook descriptions, but unfortunately in actual clinical situations the determination of motivation becomes a highly subjective process. A complicating factor is the unreliability of information provided by persons who are, by definition, deceptive.

There are two primary forms of factitious behavior. The first is self-induced or simulated disease, known at times by the eponym Munchausen syndrome, and the second is factitious disease induced or simulated in others, also commonly known as Munchausen syndrome by proxy. Although these two forms of factitious illness overlap at certain points, they are discussed separately here to provide clarity on various important clinical and legal issues. Malingering, not a medical diagnosis per se, is discussed separately from the factitious disorders.

Interest in factitious disorders has increased markedly since the publication of Richard Asher's seminal paper in 1951. As of 2010, there are more than 2,500 publications in the medical literature focused on factitious disorders. There have been descriptions of several other syndromes related to factitious disorder, such as factitious allegations of sexual abuse (Feldman et al. 1994; Feldman-Schorrig 1996; Gibbon 1998), the "angel of death" syndrome (Yorker et al. 2006) (in which a nurse creates emergency situations in his or her patients), and even production of disease in one's pets (Munro and Thrusfield 2001). There are increasing reports of the use of the Internet to obtain medical information and even download medical reports to present as one's own (Levenson et al. 2007). Persons also may assume a false identity to enter chat rooms and support groups for chronic diseases (Feldman 2000).

Hardie and Reed (1998) described the overlaps in characteristics of persons who have pseudologia fantastica (Table 13-1), create factitious disorders, and engage in impostorship. They proposed the term *deception syndrome* to describe these syndromes—a concept that would provide more unity than does the current tendency to create increasing numbers of new syndromes and eponyms.

TABLE 13-1. Pseudologia fantastica

Childhood traumatic experiences

Factitious Disorders

Persons who have factitious disorders intentionally feign, exaggerate, aggravate, or self-induce symptoms or disease. They are conscious of their behaviors, although the underlying motivation may be unconscious. By convention, this diagnosis is also characterized by the surreptitious nature of the behavior. Patients who acknowledge that they have produced their own self-harm (e.g., self-mutilators) are not included in this diagnostic group. Inherent in factitious disorders is a paradox: the patient presents to a physician or other health care provider with the request for medical care but simultaneously conceals the known cause of the problem.

Risk factors for factitious disorder vary according to the subtype of the clinical syndrome. The most common subtype is common factitious disorder (or nonperegrinating factitious disorder), in which the person does not use aliases or travel from hospital to hospital. In this syndrome, female gender, unmarried status, age in the 30s, prior work or experience in the health care professions (e.g., nursing), and Cluster B personality disorders with borderline features are frequently found. For full-blown Munchausen syndrome, in which the patient uses aliases and travels from hospital to hospital (and often from state to state), risk factors include male gender, single marital status, age often in the 40s, and a personality disorder of the Cluster B type with at least some antisocial features. In their review of 93 cases of factitious disorder diagnosed at the Mayo Clinic, Krahn et al. (2003) found that 72% were women, of whom 65.7% had some association with health-related occupations. The mean age for women was 30.7 years, and the mean age for men was 40.0 years.

Few epidemiological data are available for factitious disorders. An Italian community study found a lifetime prevalence of 0.1% (Faravelli et al. 2004). Most investigators

believe that factitious disorder is a relatively uncommon but not extremely rare disorder. For example, Sutherland and Rodin (1990) noted that 10 of 1,288 psychiatric consultations at a large teaching hospital in Toronto, Ontario, included a diagnosis of factitious disorder. A similar percentage of 0.6% was reported for a German university hospital psychiatric consultation service (Kapfhammer et al. 1998). These differing methods of determining incidence reflect a very large range. If the number of diagnoses established by psychiatric consultation is used as an estimate, then—with the assumption that no more than 1 in 10 medical inpatients is seen in psychiatric consultation—the incidence would be less than 1 in 10,000 admissions to medical-surgical services. However, many patients with factitious disorder may successfully evade detection and thereby go through the system undiagnosed.

Clinical Features: Phenomenology, Course, and Prognosis

Self-induced factitious disorders fit into two major syndromes. Unfortunately, the terminology in the general medical literature is inconsistent, and the terms *Munchausen syndrome* and *factitious disorder* are often used interchangeably (Fink and Jensen 1989). In this chapter, *Munchausen syndrome* refers specifically to the subtype of factitious disorders originally described by Richard Asher in 1951.

Classic Munchausen syndrome consists of three essential components: the simulation or self-induction of disease, pseudologia fantastica, and travel from hospital to hospital, often using aliases to disguise identity. These patients frequently present in the emergency department with dramatic symptoms such as hemoptysis, acute chest pain suggesting a myocardial infarction, or coma from self-induced hypoglycemia. Munchausen patients may make a career out of illness and hospitalizations; as many as 423 separate hospitalizations for an individual patient have been reported (von Maurer et al. 1973).

The types of symptoms and different diseases that have been simulated defy the imagination (Table 13-2). Essentially every subspecialty journal has published case reports of self-induced illness related to that particular subspecialty. Among the most common presentations have been chest pain, endocrine disorders such as hyperthyroidism or Cushing's syndrome, coagulopathies, infections, and neurological symptoms. The Munchausen patient often presents during evening or weekend hours, presumably in order to be evaluated by less senior or experienced clinicians. The patient is frequently admitted to an inpatient service, where he or she may become the "star patient" in view of the dramatic nature of the symptoms or the rarity of the presumed diagnosis. In addition, the patient may call attention to himself or herself by providing false information such as

claiming to be a former professional football player, a recipient of the Medal of Honor, or perhaps the president of a foreign university. Despite such reputed prominence, these patients and their physicians rarely receive telephone calls from concerned family members or friends. The Munchausen patient is usually willing to undergo multiple diagnostic studies. When inconsistencies in history, medical findings, or laboratory examinations create suspicions, caregivers often become more confrontational. At this point, the patient generally responds with irritation, new complaints, disruptive behavior, or threats to file a lawsuit. He or she may request discharge against medical advice or may simply disappear. Embarrassed and angry clinicians on the treatment team may console themselves by preparing a case presentation for grand rounds or perhaps for publication.

Munchausen syndrome is the most dramatic form of factitious behavior, and the eponym certainly has great popularity, but much more frequently seen is what has been termed *common factitious disorder*. In this syndrome, the patient does not use aliases and tends to seek treatment repetitively with the same physician or within the same health system. She may carry a diagnosis—which, on careful reflection, was made with imprecise criteria—such as a bleeding coagulopathy or a collagen disease. In retrospect, when the true diagnosis is discovered, it can be determined that the history, both medical and personal, was inaccurate. These patients are not, however, as inclined to pseudologia fantastica as are patients with full-blown Munchausen syndrome.

Symptoms and signs for patients with common factitious disorder tend to be less dramatic, and their complaints are often more chronic or subjective. Some common symptoms include joint pain, recurrent abscesses, failure to heal following operations, hypoglycemic episodes, simulated renal colic, and blood dyscrasias. Factitious disorder as a cause for these patients' symptoms may not be suspected for months or even years. When the diagnosis is finally established, there may be disbelief among the medical care providers. "Splitting" behavior, in which the patient plays one group of providers against another group, is frequently seen.

Factitious Disorder With Psychological Symptoms

The large majority of published cases of factitious disorder describe physical symptoms alone. When factitious psychological symptoms are recognized, they are generally in association with either authentic or fabricated physical complaints. The reason for this may be that subspecialists in psychosomatic medicine are more likely to encounter patients with factitious psychological symptoms who are hospitalized on medical-surgical wards, or in the emer-

TABLE 13-2. Examples of factitious diseases

Symptom/disease	Method of production	Diagnostic clue
Infections	Injections of saliva or feces	Polymicrobial cultures
Hypoglycemic coma	Self-injection of insulin	Low C-peptide
	Oral hypoglycemic agents	Glyburide in urine
Fever of unexplained etiology ^a	Manipulation of thermometer	Dissociation of fever/pulse
Neurological disease	Anisocoria secondary to anticholinergic eyedrops	Variable reactivity of pupils
Diarrhea	Laxative abuse	Laxative in stool
Pheochromocytoma	Epinephrine in urine	Low blood chromogranin A
Electrolyte imbalance	Diuretics	High urinary potassium
Vomiting	Ipecac	Increased urinary potassium with low chloride
Coagulopathies	Warfarin	Serum assay
Anemia	Self-bloodletting	No bleeding site or iron malabsorption
Pancytopenia	Methotrexate	Serum assay
Proteinuria	Egg white in urine	Large daily variations of urine protein
Purpura	Quinidine	Serum or urinary assay
Hyperthyroidism	Exogenous thyroid	Low serum thyroglobulin
Hematuria	Finger-prick blood to urine	

^aNow uncommon because of the use of instantaneous electronic thermometers.

gency department, than to see such patients on psychiatric units. One study of Spanish psychiatric inpatients found that 8% had factitious symptoms (Catalina et al. 2008). These were interpreted as largely being exaggeration or invention of symptoms to find support, social relationships, and safety in the hospital. Patients with factitious psychological symptoms fabricate a wide range of symptoms. The most commonly reported include depression and suicidal thinking tied to claims of bereavement (Phillips et al. 1983; Snowden et al. 1978). The patient reports that his or her emotional distress is due to the death of someone close such as a parent or child. Distress appears genuine, is often accompanied by tears, and characteristically elicits sympathy from medical personnel. Later, staff members may discover that the mourned person is very much alive, that the circumstances of the death were less dramatic than the patient reported, or that the death was many years in the past. Case reports of factitious psychological symptoms also describe feigned multiple personality disorder, substance dependence, dissociative and conversion reactions, memory loss, and posttraumatic stress disorder. Multiple feigned psychological symptoms may be present in the same patient (Parker 1993). Some authors urge caution in diagnosing factitious disorder with predominantly psychological symptoms, especially factitious psychosis, because some patients with these symptoms eventually manifest clear-

cut severe mental illness (Nicholson and Roberts 1994; Rogers et al. 1989).

Ganser's syndrome is closely related to factitious disorder, with predominantly psychological symptoms (Wirtz et al. 2008). This syndrome is characterized by the provision of approximate answers (*Vorbeireden*) to questions (e.g., the examiner asks, "What is the color of snow?" and the patient answers, "Green"). Complaints of amnesia, disorientation, and perceptual disturbance are generally present as well. This syndrome was originally described by the nineteenth-century German psychiatrist Sigbert Ganser (1965) as a form of malingering seen in prisoners, but it also has been described in other settings, including general hospital units (Dalfen and Anthony 2000; Weiner and Braiman 1955). Ganser's syndrome was described in one patient who also had clear-cut factitious physical and psychological symptoms (Parker 1993). The etiology of this syndrome remains in question, and malingering, dissociation, and organic brain disease (Sigal et al. 1992) have been proposed as contributing factors.

When the patient presents with both physical and psychological factitious symptoms and neither predominates, the appropriate diagnosis is factitious disorder with combined physical and psychological symptoms. The aforementioned case reported by Parker (1993) included pseudodementia (Ganser's syndrome), feigned bereave-

ment, factitious rape, pseudoseizures, and simulated renal failure.

The prognosis of patients with factitious symptoms is unclear. Some patients may, at some point in their life, abandon their behavior. Death, probably as a result of the patient's miscalculations of the risk of the behavior, also has been reported (Eisendrath and McNeil 2004; Nichols et al. 1990).

Diagnosis and Assessment

The diagnosis of factitious disorder may be suggested by inconsistent laboratory results, physical findings that do not conform to reported symptoms, failure to respond as predicted to effective treatment for the disorder in question, or, most frequently, the accidental discovery of medical paraphernalia on the patient's person or in the room. For example, a syringe may be found taped onto the inside portion of a toilet lid or a nurse may come into a patient's room unannounced and find the patient digging in a surgical wound with a foreign body. Ultimately, the diagnosis of factitious disorder is made via detective work by health care providers who have a high index of suspicion. A review of past medical records from other institutions may be essential to establish the diagnosis (Krahn et al. 2003). On the surface the patient may appear normal, and a psychiatric interview per se cannot establish the diagnosis unless there is a "confession." The patient, even when confronted with irrefutable evidence of factitious behavior, typically denies that the illness was self-induced.

The differential diagnosis of factitious disorder includes unusual, rare, or as-yet undescribed and unknown diseases; somatoform disorders; and overt malingering.

Etiology

The reasons that a person might engage in factitious illness behavior are to a large extent speculative. Even when seen in long-term treatment, these patients are resistant to articulating their motivations. Furthermore, the essential quality of these persons—the need to deceive—creates a question of validity. Proposed underlying motivations are outlined in Table 13-3.

The large majority of patients with factitious disorder have an underlying severe personality disorder, usually of the Cluster B type. Factitious behavior can be seen as a form of acting out, similar to other acting-out behaviors seen in Cluster B personality disorders. Axis I comorbidity, including major depression and schizophrenia, has been described but is not common. However, it must be kept in mind that psychiatric symptoms also may be simulated.

Few patients have been extensively studied with regard to developmental history because very few will agree to see a psychotherapist, and even fewer open up honestly. In the

TABLE 13-3. Proposed motivations for factitious disorder

Need to be the center of attention
Longing to be cared for
Maladaptive reaction to loss or separation
Anger at physicians or displaced onto physicians
Pleasure derived from deceiving others ("duping delight")

very select few who have, a childhood history of parental illness, death, or abandonment, or personal illness or institutionalization, is common (Ford 1973). As a result of these childhood experiences, factitious behavior may be viewed, at least in some circumstances, as a learned coping mechanism.

The possible role of cerebral dysfunction for at least some patients has been proposed. Pankratz and Lezak (1987) reported that approximately one-third of the Munchausen patients in their series had deficits in conceptual organization. Abnormal findings on brain imaging also have been reported (Babe et al. 1992; Fenelon et al. 1991). Brain dysfunction also has been reported in approximately 20%–25% of persons with pseudologia fantastica and/or Munchausen syndrome (Ford 1996; King and Ford 1988).

Management and Treatment

In the past, it was suggested that blacklists should be created, disseminated, and maintained at various hospitals to identify Munchausen patients when they present for care (Mohammed et al. 1985). A variant of this concept for an individual hospital is to mark the old chart in some conspicuous manner to identify the patient when he or she presents to an emergency department. Such blacklists have found disfavor in the United States largely because of legal and ethical concerns and would be considered a violation of regulations under the Health Insurance Portability and Accountability Act of 1996 (P.L. 104-191). However, identification of past factitious illness behavior is facilitated in systems with a common electronic medical record (e.g., U.S. Department of Veterans Affairs). Diagnosis of a factitious disorder by use of an electronic medical record (EMR) search was reported by Van Dinter and Welch (2009). These authors emphasized the importance of attention to legal and ethical issues in reviews of EMRs.

A major question in management is how to deal with a patient once a definitive diagnosis of factitious disorder has been established. No matter how understandable the anger at these deceptive patients might be, the temptation to "let them have it" must be resisted. To act out in an angry way only plays into the patient's pathology by drawing the physician into a dramatized scene. A direct, accusative confrontation is likely to result in anger from the patient

and in his or her subsequent departure from the hospital, often against medical advice, or with threats to bring a lawsuit for defamation. It has been suggested that the confrontation be more indirect, in a manner that allows face-saving for the patient or an opportunity for therapy. For example, a patient may be told, "When some patients are very upset, they often do something to themselves to create illness as a way of seeking help. We believe that something such as this must be going on, and we would like to help you focus on the true nature of your problem, which is emotional distress." Unfortunately, such an approach, although logical and humane, does not usually result in the patient's acknowledgment of factitious illness behavior and acceptance of psychological treatment.

When present, comorbid psychiatric disorders such as depression (if not believed to be also factitious) should be appropriately treated; in at least one case in the literature, remission of factitious behavior with antidepressant medication was reported (Earle and Folks 1986). Psychotherapy with the patient who engages in factitious behavior is, at best, extremely difficult. Treatment for these patients should be conceptualized essentially as being for a severe underlying personality disorder manifested by acting-out defenses. M.H. Stone (1977) proposed vigorous persistent confrontation of the behavior, but most clinicians who have had experience with these patients find that such confrontation results in abandonment of treatment or increase in acting-out behaviors. Instead of direct confrontation, the patient may be provided with indirect confrontation or interpretation in ongoing supportive psychotherapy (Eisendrath 2001). This technique is based on the premise that if the patient can maintain a relationship with a physician that is not contingent on development of new physical symptoms, factitious behavior may be reduced. Such a treatment approach must be viewed as primarily symptomatic with no expectation of changes in the basic personality structure that predisposes a person to factitious illness behavior. Experience with this type of treatment indicates that there may be remissions that last a few months but that they are often followed by the patient leaving treatment without warning and reengaging in factitious illness behavior elsewhere. A systematic review of all known published reports of the management and outcome of patients with diagnosed factitious disorder found no evidence for any effective treatment (Eastwood and Bisson 2008). A nonsignificant trend was that patients who had longer treatments had better outcomes.

In the medical care of patients with any somatizing disorder (including factitious illness and malingering), the physician should proceed with invasive diagnostic and treatment procedures only when objective evidence is available. Furthermore, physicians must be cautious when pre-

scribing any potentially dangerous or habituating medication (Ford 1992).

Legal and ethical issues frequently arise in the assessment and treatment of patients with factitious disorder. In the past, the paternalistic model of medicine suggested that the physician was permitted to do essentially anything that would help establish the diagnosis. More recently, particularly in the United States, medical practice has emphasized patients' rights and informed consent. This creates a dilemma. On one hand, a failure to do all that is necessary to establish the diagnosis might be regarded as abdication of medical responsibility and ultimately harmful to the patient. On the other hand, even patients suspected of factitious behavior have rights to personal privacy, including privacy in one's belongings, confidentiality, and informed consent. One approach is to tell the patient that factitious illness behavior is suspected and request permission to rule this out. This has the risk of alienating a patient who does not have factitious illness. It may result in the patient with factitious disorder refusing permission, leaving the hospital, and perpetuating the same behavior at another medical facility.

Physicians may believe that the patient's outrageous behavior of factitious disease production would leave them free from the risk of malpractice suits. This is untrue, and there have been numerous reports of lawsuits initiated by these patients (Eisendrath and McNeil 2004; Janofsky 1994). The reasons for lawsuits may include overt greed, rage at a physician who was previously idealized (borderline behavior), or perhaps the opportunity to change one's highly dramatized role as a patient in a hospital to an equally dramatized role as a plaintiff in a courtroom.

Because patients with factitious disorder do create legal and ethical problems, it is prudent for the psychiatric consultant to suggest that the management plan require careful multidisciplinary collaboration and appropriate consultation with hospital administrators, hospital and personal attorneys, and the hospital ethics committee. It cannot be overemphasized that any decision to deviate from usual medical practice with such patients should not be made by a solitary individual. Such decisions should be carried out, and their rationale noted, with the patient's best interests at heart and should be documented in the chart. When factitious disorder is suspected, chart documentation in a factual, nonspeculative manner is highly recommended.

In view of these patients' self-destructive nature, many physicians, including psychiatrists, may question whether involuntary psychiatric hospitalization is indicated. Thresholds for involuntary commitment vary from state to state and from country to country. In the United States, because factitious disorder represents chronic behavior, which is not

immediately suicidal, these patients usually do not meet the criteria for involuntary psychiatric hospitalization. In one case in Oregon, outpatient commitment resulted in lower medical costs and less iatrogenic morbidity for a patient with factitious disorder (McFarland et al. 1983).

Factitious Disorders by Proxy (Factitious Disorder Not Otherwise Specified)

In DSM-IV-TR, the diagnostic code *factitious disorder not otherwise specified* includes a variety of factitious diseases and symptoms described or induced by another person. This particular syndrome is far better known by the eponym Munchausen syndrome by proxy, and most case reports describe parents (particularly mothers) who have induced disease in their children. The appropriateness of the term *Munchausen by proxy* has been debated (Pankratz 2006). Some authors prefer terms such as *illness falsification*, whereas others prefer to describe the behavior simply as "child abuse." The latter removes any implication of motivation (Stirling 2007). There are, however, some reports of adults inducing disease in other adults, particularly when in a caregiver setting; for example, a nurse caring for a bedridden patient (Meadow 1998; Yorker 1996).

Munchausen syndrome by proxy is an invidious behavior that, when it involves children, should be considered a form of child abuse. The syndrome was initially described by Meadow (1977), who coined the term; subsequent to his initial report, there have been numerous reports from around the world, including non-Western cultures (Bap-pal et al. 2001).

The incidence of Munchausen syndrome by proxy is sufficiently high that children's hospitals see several cases per year. Denny et al. (2001) found the incidence in New Zealand to be 2.0 per 100,000 in children younger than 16 years. McClure et al. (1996) computed the annual incidence in the United Kingdom to be at least 2.8 per 100,000 for children younger than 1 year and 0.5 per 100,000 for those between ages 1 and 16 years.

Clinical Features: Phenomenology, Course, and Prognosis

The typical presentation of Munchausen syndrome by proxy is that of a child admitted to a hospital with symptoms such as seizures, bleeding, diarrhea, or respiratory difficulties (including apnea). The mother, who often has a history of some medical training, characteristically assists the nurses and readily consents to any invasive diagnostic procedures proposed for the child. Discovery of the mother's role in the production of the child's symptoms

may occur accidentally, such as by finding her smothering the child with a pillow or introducing a toxic substance into the child's mouth or intravenous tubing. Suspicions also may arise if symptoms or episodes of the illness occur only when the mother is alone with the child, if another child in the family has had unexplained illnesses, or if the child's medical problems do not have a predictable response to appropriate treatment.

Sheridan (2003) reviewed and summarized published data from 451 cases of Munchausen syndrome by proxy. Her findings indicated no gender bias of the child victims, who were usually age 4 years or younger. In most of the situations, the perpetrator actively produced symptoms by smothering or poisoning the child, although some instances involved exaggeration or lying about symptoms. The most frequently noted symptoms of the child victims were, in order, apnea, anorexia, feeding problems, diarrhea, seizures, and cyanosis. The mortality rate for identified children victims was 6.0%, but 25% of known siblings were known to be dead! This implies a much higher mortality rate (than 6.0%) when the diagnosis is unrecognized. Other reports also have emphasized the high mortality rate associated with Munchausen syndrome by proxy (Bools et al. 1993; Rosenberg 1987).

Diagnosis and Assessment

The diagnosis of Munchausen by proxy should be assigned only after a careful consideration of differential diagnoses such as somatization by proxy (Table 13-4) because it is, in essence, an accusation of child abuse. As noted in the previous subsection, the diagnosis may become apparent by fortuitous findings such as the discovery of secret paraphernalia or drugs or the accidental observation of the mother smothering the child. However, when Munchausen syndrome by proxy is suspected but not confirmed, several procedures to confirm the diagnosis have been proposed. These include 1) a review of medical records of other siblings, looking for a pattern of chronic illness or unexplained death; 2) the separation of the child from the parent to determine whether a change occurs in the child's course of illness (e.g., many children suddenly recover when separated from the parent for several days or weeks); and 3) the controversial technique of video surveillance with a hidden camera. Ethical and legal questions may arise as to whether video surveillance involves an invasion of privacy. Such a procedure should be undertaken only after appropriate consultation with hospital legal staff, administration, and child protective services; such surveillance may place the child at risk (Hail et al. 2000; Southall et al. 1997).

Ayoub et al. (2002) stated that perpetrators of factitious disorder by proxy should be diagnosed with factitious disorder not otherwise specified, DSM-IV-TR code

TABLE 13-4. Differential diagnosis of Munchausen syndrome by proxy

Pediatric somatization syndromes

Unrecognized physical disease

300.19. However, providing a DSM-IV-TR diagnosis to any person who perpetuates factitious behavior is controversial because an official diagnosis might imply mitigation for misbehavior—criminal behavior in the case of Munchausen syndrome by proxy (Ford 2005).

The differential diagnosis of Munchausen syndrome by proxy, of course, always includes the possibility of underlying genuine physical disease and the fact that at times an older child may produce illness in himself or herself (Libow 2000; Peebles et al. 2005) (see Table 13-4). There also may be “blended cases” in which the child or adolescent self-produces symptoms but with the active help of the parent, who may coach the behavior (Libow 2002). At present, most pediatricians and child protection caseworkers are well aware of Munchausen syndrome by proxy, and there is a risk of becoming overly zealous in making the diagnosis. Rand and Feldman (1999) reported 4 cases of misdiagnosed Munchausen syndrome by proxy and identified another 11 cases in their review of more than 200 articles and books.

Etiology

In Munchausen syndrome by proxy, the identified patient is the victim of misbehavior by another. Adults who perpetrate this disorder may superficially seem quite normal, and frequently evaluation of them does not result in a psychiatric diagnosis (Sanders and Bursch 2002). Others may meet criteria for a somatoform disorder or a personality disorder or have previously produced factitious disease in themselves (Bools et al. 1994). Most explanations for perpetrating this behavior revolve around the idea that the perpetrator is motivated by the need to become the center of attention by playing the role of concerned parent in the high drama of life and death in a hospital.

Characteristics of perpetrators as computed by Sheridan (2003) include motherhood (76.5%); some features of personal Munchausen syndrome (29.3%); a psychiatric

diagnosis (22.8%), usually depression or personality disorder; and a personal history of abuse (21.0%).

Family dynamics and the individual psychodynamics of the perpetrator are believed to be important, but there has not been any large-scale systematic study (Mercer and Perdue 1993). Griffith (1988) studied some families with Munchausen syndrome by proxy and proposed several commonly observed features that reflect multigenerational dysfunctional families. Mercer and Perdue (1993) suggested that the mother may be both victim and perpetrator, and her behavior is an attempt to gain power and control in a powerless existence.

Management and Treatment

Ethical and Legal Issues

The primary and immediate goal in treatment of Munchausen syndrome by proxy is cessation of the behavior that perpetrates symptoms. Separation between the perpetrator and the victim is usually necessary to accomplish cessation of the behavior. In the most common form of factitious disorder by proxy (parent-perpetrated), it is necessary to place the child into some type of foster care. Visits by the parents during these separations must be carefully monitored. Such placement requires a legal hearing and involvement of the agencies that have responsibility for protecting child welfare. It is amazing to see how a chronically sick child blooms when separated from the perpetrating parent. Permanent separation of parent and child is a major legal and ethical issue; courts are understandably reluctant to act in such a manner without very serious consideration. The key question is whether the parent has been sufficiently rehabilitated to reduce risk to the child, but the nature of the support system (other parent, other family members, availability of caseworkers) is also crucial (Sanders and Bursch 2002).

Therapy for the Perpetrator

The perpetrator, who is usually the mother, should receive psychological treatment. The effectiveness of such intervention is dependent on the perpetrator's open and honest acknowledgment of his or her behavior. Unfortunately, this does not usually occur.

Treatment of the Victim

It is recognized that victims of factitious disorder by proxy experience a high incidence of varied psychiatric disorders (Bools et al. 1993; Bryk and Siegel 1997). To date, no systematic studies of treatment have been done. The specifics of treatment are dependent on the nature of the problem. One role of psychotherapy is to help the victim deal with feelings about an abusive parent.

Hospital Epidemics of Factitious Disorder by Proxy

The term *angel of death syndrome* was first used in newspaper reports (later proven to be inaccurate) in which a Las Vegas, Nevada, nurse was accused of tampering with patients' life-support equipment. The motivation was allegedly to help friends win a betting pool dealing with times of patients' deaths (Kalisch et al. 1980).

Although the case against the Las Vegas nurse was disproved, there have been multiple subsequent reports in which health care providers have been accused of causing epidemics of acute cardiac or pulmonary arrests and unusual patterns of deaths (Yorker et al. 2006). Tragically, many of these epidemics have been shown to be caused by the very persons entrusted with the patients' care. In their detailed review of multiple hospital epidemics, Yorker et al. (2006) concluded that the perpetrators were usually nurses or nurse's aides and that the victims were physically compromised: critically ill, elderly, or very young.

The epidemics tended to cluster on evening and night shifts and also involved numerous—often successful—resuscitations. Yorker et al. (2006) proposed that one motive of the perpetrators is the excitement and exhilaration derived from participating in "codes."

This kind of behavior constitutes serial murder, and prosecution has resulted in several convictions. Epidemiological techniques have been used to identify probable perpetrators, but such evidence is circumstantial and cannot be used alone to establish guilt (Sacks et al. 1988).

Malingering

By definition, individuals with malingering are motivated by specific, recognizable external incentives to produce, exaggerate, or simulate physical or psychological illness (American Psychiatric Association 2000). Incentives may be deferment for military service, avoidance of hazardous work assignments, escape from incarceration (e.g., being judged not guilty by reason of insanity), or procurement of controlled substances. Perhaps the most common incentive is financial gain, such as the receipt of disability payments or the hope of damages to be awarded in a lawsuit. It must be kept in mind that malingering is less a diagnosis than a socially unacceptable behavior with legal ramifications (Szasz 1956). Malingering often must be considered in a differential diagnosis, but much caution must be exercised in making such a "diagnosis" (Drob et al. 2009).

Malingering is most common in settings where there are external and tangible gains accrued by illness. Among these settings are prisons, military service, courtroom set-

tings that involve personal or industrial injury, and the offices of physicians who perform disability evaluations. Frueh et al. (2005) found that of men seeking Veterans Affairs specialty care for combat-related posttraumatic stress disorder, 5% had made false claims of Vietnam military service, and another 32%, while serving in Vietnam, had no documentation of combat exposure. Kay and Morris-Jones (1998) found clear-cut surveillance videotape evidence that at least 20% of the litigants registered in a pain clinic were overtly malingering their symptoms. Financial incentives *do* make a difference in symptoms and disability. In their meta-analysis of 2,353 subjects, Binder and Rohling (1996) found more abnormality and disability in patients with mild closed head injury who had financial incentives than in those who did not have such an incentive. Similarly, Paniak et al. (2002) found that when financial compensation was at issue, patients with mild traumatic brain injury had significantly increased symptoms. In contrast, Mayou (1995) conducted a prospective study in the United Kingdom on the outcome of persons involved in motor vehicle accidents and found that malingering to gain compensation was remarkably uncommon. He suggested that the high rates found in some tertiary care centers represent atypical and selected samples. The legal climate regarding lawsuits varies widely from country to country.

Clinical Features: Phenomenology, Course, and Prognosis

Malingering symptoms fall into four major categories: 1) production or simulation of an illness, 2) exacerbation of a previous illness, 3) exaggeration of symptoms, and 4) falsification of laboratory samples or laboratory reports. Embellishment of previous or concurrent illness is probably the form of malingering most frequently encountered by psychosomatic subspecialists. Bellamy (1997) noted that most exaggerated illnesses in compensation situations are a result of a combination of suggestion, somatization, and rationalization. Symptoms are usually subjective and difficult to quantify and include feigned dizziness, weakness, seizures or spells, and features of posttraumatic stress disorder (Sparr and Pankratz 1983). Patients may intensify their complaints when they are asked directly about their symptoms or when they think they are being observed. When distracted, they become physically more relaxed and at times may be seen to engage in physical activities incompatible with their symptom reports.

The malingered symptom generally disappears when the person either obtains the desired goal or is confronted with irrefutable evidence of malingering. However, it has been noted that some malingered symptoms persist even after these occurrences. It may be that the person main-

tains symptoms as a face-saving mechanism, or perhaps the symptom has in some way been incorporated as a habit into the individual's lifestyle.

Diagnosis and Assessment

As noted earlier, identification of malingering is more an issue of socially unacceptable behavior, an accusation of a person's external motives, than a psychiatric diagnosis. The clinician should consider malingering when symptom complaints and objective data are incongruent. However, the presence of secondary gains, concurrent litigation, and seeking disability are *not* evidence of malingering per se. Thus, there must be not only verification of an external motivation but also objective evidence to confirm the probability of malingering. For example, a patient who cannot walk independently when seen in the consultation suite might later be seen walking normally on a sidewalk outside the hospital. Insurance companies at times engage private investigators who use video surveillance to obtain objective evidence of malingering. For example, a man who claimed an inability to raise his arms above his shoulder was videotaped climbing a ladder onto his roof and installing a television antenna.

Psychological testing is often helpful in identifying malingering patients. The Minnesota Multiphasic Personality Inventory-2 is a useful test for patients who distort their presentations (Arbisi and Butcher 2004; McCaffrey and Bellamy-Campbell 1989; Wetzler and Marlowe 1990). This test and others have diagnostic value in assessing those who exaggerate physical and psychological symptoms (Cliffe 1992; Rawling 1992; Walters et al. 2008). Screening instruments with face validity such as the Beck Depression Inventory and the Hopkins Symptom Checklist-90 are easily distorted by patients who embellish their symptoms (Lees-Haley 1989a, 1989b), and these instruments have very limited value in the determination of malingering. Forced-choice psychological tests may be valuable in detecting malingering. If a person makes more errors than would be expected by chance, a statistical probability can be determined as to whether the person actually knew the correct answers. A recent review (McDermott and Feldman 2007) describes many of the findings and psychological tests that have been used in attempts to distinguish malingering from genuine illness.

Functional neuroimaging has been used in experimental situations to distinguish patients with feigned weakness from those with motor conversion symptoms (J. Stone et al. 2007) and to detect feigned memory impairment (Browndyke et al. 2008). However, the use of functional magnetic resonance imaging for forensic evaluations is fraught with ethical and legal questions (Moriarty 2008).

No single evaluation technique will unequivocally identify malingerers. This is particularly true when the examiner makes a subjective assessment of a feature such as sincerity of effort (Lechner et al. 1998; Main and Waddell 1998). Rather, patients must be evaluated from a complete physical and psychosocial perspective that includes various other possibilities, such as "pseudomalingering" (Ford 1983). Pseudomalingering arises when the patient uses an external incentive as a rationalization for malingered symptoms, thereby shielding himself or herself from awareness of unconscious determinants (Ford 1983; Schneck 1962). For example, a genuinely psychotic person may believe he or she is feigning psychosis to escape punishment for a crime. By believing that one is feigning the psychosis, the person is defensively shielded from conscious awareness of actual mental illness and thus incorrectly believes that he or she is in control of his or her thought processes. Another form of pseudomalingering may exist when a person consciously exaggerates a symptom because he or she truly believes that there is an underlying problem. An underlying problem may exist, but the examiner who picks up on the malingering may mistakenly attribute the entire problem to malingering.

The differential diagnosis of malingering includes somatoform disorders as well as factitious disorders. These clinical syndromes have indistinct boundaries, and a person may meet criteria for different disorders at different times (Ford 1992; Jonas and Pope 1985; Nadelson 1985). Relevant factors that may play a role in assessment include evidence of past somatization as well as coexistence of anxiety, mood, substance, or personality disorders. Patients with unconsciously determined somatoform disorders (e.g., conversion) are usually consistent in their symptom presentation irrespective of their audience or whether they believe they are being observed.

Etiology

By definition, the etiology of malingering is to obtain external gain as a result of the symptoms. However, malingering does tend to be more common in persons who may have hysteroid features. Because of personality characteristics (e.g., histrionic or sociopathic) or cognitive style, some persons may be more inclined toward simulated illness.

Management and Treatment

Malingering is more a management problem than a therapeutic issue. With this in mind, the primary physician and psychosomatic subspecialist must be circumspect in their approach to the patient. Every note must be written with the thought in mind that it may be read by the patient or even become a courtroom exhibit. Malingering is often

listed among diagnostic possibilities but is rarely proved conclusively in medical settings.

The person who is suspected of malingering, as a rule, should not be confronted with a direct accusation. Instead, subtle communication can indicate that the physician is "on to the game" (Kramer et al. 1979). One technique is to mention, almost in passing, that diagnostic tests indicate no "serious" basis for the symptoms. The malingerer may feel freer to discard the symptom if the physician suggests that patients with similar problems usually recover after a certain procedure is performed or a particular length of time has passed. Such suggestions are often followed by perceptible improvement, if not recovery. This technique provides face-saving mechanisms for the patient to discard the symptom. Still, some patients, particularly those seeking drugs, will leave treatment and seek medical care elsewhere. Others, in an effort to prove the existence of their disease, may vastly intensify their symptoms. In doing so, they may create such caricatures of illness that their efforts to malingering become obvious to all.

Conclusion

Requests for psychiatric consultation on patients with suspected factitious disorder or malingering are relatively infrequent. However, when the psychosomatic medicine subspecialist does become involved with one of these cases, a disproportionate amount of time is typically required. Issues of diagnosis, legal and ethical considerations, and the need to provide liaison with the medical staff may make one of these patients the primary focus of one's clinical activities for several days. Nevertheless, they are fascinating patients who demonstrate the extreme end of the continuum of abnormal illness behavior. They are rarely forgotten.

Eating Disorders

Michael J. Devlin, M.D.

Joel P. Jahraus, M.D.

Ilyse Dobrow DiMarco, Ph.D.

ALTHOUGH FULL-SYNDROME eating disorders are relatively rarely diagnosed in medical settings, eating disorder symptoms—such as uncontrolled eating, excessive dieting, and marked body image distress—occur quite commonly. Two important trends may account, at least in part, for the upsurge in these symptoms: 1) the well-documented increase in the prevalence of overweight and obesity in the United States (Ford and Mokdad 2008); and 2) the marked decrease in percentage of body fat of the culturally defined “ideal woman,” as exemplified by Miss America pageant winners (Rubinstein and Caballero 2000). Caught between the reality of an obesity-promoting environment and an increasingly unattainable body image ideal, it is perhaps unsurprising that growing numbers of individuals, particularly women, engage in the desperate attempts to lose weight and the dysregulated eating that characterize the eating disorders.

The mortality and morbidity rates in eating disorders are considerable. Anorexia nervosa is among the most lethal of psychiatric disorders, with mortality rates of approximately 5% per decade of illness in the longest follow-up studies (Papadopoulos et al. 2009). Although the lethality of bulimia nervosa is much less than that of anorexia nervosa, the purging behaviors characteristic of this disorder can lead to significant medical and dental morbidity. Binge eating, to the degree that it contributes to the onset or maintenance of obesity, may contribute to obesity-related morbidity and death (Schelbert 2009). But perhaps the greater costs of eating disorders are the time and

energy spent on the pursuit of thinness, often to the exclusion of interpersonal, vocational, and recreational sources of satisfaction; the shame and secrecy that often accompany these illnesses; and the ultimate loss of function when the symptoms remain untreated.

Among the most puzzling of psychiatric illnesses for practitioners who regard eating as a healthy and satisfying part of life, eating disorders are also among the most difficult to treat. Yet, as summarized in this chapter, progress is being made in the conceptualization, characterization, and treatment of eating disorders.

Definitions and Clinical Features

The diagnosis and treatment of disordered eating in the medical setting are among the most poorly studied and most important areas for ongoing clinical research. To fully appreciate the spectrum of eating disorders presenting in primary care and general medical settings, it is useful to apply both a categorical and a dimensional approach. The major eating disorder syndromes, including the DSM-IV-TR (American Psychiatric Association 2000) diagnostic categories for eating disorders, are discussed in the subsections that follow. Paradoxically, the most common eating disorder, eating disorder not otherwise specified (NOS), is also the most poorly defined and studied, and the dimensional approach to assessment may be of particular use in patients with this diagnosis.

Anorexia Nervosa and Bulimia Nervosa

Anorexia Nervosa

Anorexia nervosa is first and foremost a syndrome of voluntary starvation. However, the term *voluntary* must be interpreted with caution. Although it is true that patients with anorexia nervosa in some sense choose to restrict their eating, this choice is greatly influenced by genetic vulnerabilities, cultural forces, and life events. Patients in the late stages of anorexia nervosa will often clearly describe that any sense of free will they once may have had regarding their condition has, to a great degree, vanished.

The phenomenon of unexplained starvation, or “nervous consumption,” in an otherwise healthy individual was reported as long ago as the late seventeenth century (Morton 1689). Although the practice of extreme food restriction for reasons generally unrelated to body image occurred before the nineteenth century (Brumberg 1988), it was not until the 1870s that the modern syndrome of anorexia nervosa was recognized nearly simultaneously by Lasègue (1873) and Gull (1874), the latter of whom coined the term *anorexia nervosa*. This modern concept was further refined in the 1960s by psychiatrist Hilde Bruch (1973) and others, who recognized low self-esteem and body image distortion as core features of the disorder.

In keeping with earlier conceptions, the current definition of anorexia nervosa is centered on the behavioral feature of starvation. To be diagnosed with anorexia nervosa, patients must manifest weight loss, or the absence of expected weight gain, leading to a state of significant undernourishment, as reflected by a weight markedly (i.e., at least 15%) lower than expected for gender and height. However, to meet modern (DSM-IV-TR) criteria for anorexia nervosa, an individual must manifest the more recently identified psychological features. The diagnosis requires an overconcern with weight and shape, which may or may not take the form of an actual misperception of body fatness but must reflect an overinvestment in thinness as a central feature of one's self-worth. In addition, amenorrhea is a requirement for postmenarchal women. A non-fat-phobic variant of anorexia nervosa has been described, particularly in non-Western societies; interestingly, it appears to be associated with milder eating pathology (Thomas et al. 2009) and a lower likelihood of progressing to bulimia nervosa in outcome studies (Lee et al. 2003).

Although patients with anorexia nervosa often view their illness as that which makes them unique or special, there is a surprising uniformity in the way they present, and there are a number of associated features that occur quite predictably. In addition to severely restricting their intake of food, many individuals with anorexia nervosa are also compulsive exercisers. Some anorexic patients engage in strict di-

eting without any binge eating or purging (restricting type), whereas others periodically engage in purging (e.g., vomiting, laxative abuse) or uncontrolled binge eating (binge-eating/purging type). Patients with anorexia nervosa are often rigid and perfectionistic, not only in their adherence to restrictive eating and compulsive exercise practices but also in other areas of life. Interestingly, the narrowing of interests, increasing focus on food, and peculiar food-related rituals (toying with food, consumption of unusual food combinations, possessiveness toward food) were also observed in the Minnesota semistarvation study subjects. These subjects were male World War II conscientious objectors who volunteered to participate in a study of the physiological and psychological effects of starvation, eventually losing 25% of their body weight (Franklin et al. 1948). The fact that these men, who had no prior histories of eating disorders, exhibited behaviors so reminiscent of those seen in anorexia nervosa suggests the degree to which these features of the illness are driven by the physiological effects of starvation.

Bulimia Nervosa

The other major eating disorder currently defined in DSM-IV-TR is bulimia nervosa, popularly known as the binge-purge syndrome. This syndrome, first described as a variant of anorexia nervosa (Russell 1979) and later applied to individuals of normal weight, comprises regular uncontrolled consumption of objectively large amounts of food (binge eating), regular use of unhealthy compensatory methods intended to undo the effects of eating, and preoccupation with weight and/or shape as a central component of self-worth. Eating binges typically consist of more than 2,000 kcal and, contrary to popular belief, are not primarily composed of carbohydrate (Walsh et al. 1989). Compensatory behaviors include purging methods (i.e., elimination of food and fluids from the body by the use of vomiting, laxatives, diuretics, or enemas) and nonpurging methods (such as fasting or excessive exercise) for preventing weight gain. Patients with diabetes mellitus who have bulimia nervosa may attempt to purge by reducing or omitting their insulin dosage to promote glycosuria, thereby eliminating calories from the body. Although most individuals who present for treatment for bulimia nervosa are of normal weight, the diagnosis can also be made in overweight or obese individuals. Under the current diagnostic system, individuals who simultaneously meet criteria for anorexia nervosa and bulimia nervosa are diagnosed as having anorexia nervosa, binge-eating/purging type. In fact, the progression from anorexia nervosa to bulimia nervosa is quite common, occurring in about one-half of patients with restricting anorexia nervosa (Bulik et al. 1997). Normal-weight patients with bulimia nervosa progress to anorexia nervosa somewhat less frequently.

Psychiatric Comorbidity of Anorexia Nervosa and Bulimia Nervosa

Individuals with anorexia nervosa and bulimia nervosa often manifest comorbid symptoms of depression and anxiety. Many studies suggest that, at least in clinical samples, a majority or significant minority of individuals with eating disorders also have a lifetime diagnosis of affective or anxiety disorder (Godart et al. 2007; D.B. Herzog and Eddy 2007; Hudson et al. 2007; Kaye et al. 2004). Among affective disorders, major depressive disorder occurs most frequently, although eating disorders also appear prevalent among patients with bipolar disorders and are associated with obesity and other psychiatric morbidity (Wildes et al. 2008). Among anxiety disorders, obsessive-compulsive disorder (OCD) is particularly prominent (Kaye et al. 2004) and has been of particular interest because eating- and exercise-related practices, particularly in individuals with anorexia nervosa, may include the repetitive, ritualized behaviors characteristic of OCD. According to a recent report, a history of overanxious disorder of childhood is present in nearly 40% of individuals with anorexia nervosa and usually precedes onset of the eating disorder. Individuals with this history reported more severe eating disorder pathology than the noncomorbid group (Raney et al. 2008). Although in some cases anxiety or depressive symptoms may be secondary to disordered eating, it is likely that shared etiological factors largely account for the observed comorbidity (Bulik 2002). In any case, a diagnosis of depression or anxiety disorder, particularly in an individual at risk for an eating disorder (i.e., adolescent and young adult women) should raise the clinician's level of suspicion that an eating disorder may also be present. In addition, the comorbid diagnosis must of course be taken into account in devising the treatment plan. In general, treatment can proceed simultaneously with the emphasis, for individuals with anorexia nervosa, on weight restoration as a precondition for successful treatment of comorbid conditions.

The relationship between eating disorders and substance use disorders is of great theoretical as well as practical interest, because the idea of "food addiction" suggests the possibility of common underlying pathophysiological mechanisms (Del Parigi et al. 2003). It is certainly the case that eating and substance abuse disorders co-occur at a rate significantly higher than that explainable by chance (Holderness et al. 1994), and substance use disorders are particularly associated with bulimic symptomatology (Root et al. 2010). However, in contrast to the data on the overlap between eating, affective, and anxiety disorders, the available data on familial transmission of eating and substance abuse disorders fail to support the existence of common genetic risk factors (von Ranson et al. 2003; Wil-

son 2002). An exception to this general pattern for eating disorders is binge-eating disorder, for which there is evidence for shared transmission with substance use disorders (Lilenfeld et al. 2008). At a phenomenological level, the experience of patients with eating disorders, and even the terminology patients use (e.g., "compulsive" exercise, "going on a binge"), can often mimic the argot of substance abuse. Of course, the one major difference is that, to the degree that food is considered the abused substance, abstinence is not a therapeutic option. For patients with comorbid eating and substance use disorders, it is recommended that the substance abuse problem be prioritized. For patients in whom substance abuse is not severe, treatment for the two disorders may proceed simultaneously (Wilson 2002). Substance use disorders may significantly affect the outcome of eating disorders. In one large-scale study, severity of alcohol use disorder was a significant predictor of death in anorexia nervosa, with a significant minority of patients apparently developing alcoholism subsequent to the onset of their eating disorder. This finding suggests that patients with eating disorders should be carefully assessed over time for the emergence or worsening of a substance use disorder (Keel et al. 2003).

Published rates of Axis II comorbidity in eating disorder samples have been highly variable. However, it is clear that there is no one personality type that characterizes individuals with anorexia nervosa or bulimia nervosa. Rather, in an examination of individuals with eating disorders across diagnoses, Westen and Harnden-Fischer (2001) reported that three personality clusters emerged: high-functioning/perfectionistic, constricted/overcontrolled, and emotionally dysregulated/undercontrolled. These personality subtypes have also been observed in adolescents with eating disorders (Thompson-Brenner et al. 2008). The assessment of personality dimensions may be important when planning treatment for individuals with eating disorders (Tasca et al. 2009).

Eating Disorders and Obesity

Although obesity is not, in and of itself, an eating disorder (Devlin et al. 2000), obese individuals may have eating disorders such as binge-eating disorder (BED), night-eating syndrome, and sleep-related eating disorders (Howell et al. 2009; Stunkard and Allison 2003). BED (uncontrolled binge eating in the absence of regular compensatory behavior) has been a particular focus of research since it was identified in Appendix B of DSM-IV (American Psychiatric Association 1994) as a criteria set requiring further study. Although the status of BED is uncertain (Devlin et al. 2003), the phenomenon of binge eating among the obese has been clearly identified, and its associated features have

been studied (Dingemans et al. 2002). In particular, binge eating in the obese has been found to be associated with higher rates of major medical disorders, greater health dissatisfaction, and a higher lifetime prevalence of depression, panic, phobias, and alcohol dependence (Bulik et al. 2002), and stopping binge eating has a favorable effect on weight loss outcomes (Gorin et al. 2008).

Night-eating syndrome—characterized by a disrupted circadian eating rhythm with excessive consumption at the end of the day—has been much less thoroughly studied, but preliminary studies suggest that it has distinct behavioral/psychological and physiological features. Nocturnal sleep-related eating disorders among the obese represent a similar phenomenon but are characterized by recurrent episodes of eating after arousal from sleep, sometimes with amnesia or consumption of unusual food items, often with associated sleep disorders (Howell et al. 2009). Similar patterns have been noted to occur as a side effect of zolpidem (Najjar 2007) and similar hypnotics. Although the best methods for sequencing or combining treatments for obesity and eating disorders have not yet been fully worked out, approaches for simultaneously treating eating disorders and obesity have been described (Devlin 2001).

Atypical Eating Disorders

A final category of eating disorders in DSM-IV-TR is eating disorder NOS, defined as a clinically significant eating disorder that does not meet diagnostic criteria for any defined eating disorder diagnosis. Examples are 1) regular occurrence of subjective binge episodes (i.e., uncontrolled consumption of amounts of food not deemed large) followed by purging, 2) strict dieting and weight loss without amenorrhea, or 3) continuous uncontrolled snacking throughout the day with no discrete binge episodes. Notably, the phenomenon of purging in the absence of binge eating has recently received consideration as an independent eating disorder called purging disorder (Keel et al. 2005). Preliminary studies have demonstrated that this disorder appears to be distinct from bulimia nervosa in regard to subjective and physiological responses to a test meal (Keel et al. 2007). In addition, patients who have behaviors typical of eating disorders, such as food avoidance or vomiting, but who deny body image concern—attributing their symptoms instead to somatic sensations such as bloating, nausea, intolerable fullness, or extreme discomfort after eating—may be diagnosed as having eating disorder NOS once medical etiologies have been ruled out. Community-based studies have typically found that these atypical eating disorders are more common than anorexia nervosa and bulimia nervosa. Nonetheless, they have received relatively little attention in the literature and are

poorly understood at this point. Although much of the literature is based on samples seen in eating disorder clinics that are geared toward treating patients with full-blown anorexia nervosa and bulimia nervosa, individuals seen in the medical setting who are not specifically presenting for treatment of an eating disorder may be particularly likely to manifest eating disorder NOS.

Given this state of affairs, it is perhaps useful to transcend conventional diagnostic categories and consider a transdiagnostic or dimensional approach to the classification (Fairburn et al. 2003) and treatment (Fairburn 2008) of eating disorders. One dimension of the patient's condition is *nutritional*, with the spectrum ranging from undernourished to severely obese. A second dimension is *behavioral*, with behaviors of interest including binge eating, nighttime eating, uncontrolled eating of some other variety, extreme dieting, purging, and so forth. A third dimension is *psychological*. This dimension includes body image distress—perhaps the most unifying feature of individuals with eating disorders, be they emaciated, of normal weight, or obese—and psychiatric comorbidity. In addition to assessing the psychological dimension, it is important to assess the patient's *motivation for change*. In contrast to anorexia nervosa, which is often embraced by patients as a lifestyle choice that they are ambivalent about relinquishing, patients with bulimia nervosa are generally more motivated to break the binge-purge cycle, although they may be less enthusiastic about confronting the dieting and body obsession that underlie the behavior. Obese patients with eating disorders may be highly motivated to lose weight but may have unrealistic expectations of thinness that continually undermine their weight-control attempts. A consideration of the various dimensions of a given patient's eating disorder syndrome and the particular history of the patient (e.g., chronicity, rapidity of change, and functional impairment) may assist the practitioner in the difficult task of applying findings from clinical studies of typical eating disorders to the atypical eating disorders more commonly observed in the medical setting.

Eating Disorders in Children

Eating disorders in children and adolescents represent a particular concern because, if not diagnosed and treated, they may have lifelong psychological and medical consequences (see also Chapter 34, "Pediatrics"). As is the case for adult eating disorders, the classification of child and adolescent eating disturbances is the subject of active debate (Bravender et al. 2007). Disordered eating patterns occurring before puberty include food avoidance emotional disorder, selective eating, pervasive refusal syndrome, food phobias, functional dysphagia, and full-syndrome anorexia nervosa (Lask and Bryant-Waugh 1997; Nicholls and

Bryant-Waugh 2009; Rosen 2003). *Food avoidance emotional disorder* is similar to but less severe than anorexia nervosa and carries a better prognosis. *Selective eating* is diagnosed in children who eat only a small number of foods but whose growth and development are generally normal. *Pervasive refusal syndrome* is a severe disorder in which refusal to eat is accompanied by refusal to function in other spheres (e.g., walking, talking, self-care) and is probably not best viewed as an eating disorder. Similarly, specific *food phobias* are often reflective of more pervasive anxiety disorders, and obsessional fears related to food may be particularly common in boys presenting with childhood anorexia nervosa. Children with *functional dysphagia* avoid food due to a fear of swallowing, choking, or vomiting for which no organic etiology can be identified. Bulimia nervosa is thought to occur quite rarely before puberty. Problems of food refusal, selective eating, phobias, failure to thrive, pica, and rumination in children are discussed in detail in Chapter 34, "Pediatrics." However, it is notable that symptoms such as eating conflicts, struggles with food, and unpleasant meals in early childhood have been found to be associated with the later development of eating disorders (Kotler et al. 2001) and therefore should be followed closely.

As reviewed in a Society for Adolescent Medicine position paper (Rome et al. 2003), dieting among school-age girls is increasingly common, and prevention and screening for eating disorders may avert the progression from pathological dieting to clinically significant eating disorders. Just as for adults, eating disorder symptoms in adolescents carry significant medical and psychiatric comorbidity (Herpertz-Dahlmann 2009). Thus, the identification of a significant eating disorder symptom, even in the absence of a formal diagnosis, should trigger some form of intervention to address the problem rather than a wait-and-see approach, which may allow the problem to become more entrenched. Pathological dieting is in some cases difficult to differentiate from normative dieting, but extreme distress about weight or shape, rapid weight loss, frequent weight or size checking, rigid adherence to dietary or exercise regimens, and use of unhealthy dietary practices are all worrisome signs. From a prevention standpoint, eating disorder NOS should probably be the most commonly diagnosed eating disorder in this group.

Feeding Disorders of Infancy or Early Childhood

Quite distinct from the eating disorders described in the preceding subsections are the feeding disorders seen in infants and children, including pica, rumination disorder, and feeding disorder of infancy or early childhood (Nicholls and Bryant-Waugh 2009). *Pica* refers to the consumption of nonnutritive substances such as hair, dirt, pebbles, or clay, sometimes but not always occurring in

individuals with mental retardation, but meriting a separate diagnosis only if it is sufficiently severe to warrant independent clinical attention. *Pica* may be associated with poisoning (e.g., from lead paint) or mechanical obstruction. *Rumination* refers to the regurgitation, rechewing, and reswallowing of ingested food. Although most commonly seen in infants, rumination may also be seen in older children with mental retardation. Interestingly, a small proportion of adolescent and adult patients with anorexia nervosa and bulimia nervosa report rumination.

Finally, feeding disorder of infancy or early childhood is usually diagnosed in the first year of life but sometimes in children up to 3 years of age, for whom food intake is inadequate to support normal growth and development. As reviewed by Rudolph and Link (2002), the early recognition of feeding problems and diagnostic workup to exclude gastrointestinal, metabolic, sensory, or other general medical etiologies can lead to more appropriate management of affected children and their families.

Epidemiology

A number of researchers have attempted to establish incidence and prevalence rates for anorexia nervosa, bulimia nervosa, and (to a lesser extent) BED, and findings have been well summarized (Keski-Rahkonen et al. 2008). Anorexia nervosa is thought to have a lifetime prevalence of approximately 0.9%–2.2% in women and 0.2%–0.3% in men. Its incidence appears to have increased during the decades of the 1960s and 1970s but to have stabilized thereafter. In the United States, the National Comorbidity Survey Replication yielded a lifetime prevalence of 0.9% in women and 0.3% in men (Hudson et al. 2007). Studies of anorexia in non-Western countries demonstrate that it does occur, but overall at lower rates than in Western societies. However, subgroups in these countries (e.g., the minority mixed and white population in Curaçao) may show incidence rates similar to those in Western developed countries (Hoek et al. 2005).

Bulimia nervosa is somewhat more prevalent than anorexia nervosa, with lifetime prevalence rates of 1.5%–2% in women and 0.5% in men (Keski-Rahkonen et al. 2008). The National Comorbidity Survey Replication yielded lifetime prevalence rates of 1.5% and 0.65% among women and men, respectively (Hudson et al. 2007). Like anorexia nervosa, bulimia nervosa most often affects Western Caucasian adolescents and young adults. Regarding time trends, the most recent evidence suggests that rates of bulimia nervosa peaked in the early 1990s and have begun to decrease in Western developed countries though its clinical prevalence in non-Western countries may be rising (Lee et al. 2010). Some research has suggested that certain seg-

ments of the population, such as elite athletes (Smolak et al. 2000) and dancers (Dotti et al. 2002), are at particular risk for developing symptoms of bulimia nervosa or anorexia nervosa.

There have been few studies of the epidemiology of BED. The limited data that have been collected suggest that BED has a lifetime prevalence similar to or slightly higher than that of bulimia nervosa, with the National Comorbidity Survey Replication yielding rates of 3.5% and 2.0% for women and men respectively (Hudson et al. 2007). Roughly 5%–10% of those seeking treatment for obesity have BED. Unlike anorexia nervosa and bulimia nervosa, approximately a quarter of those with BED are male, and most patients with BED present with the illness in their 40s.

In establishing epidemiological data for eating disorders, it is important to consider not only individuals who meet diagnostic criteria for anorexia nervosa, bulimia nervosa, and BED but also the large numbers of individuals who are diagnosed with eating disorder NOS or who do not fulfill all DSM-IV-TR criteria for an eating disorder but nonetheless have serious eating pathology. In terms of eating disorder NOS, Fairburn and Harrison (2003) cited three community-based case series studies that all found eating disorder NOS to be a more common diagnosis than anorexia nervosa or bulimia nervosa. In addition, studies of subsyndromal anorexia nervosa, bulimia nervosa, and BED indicate that these subthreshold diagnoses are strikingly similar to their diagnostic counterparts in terms of distress and functional impairment. Therefore, to make a truly accurate assessment of the degree of eating pathology in the general population, epidemiologists must consider both eating disorder NOS and subthreshold eating disorders in addition to anorexia nervosa, bulimia nervosa, and BED.

Course and Outcome

Studies of the long-term course of anorexia nervosa suggest that there is no one typical outcome. Rather, the illness tends to require long-term treatment, with some patients achieving full recovery, others experiencing a longer course of partially remitted or unremitted illness, and some dying as a direct or indirect result of the illness (Pike 1998), with risk of suicide particularly pronounced (Berkman et al. 2007). Mortality rates are as high as 5% per decade of illness in the longest follow-up studies (Nielsen 2001); of surviving patients, fewer than half recover fully, one-quarter to one-third recover partially, and one-fifth remain chronically ill (Steinhausen 2002, 2009). These figures are cross-nationally consistent (Lee et al. 2003). The outcome of patients treated as adolescents appears to be

more favorable (Strober et al. 1997), underscoring the importance of early intervention or, ideally, prevention. Bulimia nervosa generally has a more favorable course than anorexia nervosa. Unlike anorexia nervosa, bulimia nervosa does not appear to be associated with increased mortality risk (Berkman et al. 2007). However, long-term follow-up studies suggest that 10 years after presentation, nearly one-third of patients continue to binge and purge regularly (Keel et al. 1999). The outcome of eating disorder NOS is less well defined. However, it is clear that these atypical eating disorders often represent partial recovery from full-syndrome eating disorders or evolve into fully developed anorexia nervosa and bulimia nervosa (Fairburn and Harrison 2003); careful diagnosis and aggressive treatment are therefore warranted.

Several studies have identified specific historical and medical factors that predict good versus poor outcome in eating disorders (Table 14-1). In addition, treatment-related and posttreatment characteristics may predict response. For anorexia nervosa, a high rate of weight gain during inpatient treatment (Lund et al. 2009), higher post-treatment body mass index (BMI), lower rate of weight loss and lack of excessive exercise during the initial weeks following inpatient discharge (Carter et al. 2004; Kaplan et al. 2009), high motivation to change at discharge (Castro-Fornieles et al. 2007), low residual concern about shape and weight (Carter et al. 2004), higher percentage body fat following weight restoration (Mayer et al. 2007), and higher dietary energy density and diet variety score following weight restoration (Schebendach et al. 2008) are all predictive of good outcome. For bulimia nervosa, early change in treatment (Agras et al. 2000a; Fairburn et al. 2004), post-treatment binge abstinence, less-restricted food intake, low cue reactivity (i.e., urges to binge eat in response to cues) (Bulik et al. 1998), and less preoccupation with and ritualization of eating following treatment (Halmi et al. 2002) are all predictive of good outcome.

Assessment and Diagnosis

Assessment

The assessment of patients with symptoms suggestive of eating disorders presents several challenges. The clinical presentation may be confusing in that it may be difficult to determine whether behaviors such as food restriction or vomiting are driven by psychological or somatic distress, and the medical history is often vague and nonspecific. Moreover, as summarized above under "Psychiatric Comorbidity of Anorexia Nervosa and Bulimia Nervosa," comorbid psychiatric conditions frequently occur and may further complicate the presentation. It is often difficult to

TABLE 14-1. Prognostic factors in eating disorders

Factors predicting negative outcome	Factors predicting favorable outcome
Anorexia nervosa	
History of premorbid development or clinical abnormalities	Early age at onset
Binge eating and/or purging	Hospitalization for an affective disorder before baseline assessment
Long duration of illness	Short interval between symptom onset and beginning of treatment
Low body mass index at hospital admission	Conflict-free child-parent relationships
High serum uric acid level	Histrionic personality traits
High serum creatinine level	
Low serum albumin level	
Obsessive-compulsive personality traits	
Comorbid affective disorder	
Comorbid substance abuse	
Severity of alcohol use disorder during follow-up	
Bulimia nervosa	
Poor pretreatment global functioning	Younger age
Premorbid parental obesity	Shorter duration of symptoms
History of obesity	Less severe symptoms
Low self-esteem	Absence of concurrent disruptive pathology
Comorbid major depression	Strong motivation for treatment
Comorbid anxiety disorder	High self-directedness (TCI)
Comorbid alcohol abuse	
Impulsivity	
Comorbid personality disorders (particularly borderline)	

Note. TCI = Temperament and Character Inventory (Cloninger CR: The Temperament and Character Inventory [TCI]: A Guide to Its Development and Use. St. Louis, MO, Center for Psychobiology of Personality, Washington University, 1994).

ascertain whether the comorbid psychiatric illness is causally related to the eating disorder or is more indirectly involved in the manifestation of the eating disorder. As an illustration of the latter, an individual with comorbid social phobia may experience a flare-up of eating disorder symptoms in social situations.

Probably the single most important component of the workup for eating disorders is a thorough history, covering the nutritional, behavioral, psychological, and motivational features discussed above under "Atypical Eating Disorders." The history should include past and recent patterns of eating, abnormal weight control behavior, associated beliefs and attitudes, timing of emergence of issues with eating and weight, lifetime weight course, and attitudes toward body image. Although obesity and extreme emaciation are readily apparent, the behaviors associated with these bodily states are not. Normal-weight patients

with eating disorders may appear entirely healthy, and patients with anorexia nervosa may attempt to persuade the clinician that they are "naturally thin." Patients with eating disorders may hide their symptoms for several reasons. Behaviors such as binge eating and purging are often experienced by patients as shameful or disgusting. Patients with anorexia nervosa often feel that they must hide their restrictive dieting and compulsive exercise to avoid being prevented from continuing them. Obese patients with eating disorders may be particularly likely to minimize contact with health care providers because they fear being blamed or because they blame themselves for their obesity. Bearing this in mind, clinicians should employ a nonjudgmental assessment style that recognizes the patient's ambivalence and engages the patient in a medically informed discussion of the nature of the illness and the options for treatment. A useful approach to the assessment of eating

disorder symptoms in a primary care setting was described by Kreipe and Yussman (2003).

Of particular importance to psychosomatic medicine specialists is the medical evaluation of patients with eating disorders. When the patient displays behaviors and attitudes characteristic of eating disorders (e.g., a classic binge-purge pattern, an unhealthy and excessive dieting regimen, or a lack of concern about weight loss or abnormal eating behaviors), the workup to establish a diagnosis of an eating disorder need not be exhaustive in ruling out primary organic disorders. No laboratory testing is required to make the diagnosis of an eating disorder unless the historical or physical evidence suggests the possibility of an organic etiology. However, for patients with an atypical presentation or those in whom an eating disorder is essentially a diagnosis of exclusion, the workup should be more extensive and the level of suspicion for an underlying organic etiology or sociocultural explanations should remain high. In patients known to have an eating disorder, physical examination and laboratory testing are key in evaluating any medical complications (see "Medical Complications" later in this chapter) or comorbid medical illnesses and in guiding treatment.

When the medical provider is seeing the patient for the first time, he or she must, in collaboration with the mental health provider, determine the level of care that is needed and the urgency of intervention. As outlined in the American Psychiatric Association (2006) "Practice Guideline for the Treatment of Patients With Eating Disorders," the physical assessment of the patient should include 1) complete physical examination, with attention to evidence of dehydration, acrocyanosis, lanugo, salivary gland enlargement, and scarring on the dorsum of the hands (Russell's sign); 2) vital signs with orthostatic determination of blood pressure and pulse; 3) assessment of physical and sexual growth and development, including height and weight (for pediatric patients a review of the patient's growth chart may be helpful); and 4) dental examination.

Laboratory evaluation should be individualized for the particular patient. In accordance with the American Psychiatric Association (2006) "Practice Guideline for the Treatment of Patients With Eating Disorders," the routine workup should include serum electrolytes, blood urea nitrogen and creatinine, liver enzymes, serum albumin, thyroid function tests, complete blood cell count, and urinalysis. Severely malnourished patients should receive additional blood chemistry assessments—including calcium, magnesium, phosphate, and ferritin levels—and an electrocardiogram, as well as 24-hour urine for creatinine clearance. Patients who are chronically underweight should be assessed for osteopenia and osteoporosis using dual-energy X-ray absorptiometry, and serum estradiol (or tes-

tosterone in males) may be assessed. Other tests that are not performed routinely but may be indicated in particular clinical situations include serum amylase, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels; computed tomography or magnetic resonance imaging (MRI) of the brain; screening stool for blood, and screening stool or urine for bisacodyl, emodin, aloecmodin, and rhein in patients with suspected laxative abuse. Although elevated serum amylase concentration is a frequent concomitant of vomiting, this test is not sufficiently sensitive or specific to serve as a useful screening tool for unreported vomiting (Walsh et al. 1990).

Large-scale screening for eating disorders may be a priority in some settings, particularly those in which the prevalence is known to be relatively high, such as high school or university health services. Although a variety of self-report and interview-based assessment tools are frequently used in research settings, one well-established instrument that can be recommended for its brevity and ease of use is the Eating Attitudes Test (EAT-26), originally developed to assess attitudes and behaviors characteristic of anorexia nervosa and also useful in detecting bulimia nervosa (Garner et al. 1982). Another more recently developed screening tool is the SCOFF, a five-item scale that, in initial studies, has good sensitivity and specificity for detecting anorexia nervosa and bulimia nervosa in adults (Morgan et al. 1999). The SCOFF questions are 1) Do you make yourself Sick because you feel uncomfortably full? 2) Do you worry you have lost Control over how much you eat? 3) Have you recently lost more than One stone (14 pounds) in a 3-month period? 4) Do you believe yourself to be Fat when others believe you are too thin? and 5) Would you say Food dominates your life?

Differential Diagnosis

Hyperphagia, hypophagia, and altered eating patterns occur as features of a variety of medical and psychiatric illnesses and do not, in and of themselves, constitute formal eating disorders according to the standard of DSM-IV-TR. Table 14-2 lists some medical and psychiatric illnesses to consider in the differential diagnosis of an eating disorder. Two conditions of particular interest are Prader-Willi syndrome and Kleine-Levin syndrome.

Prader-Willi syndrome (PWS) is a multisystem disorder characterized by neonatal hypotonia, later obesity, hyperphagia, hypogonadotropic hypogonadism, and mental retardation. In contrast to most obese individuals, those with PWS have markedly elevated levels of ghrelin, an enteric hormone that stimulates growth hormone secretion and food intake (Haqq et al. 2003). PWS occurs sporadically, as a result of either microdeletion of chromosome 15p (70%) or maternal disomy of chromosome 15 (30%).

TABLE 14–2. Medical and psychiatric differential diagnosis of eating disorders

System	Diagnosis
Endocrine	Diabetes mellitus, hyperthyroidism, Addison's disease, Sheehan's syndrome (postpartum pituitary necrosis), panhypopituitarism
Gastrointestinal	Malabsorption, pancreatitis, cystic fibrosis, inflammatory bowel disease, peptic ulcer disease, superior mesenteric artery syndrome, Zenker's diverticulum, dysmotility disorders, gastric adenocarcinoma
Neurological	Psychomotor or limbic seizures, degenerative neurological conditions (Pick's disease, Alzheimer's disease, Huntington's disease, Parkinson's disease), hypothalamic or diencephalic tumor
Other medical	Malignancies (especially lymphoma and gastrointestinal cancers), collagen vascular disorders, chronic infections (especially tuberculosis, human immunodeficiency virus, fungal disease), parasitic infections, chronic renal failure, drug-induced appetite/weight change (e.g., corticosteroids, novel antipsychotics)
Psychiatric	Body dysmorphic disorder, melancholic major depression, atypical depression, obsessive-compulsive disorder, substance use disorder, dementia, factitious disorder, somatization disorder, psychotic disorder

Care of individuals with PWS can be challenging, primarily due to hyperphagia, food seeking and obesity, and conduct disorder, particularly manifested as tantrums or oppositional behavior (Couper 1999).

Kleine-Levin syndrome is a rare self-limited disorder of unknown origin that usually affects adolescent males and is characterized by episodic hypersomnia, increased appetite, and behavioral and psychiatric disturbances. Individuals typically function normally between episodes (Papacostas and Hadjivasilis 2000).

The presence of body image disturbance or intentional weight manipulation is usually quite useful in differentiating true eating disorders from other eating-related disorders. In the absence of these features, the diagnosis of an eating disorder should be regarded as provisional, and medical disorders such as those listed in Table 14–2 should be thoroughly considered in the differential diagnosis.

Risk Factors and Etiology

As research on the etiology of eating disorders has progressed, it has become clear that the onset of an eating disorder results from a confluence of factors: sociocultural, biological, and genetic. Most of what is currently known about the etiology of eating disorders focuses on anorexia nervosa and bulimia nervosa. Risk factors for BED may overlap with—but are not the same as—those for anorexia nervosa and bulimia nervosa and are considered briefly below under “Etiology of Binge-Eating Disorder.”

Culture

Although eating disorders were once thought to affect mainly upper-class, Western women from majority cultures, they are increasingly prevalent among individuals from lower socioeconomic sectors and minority ethnic

groups, both in the United States and in other countries (Gard and Freeman 1996; Striegel-Moore 1997). Despite the limitations of existing research in this area, a few facts have been reasonably well established. Across cultures, female gender is a robust risk factor for eating disorders, and the period of greatest risk of onset is during adolescence. Media exposure to the idealization of thinness appears to confer increased risk at least in the short term (Striegel-Moore and Bulik 2007). As Polivy and Herman (2002) explain, the “idealization of thinness” in cultures of abundance may trigger for some an intense focus on their body shape and weight. This intense focus, in turn, may precipitate the development of eating disorder pathology. Thus, a culture of abundance (and the thin ideal that comes with that culture) may be a necessary, but not sufficient, precursor to the development of eating disorders.

Some have suggested that the process of cultural change may be associated with increased vulnerability to eating disorders, especially as developing cultures embrace the modern Western body ideal of thinness. Such change may occur across time within a given society or on an individual level (Lee et al. 2010; M.N. Miller and Pumariega 2001). Cross-cultural differences in the presentation and meaning of eating disorders contribute to challenges in classifying eating disorders, and suggest the need for a more flexible or dimensional classification system that reflects cross-cultural differences (Becker 2007).

Family and Individual Environment

Along with cultural pressures toward thinness, familial and peer pressures to uphold the thin ideal have been cited as potential contributors to eating disorder pathology (Branch and Eurman 1980; Levine et al. 1994; Shisslak et al. 1998; Stice 1998; Wertheim et al. 1997). Furthermore, it has been argued that certain types of familial environ-

ments—namely, those in which parents are overly critical, hostile, and coercive and are overly enmeshed in their children's lives (e.g., Haworth-Hoepfner 2000; Minuchin et al. 1978)—may more readily breed eating disorder behaviors. However, none of these assertions concerning the role of peers and family in the development of eating disorders have been proven conclusively, and therefore further study encompassing a wide range of adversities is necessary (Stice 2002). Risk factor research is only now reaching a level of sophistication that will allow the identification of particular risk factors that interact with specific genetic vulnerabilities to increase a given individual's risk for developing a particular form of disordered eating (Mazzeo and Bulik 2009).

Certain environmental risk factors have received particular attention and have both heuristic value and important implications for the treatment of affected individuals. A predisposition to eating disorders has been noted among individuals who participate in certain activities that promote thinness, such as ballet dancing, modeling, and some sports that emphasize weight and body shape (Kann et al. 2000). A history of sexual abuse or trauma appears to be a nonspecific risk factor for developing eating problems and is particularly associated with bulimic disorders. Trauma is associated with greater comorbidity in eating disorders, including posttraumatic stress disorder (Brewerton 2007; Kendler et al. 2000).

Genetics

Although the research discussed above under "Culture" implicates culture as an important risk factor for the development of eating disorders, it is clear that individual vulnerabilities play a substantial role. Specifically, such traits as perfectionism, impulsivity, negative affect, and low self-esteem have all been cited as potential risk factors (Fairburn et al. 1999; Polivy and Herman 2002; Stice 2002) and may account for the fact that only a minority of young women in a high-risk cultural environment actually develop clinical eating disorders. In addition, a vulnerability to obesity appears to increase risk for bulimia nervosa and BED (Fairburn et al. 1997, 1998), possibly by promoting dieting. Many such trait vulnerabilities may be largely genetically determined, and the genetics of eating disorders is a rapidly developing area of interest (Bulik et al. 2007; Monteleone and Maj 2008; Steiger and Bruce 2007; Treasure 2007).

Results of some genetic epidemiological studies have suggested that anorexia nervosa, bulimia nervosa, and atypical eating disorders aggregate in families, and it appears that at least some of the risk factors are common to both anorexia nervosa and bulimia nervosa. In other words, relatives of persons with an eating disorder are significantly more likely than members of the general population to de-

velop either the same or an alternative eating disorder. Twin studies have also suggested that genetic factors contribute substantially to the development of eating disorders (Bulik et al. 2000). In light of the evidence supporting the importance of genetic risk factors for eating disorders, the challenge of identifying meaningful intermediate phenotypes, subphenotypes, and associated biological endophenotypes that interact with environmental factors to promote the onset and maintenance of eating disorders looms large. For anorexia nervosa, obsessive-compulsive traits and perfectionism, weak set shifting, and bias toward detail may be intermediate phenotypes that confer risk. The "emotional phenotype" with abnormalities in reward and fear-anxiety systems may additionally confer risk or influence the particular symptom picture (Treasure 2007). For bulimia nervosa, relevant subphenotypes may include psychologically intact/perfectionistic, overregulated/compulsive, and dysregulated/impulsive personality traits (Steiger and Bruce 2007). At the level of genotype, the 5-hydroxytryptamine (5-HT; serotonin) 2A receptor (*5HT2A*) and brain-derived neurotrophic factor (*BDNF*) genes are promising candidates for association with the restricting subtype of anorexia nervosa (Monteleone and Maj 2008). A predisposition to obesity, particularly in its interaction with cultural values promoting thinness, may secondarily increase risk for bulimia nervosa and binge-eating disorder; genotypes of interest in this regard include variants of the melanocortin-4 receptor (*MC4R*) and fat mass and obesity-associated (*FTO*) genes (Hebebrand and Hinney 2009).

Neurotransmitters, Neuropeptides, and Neuroanatomy

A great deal of research has focused on abnormalities in the functioning of neurotransmitters, particularly serotonin, in the development and maintenance of eating pathology (Kaye 2008). A confluence of evidence suggests that serotonergic activity is increased in women who have recovered from anorexia nervosa and bulimia nervosa but is decreased in underweight individuals with anorexia nervosa and actively symptomatic women with bulimia nervosa. These findings are consistent with the idea that at baseline these patients are characterized by perfectionism and behavioral overcontrol but that when symptomatic, they may be more impulsive and undercontrolled (Kaye 2002). More recently, dopaminergic systems have been investigated in eating disorders, particularly with regard to their role in affect regulation and reward systems (Kaye 2008; Davis and Carter 2009).

Additionally, researchers have been interested in the role of appetite- and weight-regulating peptides, including those that stimulate appetite (such as neuropeptide Y, peptide YY, and galanin) and those that reduce appetite (such

as leptin and corticotropin-releasing hormone). Most, but not all, of the reported abnormalities normalize after recovery, suggesting that they may reflect the operation of physiological mechanisms triggered by malnutrition or weight loss. However, increased cerebrospinal fluid concentrations of peptide YY in women who have recovered from bulimia nervosa and reduced cerebrospinal fluid concentrations of galanin in women with anorexia nervosa who have had long-term weight restoration may represent trait abnormalities rather than transient states resulting from eating disorder symptoms. The role of these peptides in the etiology of eating disorders requires further study (Kaye 2002). Other neuropeptide systems that could play a role in eating disorders include melanocortin and cannabinoid systems (Kaye 2008).

One relatively new avenue of research into the biological underpinnings of eating disorders is brain imaging, recently reviewed by Van den Eynde and Treasure (2009). Computed tomographic and MRI studies have consistently detected ventricular enlargement and diffuse atrophy in underweight patients with anorexia nervosa. Most reported abnormalities appear to reverse with weight restoration, suggesting that they represent secondary effects of malnutrition, although there is some evidence that gray matter volume reduction persists even after weight regain. While it is unlikely to be etiological, this persistent abnormality may reflect the effect of long-term malnutrition on the brain and may be related to the high rate of relapse in recovered anorexia nervosa patients.

Functional imaging studies have not yet provided a consistent picture of the relationship between abnormal functioning in particular brain regions and eating disorder symptoms, but provocative findings are beginning to emerge. There is evidence for both global and regional (frontal and parietal cortices) decreased metabolic activity, particularly in underweight patients with anorexia nervosa. Brain activation, as gauged by regional blood flow, in response to food-related cues has been reported in several studies to differ between patients with eating disorders and unaffected individuals, although a consistent pattern of difference has yet to be established. This is an area of active research, and we are approaching the point at which neuroimaging studies, taken together with neurobiological and genetic findings, may allow for an integrative pathophysiological understanding of the onset and maintenance of eating disorders.

Etiology of Binge-Eating Disorder

It should be noted that risk factors for BED may differ in degree and kind from those for anorexia nervosa and bulimia nervosa. A case-control community study found that risk factors for the development of BED were less nu-

merous and weaker than those for anorexia nervosa and bulimia nervosa. Specific risk factors for BED include parental depression, vulnerability to obesity, and repeated exposure to negative comments about shape, weight, and eating (Fairburn et al. 1998). Genetic and environmental factors appear to interact in determining whether an individual progresses toward bulimia nervosa or BED. Genetic risk factors for binge eating and bulimia nervosa may be similar, whereas nonshared environment may be important in influencing the risk for bulimia nervosa once binge eating is initiated (Wade et al. 2000). In regard to obesity, most findings suggest that risk for binge eating is partially or largely independent of risk for obesity (Bulik et al. 2003; Hudson et al. 2006), although binge eating may contribute to the full expression of obese potential.

Medical Complications

The pathological processes associated with eating disorders are multisystemic in nature and result from the altered eating and compensatory behaviors that characterize these disorders. Medical morbidity in eating disorders results from severe restriction with extensive weight loss; self-induced vomiting; use of laxatives, diuretics, or appetite suppressants; or binge eating with excessive weight gain. These symptoms and the resultant pathological processes may occur singly, as in patients with restricting anorexia nervosa or normal-weight bulimia nervosa, or may co-occur, as in patients with anorexia nervosa purging subtype or eating disorder NOS. It is important to note that individuals with normal or above-normal body weight who lose an excessive amount of weight may manifest similar changes in medical status as those who start at normal or low body weight and lose even more. Eating disorder symptoms and their effects on medical status are summarized in Table 14-3. Medical morbidity related to obesity has been extensively reviewed elsewhere (Guh et al. 2009) and is beyond the scope of this chapter.

System-Focused Review of Medical Complications

Metabolic/Endocrine Effects

The primary pathophysiological response to starvation is reduced energy expenditure which likely occurs in two phases. Phase 1 involves a physiological adaptation with a decrease in the metabolic rate as a means of increasing metabolic efficiency. Phase 2 occurs after 2-3 weeks of undernutrition and reflects the actual loss of tissue (Winter et al. 2005). This reduction in energy expenditure has been clearly demonstrated in anorexia nervosa. Underlying the reduced metabolic rate is a change in thyroid hormone

TABLE 14-3. Eating disorder symptoms and medical effects

Symptom	Medical effect
Restrictive eating	Cognitive impairment, fatigue, cold intolerance, constipation, dizziness, hypoglycemia, acrocyanosis, orthostatic pulse and blood pressure, edema, amenorrhea
Vomiting	Dehydration, metabolic alkalosis, hypokalemia, arrhythmias, esophagitis/gastritis, esophageal tears, dental caries, parotid/submandibular gland hypertrophy, gastroesophageal reflux disease, pharyngitis
Binge eating/overeating (with increasing weight)	Obesity, dyslipidemia, hypertension, type 2 diabetes, coronary artery disease, stroke, gallbladder disease, osteoarthritis, sleep apnea, respiratory disorders
Laxative abuse	Cathartic colon, dehydration, hypokalemia, metabolic acidosis or mild metabolic alkalosis
Diuretic abuse	Dehydration, electrolyte imbalance (hypokalemia and hypomagnesemia)
Appetite-suppressant abuse	Hypertension, tremor, arrhythmias
Ipecac abuse	Generalized myopathy, cardiomyopathy
Compulsive exercise	Bradycardia, overuse syndrome, stress fractures
Water loading	Hyponatremia, headache, nausea, dizziness, seizure

synthesis characterized by normal thyroid-stimulating hormone level, low or normal thyroxine (T_4) concentration, low or normal levels of triiodothyronine (T_3), and elevated concentration of reverse T_3 —a pattern known as the euthyroid sick syndrome. It is important to remember that this is a physiological adaptation; therefore, in most cases, thyroid hormone supplementation is not warranted (Lawson and Klibanski 2008). The concept of bulimia nervosa and BED as states of intermittent starvation is controversial, and the data on energy expenditure in these conditions are inconsistent (de Zwaan et al. 2002). The typical endocrine features of starvation (increased cortisol and growth hormone levels; decreased estrogen, LH, and FSH levels in women; decreased testosterone level in men) are also seen in anorexia nervosa and resolve with weight restoration (Devlin and Walsh 1988). Cortisol excess is associated with comorbid mood disorders, neurocognitive deficits, hippocampal atrophy, amenorrhea, myopathy, and bone loss. At least in the case of bone loss, there is evidence that the level of hypercortisolemia seen in adolescent girls with anorexia nervosa is sufficient to contribute (Misra et al. 2004). The change in growth hormone represents a nutritionally mediated, acquired resistance to this hormone that is also linked to low insulin-like growth factor-1 (IGF-1) levels and lower IGF-1 bioactivity. Acute starvation blocks IGF-1 production by the liver; thus, growth hormone excess is attributed in part to lack of IGF-1-mediated negative feedback due to low IGF-1 levels. The potential consequences of growth hormone resistance include muscle atrophy, growth failure, and bone loss (Lawson and Klibanski 2008).

Starvation is also associated with a reduction in noradrenergic activity in the central and peripheral nervous systems of patients with eating disorders. This reduction can lead to hypotension, bradycardia, hypothermia, and depression (Pirke 1996). It is not uncommon for body temperature to drop to 95°F (35°C) or even lower with continued weight loss, and marked bradycardia is common in underweight patients and in those who exercise extensively. Altered autonomic control of heart rate and blood pressure appears to return to normal with refeeding and resolution of eating disorder-related symptoms (Rechlin et al. 1998).

Another metabolic concomitant of starvation is hypoglycemia which is often seen in underweight patients with anorexia nervosa (Bhanji and Mattingly 1988) and sometimes in normal-weight patients with bulimia nervosa (Devlin et al. 1990). Symptomatic hypoglycemia is uncommon, but there are case reports of coma and death attributed to severe hypoglycemia in anorexia nervosa.

Renal Failure, Loss of Fluids, and Electrolyte Imbalance

Eating disorder-related behaviors such as vomiting, laxative or diuretic use, fluid restriction, or water loading may result in substantial fluctuations in fluid status and lead to life-threatening states such as severe dehydration with hypotension, acid-base disturbances, and electrolyte imbalances. Fluid loss, particularly from vomiting, often leads to metabolic alkalosis. Patients who abuse laxatives often develop metabolic acidosis. The most common electrolyte imbalance is hypokalemia, which, if chronic and persistent, can lead to nephropathy and chronic renal failure requiring

dialysis, as well as to nephrogenic diabetes insipidus, metabolic alkalosis, renal hypochloremia, rhabdomyolysis, and intestinal ileus. Hypokalemia is a significant side effect of laxative and thiazide diuretic abuse. In one study, the creatinine clearance was found to be most reduced by chronic laxative abuse when compared with chronic vomiting or restricting (Takakura et al. 2006). Cardiac arrhythmias secondary to hypokalemia can be life-threatening; patients with arrhythmias must be given supplemental potassium as soon as possible to correct the imbalance. An electrocardiogram should be obtained and the patient should be placed on cardiac monitoring with intravenous potassium replacement if there are significant electrocardiographic abnormalities. Otherwise, oral potassium replacement is usually safe and effective if retention of the medication after ingestion can be assured. Hypomagnesemia may also be present, especially during refeeding (Birmingham et al. 2004), and may interfere with potassium normalization if it is not corrected as well. Hypocalcemia is uncommon, but when present, it (like hypomagnesemia) may be associated with prolongation of the QTc interval (see "Cardiovascular Effects" subsection below).

Serum phosphate levels also must be monitored because they are frequently low in patients with eating disorders, particularly those with low body weight. Although total body phosphate can be depleted through malnutrition, refeeding can also cause a drop to dangerous levels, and oral phosphate replacement is typically needed. During the first week of refeeding in inpatients, electrolyte including calcium, magnesium, and phosphate levels should be obtained at baseline and then monitored at least every other day for the remainder of the week. Thereafter, they can be monitored less frequently if they remain stable (Mehler and Andersen 1999). Hyponatremia can result from purging behaviors or from water loading. Significant hyponatremia is associated with increased seizure risk and therefore requires prompt detection, treatment, and close monitoring. Free water intake may need to be restricted until the sodium imbalance is corrected. Patients with normal kidney function will typically correct their fluid imbalance via spontaneous diuresis.

Plasma volume depletion and hypovolemic hyponatremia are common in the most severely malnourished patients with anorexia nervosa. Because of malnutrition, common indices of hemoconcentration may be within the normal range. In addition, hemoconcentration, when present, may mask anemia (Caregaro et al. 2005). Blood urea nitrogen is an unreliable indicator of hydration because it may be both reduced by inadequate protein intake and elevated by dehydration or increased protein catabolism.

Fluid losses caused by vomiting or abuse of diuretics, laxatives, or caffeine stimulate the renin-angiotensin sys-

tem. Particularly in laxative abusers, this stimulation results in an increase in aldosterone concentration and subsequent fluid retention that may persist for weeks, leading to significant weight gain and even frank edema that is difficult for patients to tolerate. Maintenance of proper fluid status over time will correct the fluid retention, and diuresis will eventually ensue. Erratic release of vasopressin from the posterior pituitary may result in symptoms of diabetes insipidus, including excessive urination and hypernatremia (Gold et al. 1983).

Approximately 20% of all patients with anorexia nervosa develop some form of peripheral edema during refeeding. In anorexia nervosa, as refeeding progresses, insulin levels increase. Insulin promotes sodium reabsorption through changes in tubular transport of the nephron, leading to fluid retention, weight gain, and localized—or, more rarely, generalized—edema. Refeeding edema usually resolves spontaneously but must be closely monitored (Ehrlich et al. 2006).

Central Nervous System Effects

Both structural and functional changes in the brain are seen in adults and adolescents with anorexia nervosa. Studies have shown evidence of ventricular and cortical sulcal enlargement as well as functional impairment in attention and concentration, visual associative learning, visuospatial abilities, problem solving, and attentional-perceptual motor functions. Other impairments include psychomotor slowing, poor planning, and lack of insight. Some reversal of these changes has been demonstrated with weight restoration (Chowdhury and Lask 2001; Ehrlich et al. 2008; Kerem and Katzman 2003).

From a symptomatic perspective, headaches are common in patients with eating disorders, and the incidence of migraines in patients with anorexia and bulimia is very high (75%) in comparison with that in the general population (12.5%) (Ostuzzi et al. 2008). The biochemical profiles, particularly in relation to tyrosine metabolism, suggest that migraine may constitute a risk factor for development of eating disorders in young females (D'Andrea et al. 2008).

Cardiovascular Effects

Individuals with very low body weight lose significant cardiac muscle over time. The left ventricle is particularly affected, with hypotrophy characterized by myocardial degeneration (Ulger et al. 2006). Tissue doppler imaging has shown evidence of left ventricular dysfunction (Galetta et al. 2005). Undernourished individuals may also develop clinically silent pericardial effusions (McCallum et al. 2006) as well as conduction abnormalities with arrhythmias or a prolonged QTc interval. The latter has been shown to be a marker for risk of sudden death and there-

fore requires close monitoring. Prolongation of the QTc interval is often associated with hypokalemia, hypocalcemia, or hypomagnesemia but may also be caused or exacerbated by medication (Lesinskiene et al. 2008). QT dispersion is an index of variation in ventricular repolarization, which may increase susceptibility to ventricular arrhythmias. One study showed significantly increased measures of QT dispersion in subjects with chronic anorexia nervosa compared with age-matched controls, although the QT interval did not differ between the two groups (Krantz et al. 2005). Another study found decreased levels of heart rate variability in women with anorexia nervosa. This finding is significant in that low heart rate variability may predict sudden death in patients with cardiac disorders (Melanson et al. 2004). The most common cardiovascular abnormality in anorexia is sinus bradycardia secondary to vagal hyperactivity. Mitral valve prolapse has also been noted, although its clinical significance is not fully understood; it occurs more commonly in patients with anorexia nervosa and is perhaps secondary to physical remodeling of the heart with starvation (Cooke and Chambers 1995). The cardiovascular system is particularly vulnerable to substances used by patients with eating disorders for weight loss, including ipecac, diuretics, and appetite suppressants. The effects of these substances are noted in Table 14-3. Long-term use of ipecac is particularly dangerous, because it can be associated with the development of cardiomyopathy.

Gastrointestinal Effects

Gastrointestinal complications of eating disorders vary according to the specific eating disorder symptoms the patient manifests. Restrictive eating with marked weight loss leads to a slowing of gastrointestinal motility, resulting in gastroparesis and constipation. Impaired gastrointestinal motility may also result from ongoing abuse of laxatives, often in escalating amounts due to the development of tolerance. This condition, known as *cathartic colon*, can be associated with hemorrhoids and rectal prolapse from chronic straining. Delayed gastric emptying is also problematic for individuals with both the binge/purging and the restricting subtype of anorexia; it may serve to perpetuate disordered eating behaviors due to the prolonged sensation of fullness commonly reported by these patients. In one study that followed treatment of anorexic patients over a 20-week period of refeeding, gastric emptying times normalized in the restricting subgroup but not in the binge/purging subgroup. This suggests that long-term nutritional rehabilitation may improve both dyspeptic symptoms and gastric emptying, particularly for patients with the restricting subtype of anorexia nervosa (Benini et al. 2004). Elevation of hepatic transaminases is common in underweight patients with anorexia nervosa. Autophagy

has been proposed as a cause for major hepatocyte dysfunction in anorexia nervosa with severe malnourishment even without cell death. Autophagy is a well-known survival strategy under stress conditions (Rautou et al. 2008). Steatosis is also encountered with refeeding and necessitates a reduction in the daily caloric amount and serial testing of transaminases until levels normalize. Nevertheless, continued refeeding is essential to normalization of liver function, which typically occurs quite rapidly (Narayanan et al. 2010).

Vomiting may cause complications related to acid reflux such as enlargement of salivary glands, dental caries, esophagitis, and gastritis. Gastrointestinal dysmotility, when present, is often related to hypokalemia. Forced vomiting may result in hematemesis, which may be secondary to a pharyngeal scratch from induction of vomiting but may also be secondary to gastritis, esophagitis, or (less frequently) gastric or esophageal tears. Binge eating in bulimia or anorexia can cause acute gastric dilatation, as can rapid refeeding in anorexia nervosa. This requires decompression with a nasogastric tube and fluid and electrolyte replacement. There are also case reports of acute and chronic pancreatitis in anorexia nervosa and bulimia.

Genitourinary Effects

In women with anorexia nervosa, amenorrhea is due to hypothalamic amenorrhea syndrome, in which pulsatile secretion of gonadotropin-releasing hormone (GnRH) is diminished. This reduced secretion in turn causes lower levels of LH and FSH along with low blood levels of estradiol, estrone, progesterone, and testosterone, leading to a physiological return to the prepubertal state. Although weight loss is a common precipitant of amenorrhea, a minority of patients develop amenorrhea before the onset of weight loss, indicating that other factors such as caloric restriction, excessive exercise, or psychogenic stress may also be important contributors (Morgan 1999). Menstrual cycling typically resumes with weight restoration at approximately 90% of standard body weight, although resumption may be delayed up to 6 months after that weight is achieved. Additionally, a substantial number of individuals (up to 26% in one study) require an above-average BMI to reestablish normal menstruation (Kaplan and Noble 2007; Vyver et al. 2008). Except in cases in which ovulation is induced, pregnancy is rare in women with active anorexia nervosa. However, in a study of 140 women with anorexia nervosa, 50 had conceived at 10-year follow-up, 20% of whom appeared to have done so while actively anorectic (Brinch et al. 1988).

About half of women with bulimia nervosa become amenorrheic or oligomenorrheic despite having no apparent change in percentage body fat. As in anorexia nervosa,

this condition is commonly associated with impaired follicular maturation due to reduced LH concentrations and pulse frequency. Women with abnormal menstrual cycles in bulimia nervosa appear to be underweight in relationship to their own lifetime high body weight but not to average or expected body weight for their age and height (Devlin et al. 1989; Morgan 1999). A recent study that excluded underweight participants found that high school girls who reported vomiting for weight control once per week or more often were more than three times as likely to experience irregular menses as girls who did not report such vomiting (Austin et al. 2008). Another study examined the relationship between bulimic symptoms and fluctuations in ovarian hormones in bulimic women with intact menstrual cycles (Edler et al. 2006). The researchers found that decreases in estradiol and increases in progesterone were associated with marked increases in binge eating. Despite the profound effects of eating disorders on reproductive function, outcome studies suggest that with full recovery, fertility may not be compromised (Crow et al. 2002; Mitchell-Gielegheem et al. 2002).

Musculoskeletal Effects

Severe protein-energy malnutrition gives rise to a metabolic myopathy with significant loss of muscle mass and function. Cases of rhabdomyolysis have been reported in anorexia nervosa. However, muscle is very responsive to refeeding. One study found that muscle performance improved long before the nutritional compromise was entirely corrected, with some improvement noted as early as the eighth day of refeeding (Rigaud et al. 1997).

Osteopenia and osteoporosis are relatively unique among complications of eating disorders in that they appear not to be readily reversible with weight recovery. These conditions are chronic rather than acute effects of malnutrition, because clinically significant bone loss does not usually begin until 12 months after onset of illness. Thereafter, bone loss progresses at an average annual rate of 2.5% in young women with active anorexia nervosa (K.K. Miller et al. 2006). In their study of adolescent women with anorexia nervosa, Castro et al. (2000) found that the following factors were related to development of osteopenia: more than 12 months since onset of the disorder, more than 6 months of amenorrhea, BMI less than 15 kg/m², calcium intake less than 600 mg/day, and less than 3 hours/week of physical activity. It is estimated that osteoporosis occurs in more than half of adolescent and young adult females who struggle with eating disorders, and patients with anorexia nervosa have a fracture rate seven times higher than that in healthy women (Kaplan and Noble 2007). These conditions can result in painful fractures, disfiguring kyphosis, and loss of height. The pathophysiology of bone loss in

anorexia nervosa is complex (Golden 2003; Mehler 2003; Rosenblum and Forman 2002). Whereas estrogen deficiency has been thought to mediate bone loss in anorexia nervosa, there are other factors integral to this process as well. IGF-1, a nutritionally dependent bone trophic hormone that stimulates osteoblasts to increase bone formation, is decreased in anorexic females, possibly due to decreased dehydroepiandrosterone (DHEA) in adolescent and young women with anorexia nervosa. More recently, receptor activator of nuclear factor κ B ligand (RANKL) and osteoprotegerin (OPG) have been identified as important regulators of bone turnover. Serum OPG levels may be increased by a compensatory mechanism for malnutrition and estrogen deficiency that induces an increase in bone resorption (Ohwada et al. 2007). Depression has also been associated with osteoporosis in adults, and one study suggested that comorbid depression is associated with increased risk of osteoporosis in girls with anorexia nervosa (Konstantynowicz et al. 2005). Osteopenia and osteoporosis occur in men with anorexia nervosa as well, perhaps due to a relative lack of testosterone, which is a major substrate for estrogen production (Andersen et al. 2000).

The treatment of low bone density in anorexia nervosa requires—first and foremost—refeeding. Weight restoration is found to be effective in increasing bone mass, although not to pre-illness levels (Mehler and MacKenzie 2009). Resumption of menses is critical to this process as well. In women with anorexia nervosa whose menstrual cycles recover, spine bone mass density significantly increases independently of weight gain (Lawson and Klibanski 2008). Moderate weight-bearing exercise has been shown to be protective, although strenuous activity is detrimental. The uncertain status of pharmacological treatment for osteoporosis in these individuals has been well reviewed (Golden 2003; Mehler 2003). Growth hormone has direct and indirect (via IGF-1) anabolic effects on bone. Growth hormone resistance and low IGF-1 is characteristic of anorexia nervosa. Recombinant human IGF-1 is the only medical therapy shown thus far to improve bone mass density in women with anorexia nervosa, but it is not currently approved for this indication (Lawson and Klibanski 2008). The benefit of supplemental calcium is not clear; however, the current standard practice in the treatment of anorexia nervosa is to give daily calcium (1,300–1,500 mg/day) and vitamin D (400 IU/day). There is no evidence that estrogen replacement therapy either reverses or prevents bone loss in anorexia nervosa. It may even be contraindicated, given that hormone-induced withdrawal bleeding may be misinterpreted by patients as evidence of the return of normal menstrual function, thereby offering spurious assurance that they are at a healthy body weight despite ongoing malnutrition and emaciation (Kaplan and Noble

2007). Research examining the efficacy of oral bisphosphonates in anorexia nervosa has been promising, but use of drugs in this class is not currently recommended due to a lack of long-term safety studies (Jayasinghe et al. 2008). They are contraindicated in women who may become pregnant. There is no evidence supporting the use of calcitonin in anorexia nervosa.

Integumentary Effects

The cutaneous signs of eating disorders result from malnutrition and self-induced vomiting. Findings related to malnutrition include dry, scaly skin; lanugo hair; carotenoderma; brittle nails; and hair loss. Those related to self-induced vomiting include calluses on the dorsum of the hands from constant abrasion against the front teeth with induction of vomiting (Russell's sign), and purpura and petechiae from recurrent Valsalva maneuvers to induce vomiting. Purpura and petechiae can also be seen as a result of thrombocytopenia secondary to malnutrition (Mitchell and Crow 2006). See also Chapter 29, "Dermatology."

Other Effects

Bone marrow suppression with leukopenia, anemia, and thrombocytopenia is common in states of starvation, but these abnormalities reach clinically significant levels only in the most severe cases. Particularly in regard to leukopenia, IGF-1 deficiency may play a role (Polli et al. 2008). Pulmonary complications of eating disorders are rare but include pneumomediastinum and aspiration pneumonitis from forced vomiting, and chronic starvation may promote emphysema-like lung changes (Coxson et al. 2004). Dyspnea in long-standing malnourished states is often secondary to respiratory muscle weakness, which does not always show prompt recovery with refeeding and improved nutrition (Birmingham and Tan 2003).

Eating Disorders and Pregnancy

Eating disorders affect women during the period of reproductive functioning. Several studies have shown that one-third to one-half of women attending infertility clinics have full or subsyndromal eating disorders (Kaplan and Noble 2007). However, pregnant women with eating disorders rarely disclose their eating disorder to their clinician. Poor maternal or fetal weight gain should serve as red flags regarding the possibility of a hidden eating disorder. The diagnosis of an eating disorder has clinical significance, and the timely identification of an eating disorder may enable the clinician to more effectively manage the patient and optimize outcome (Micali et al. 2007).

Although the majority of women with eating disorders have normal pregnancies resulting in healthy babies, and

eating disorder symptoms may improve during pregnancy, rates of caesarean section and of postpartum depression are elevated in women with eating disorders (Franko et al. 2001). Low prepregnancy weight and low weight gain during pregnancy are associated with low infant birth weight and a higher incidence of congenital malformations. Other maternal complications include an increase in bulimic symptoms during pregnancy as well as restrictive eating. Both low and high maternal weight gain may occur, miscarriage is more common, and hypertension is reported more often among bulimic women (Morgan et al. 2006). Considerations for hospital admission include degree of weight loss, hypokalemia and other electrolyte abnormalities, and electrocardiographic changes, as well as fetal growth and physiological profile. Birth complications seen with both anorexia nervosa and bulimia nervosa include stillbirth, low birth weight, low Apgar scores, and cleft lip and palate (Mitchell-Gielegheem et al. 2002).

Breast-feeding problems in women with eating disorders have been noted. These include complaints of insufficient lactation or of allergies or negative reactions to breast milk in the infant, resulting in early transition to bottle feeding. For women whose eating disorder treatment includes medication, the risks and benefits of breast-feeding should be carefully reviewed. Child-rearing practices may also be affected by the presence of an unresolved eating disorder in the mother. In a small proportion of cases, inadequate feeding of children has been reported with a secondary effect on the child's growth (Fairburn and Harrison 2003; Mitchell-Gielegheem et al. 2002).

A recent study examined the relationship between obstetric complications and temperament in eating disorder subjects. The findings suggest that neonatal dysmaturity and elevated harm avoidance may have a mediating role in vulnerability to and maintenance of an eating disorder (Favaro et al. 2008).

Eating Disorders and Diabetes Mellitus

Some evidence suggests that there is an increase in disordered eating in chronic medical conditions for which dietary restraint is part of the treatment plan (see also Chapter 22, "Endocrine and Metabolic Disorders"). This is particularly true of type 1 diabetes mellitus. Several studies have examined personality, temperament, and character in type 1 diabetic patients with eating disorders. Weight preoccupation was associated with the presence of an eating disorder, and borderline personality characteristics were related to withholding insulin (Mitchell and Crow 2006). The presence of a comorbid eating disorder has been associated with markedly worse outcome. A study of mortality of individuals with type 1 diabetes and anorexia nervosa reported crude mortality rates of 2.5% for type 1 diabetes, 6.5% for

anorexia nervosa, and 34.8% for concurrent cases (Nielsen et al. 2002). Individuals with anorexia nervosa and bulimia nervosa may withhold their daily insulin to prevent uptake of glucose and, in effect, purge. However, they may also manifest other symptoms such as restricting, laxative use, vomiting, use of appetite suppressants, and compulsive exercise. Blood glucose level is typically elevated, and there is an increased risk of ketoacidosis and other complications (Rodin 2002). Mean glycosylated hemoglobin has been found to be higher in subjects with diabetes mellitus who have an eating disorder (9.4%) compared with those without an eating disorder (8.6%) (Affenito and Adams 2001). Of all the problematic behavioral factors related to eating disorders, the duration of severe insulin omission is the factor most closely associated with retinopathy and nephropathy in type 1 diabetic females with eating disorders (Takii et al. 2008). The multidisciplinary team treatment of these individuals should include close endocrinological supervision. There is an ongoing need for frequent insulin changes with progression of the meal plan and activity level, or with symptom fluctuation.

Treatment

Given the contributions of cultural, familial, environmental, and genetic factors to the development of eating disorders, it is not difficult to appreciate why a biopsychosocial approach to understanding eating disorders and a multidisciplinary approach to treatment are seen as the foundation of current practice. This approach includes, at a minimum, team members to provide psychotherapy and medication management, medical monitoring and treatment, dietary management, and social service needs. The intensity of treatment and of the setting in which treatment is delivered may vary from self-help or support groups for the least symptomatic patients to weekly outpatient treatment, intensive outpatient treatment, day hospital treatment, or inpatient treatment for the most severely compromised (Kaplan et al. 2001). Patients with anorexia nervosa who are significantly underweight often require inpatient treatment, at least in the initial phase of weight restoration. Those with bulimia nervosa and BED can most often be treated as outpatients, although medical or psychiatric instability or failure of outpatient treatment options may indicate hospitalization. The treatment guidelines published by the American Psychiatric Association (2006) and by Great Britain's National Institute for Clinical Excellence (2004) provide a useful set of standards for determining the appropriate initial level of care. In addition, the American Dietetic Association (2006) has published a position paper on nutrition intervention in the treatment of eating disorders.

Nutritional Approaches

Nutritional rehabilitation is a fundamental and often extremely challenging component of treatment. Body weight may range from extremely low in patients with anorexia nervosa to high or markedly unstable in patients with bulimia nervosa and BED. Dietary history at intake may reveal various abnormalities, including avoidance of particular foods, overconsumption of low-calorie foods such as artificial sweeteners, uncontrolled binge eating, or food rituals. The latter are common and include preferences for unusually seasoned foods or combinations of foods, prolonged mealtimes, and eating alone. Strikingly, even in patients who eat very little themselves, food obsessions and a tendency to work around food are common (Rock and Curran-Celentano 1996).

Weight restoration is of primary importance for the individual with low body weight, whereas weight stabilization may be needed in individuals with normal or above-normal body weight. For obese patients, weight loss may be a goal, but this is usually best deferred until treatment for the eating disorder is well under way. An inpatient program should be considered for the most seriously nutritionally compromised patients, including those whose weight is less than 75% of ideal body weight or for those, especially children and adolescents, whose weight loss may not be as severe but who are losing weight at a rapid rate. Structured behavioral inpatient programs typically utilize multidisciplinary treatment teams in an effort to help patients meet set nutritional goals (Attia and Walsh 2009). The initial plan calls for establishment of a healthy weight target and a plan to restore weight safely and effectively while addressing body image and related concerns. A target weight for discharge from inpatient treatment is typically set at a range greater than or equal to approximately 90% of average for age and height. It is important that patients understand that this is a *minimum acceptable* rather than a recommended weight range.

Body composition is characterized by an extremely low percentage of body fat in emaciated patients with anorexia nervosa that increases rapidly with refeeding. Measurement of skinfold thickness provides a reliable estimate of body fat in these patients (Probst et al. 2001). Studies of body composition during the process of refeeding in patients with anorexia nervosa reveal that most of the non-fluid weight regained is represented by fat, accounting for 32%–77% of total weight gained (Rock and Curran-Celentano 1996), whereas muscle mass appears to lag behind (Polito et al. 1998). The initial distribution of weight regain is often disproportionately centripetal (Grinspoon et al. 2001), with redistribution occurring in the months following achievement of target weight.

Patients with anorexia nervosa may be unwilling or unable to accept food, at least initially. According to the American Psychiatric Association (2006) Practice Guideline, intake levels should usually start at 30–40 kcal/kg/day (approximately 1,000–1,600 kcal/day) and should be advanced progressively to yield a rate of weight gain of 2–3 lb/week for inpatients and 0.5–1 lb/week for outpatients. Patients may require levels of energy intake as high as 70–100 kcal/kg/day or more to accomplish this rate of weight gain, and nutritional supplements are often used in patients with high caloric requirements for weight regain. Although the oral feeding route is preferred, nasogastric feeding is utilized in the initial stage of treatment in some treatment centers. In particular, some clinicians support progressive nocturnal nasogastric supplemental feeding for individuals with low body weight as a means of minimizing somatic and psychological distress during initial weight regain and of speeding weight restoration (Robb et al. 2002; Zuercher et al. 2003). As weight gain progresses, regular meal portion sizes are gradually increased until nasogastric supplements are no longer required. If nasogastric feeding is necessary, it is recommended that normal eating behaviors (i.e., consuming foods orally during the daytime) be reinstated as soon as is feasible (Attia and Walsh 2009). Parenteral nutrition may be utilized in extreme circumstances; however, parenteral feedings are usually not given because of the associated risks of infection and increased risk of refeeding syndrome (described below in this subsection). Although weight regain is rarely steady, a particularly erratic weight-gain pattern or inability to gain weight despite increasing caloric intake may reflect covert disposal of food, exercise, purging, or water loading to make weight, and more stringent monitoring may be in order.

Physical activity during weight restoration should be adapted to the food intake and energy expenditure of the patient, taking into account the patient's history of excessive exercise. Adherence to the refeeding protocol is often linked with greater freedom to participate in activities and other rewards. Increases in physical activity must be balanced with medical stability, weight restoration, and control of eating disorder symptoms, including excessive activity. Strict limitations are required for individuals who struggle with compulsive exercise, and more intensive monitoring may be needed for those found to be exercising covertly. In most programs, activity is progressively advanced to include regimens of stretching, strengthening, and aerobic activity when appropriate (Rosenblum and Forman 2002).

Careful medical monitoring is essential throughout the refeeding period and typically includes monitoring of vital signs, renal function, food and fluid intake and output, and routine electrolytes plus magnesium, calcium,

and phosphate. In addition, patients should be observed for edema and rapid weight regain. If present, these may suggest fluid overload or congestive heart failure. Gastrointestinal symptoms of constipation, bloating, and abdominal pain should also be monitored. Cardiac monitoring may be indicated for severely malnourished individuals (below 70% of ideal body weight), especially children and adolescents and those individuals with severe electrolyte disturbances, arrhythmias, or prolonged QTc interval (Al-Khatib et al. 2003; American Dietetic Association 2006; Sylvester and Forman 2008; Yager and Andersen 2005).

Cholesterol levels in anorexia nervosa are usually normal or high despite low cholesterol intake. These levels do not result from the *de novo* synthesis of cholesterol. Rather, abnormal thyroid hormone status, low serum estrogen levels, hypercortisolism, and impaired clearance of cholesterol explain or contribute to hypercholesterolemia in this setting. Weight restoration is typically accompanied by reduction in cholesterol level and apolipoprotein B (Feillet et al. 2000), and no effort should be made to further reduce dietary fat or cholesterol (Rock and Curran-Celentano 1996). Other laboratory abnormalities that characterize starvation and early recovery such as low white blood cell count or elevated liver transaminases typically normalize with weight recovery.

One of the most serious complications of weight restoration is the refeeding syndrome, characterized by marked fluid and electrolyte abnormalities, including low serum phosphate levels. The combination of depletion of total body phosphate stores during catabolic starvation and increased cellular influx of phosphate during anabolic refeeding leads to severe extracellular hypophosphatemia. This well-recognized complication of refeeding, particularly in individuals who have very low body weight, can lead to cardiac arrhythmias, delirium, and even sudden death (Solomon and Kirby 1990). Other potential symptoms of the refeeding syndrome include abnormal sodium and fluid balance; alterations in the metabolism of glucose, protein, and fat; thiamine deficiency; hypokalemia; and hypomagnesemia (Mehanna et al. 2008). This syndrome has most often been noted in refeeding with total parenteral nutrition but can occur with oral and nasogastric refeeding regimens as well (American Psychiatric Association 2006).

In a recent review of studies of the refeeding syndrome, Mehanna et al. (2008) recommend adhering to the National Institute for Clinical Excellence (2004) guidelines for prevention of the refeeding syndrome. Per the guidelines, individuals who have “eaten little or nothing for more than 5 days” should initially be given no more than 50% of their required energy intake. Energy intake should be increased slowly, depending on each individual's needs. Individuals

who are very malnourished ($\text{BMI} \leq 14 \text{ kg/m}^2$; or have had little food intake for 2+ weeks) should be fed no more than 0.021 MJ/kg/24 hours and should be monitored for any cardiac problems. Vitamin supplements (i.e., potassium, phosphate, calcium, magnesium) should be given before and during the first 10 days of refeeding, unless blood levels are high. There is no need to address electrolyte and fluid imbalances prior to refeeding; they will be corrected during the feeding process. Mehanna et al. (2008) note that there is no consensus in the field about the best method for repletion of electrolytes during feeding.

As refeeding progresses, specific laboratory markers can be used to assess improvement or deterioration in nutritional status and in effect measure the transition from protein catabolism to anabolism. A number of different parameters have been used, including serum albumin, prealbumin, retinol-binding protein, transferrin, and C reactive protein. Serum prealbumin has a short half-life and responds rapidly to low energy intake even in the presence of adequate protein intake, making it an excellent marker of nutritional response to refeeding in severely malnourished individuals. Serum prealbumin levels of 20–40 mg/dL are considered normal, levels in the range of 10–15 mg/dL indicate mild malnutrition, levels of 5–10 mg/dL indicate moderate malnutrition, and levels of less than 5 mg/dL suggest severe depletion (Mears 1996). Caregaro et al. (2001) have studied the use of IGF-1 as a biochemical marker of malnutrition and a sensitive index of nutritional repletion in patients with eating disorders.

For patients with binge eating and/or purging, nutritional rehabilitation is geared toward the establishment of a regular eating pattern, moderation of dietary restraint, and elimination of unhealthy dieting practices. Inpatients with bulimia nervosa may require constant observation after meals to keep them from vomiting and to help them learn to tolerate the sensation of fullness following a meal. For obese patients with bulimia nervosa, weight loss may be medically indicated after resolution of the eating disorder. It is an important principle of treatment that cessation of binge eating/purging and simultaneous weight loss are incompatible goals (Rock and Curran-Celentano 1996). In contrast, for obese patients with BED, some have proposed treatments that concurrently target both obesity and binge eating (Devlin 2001).

Psychopharmacological Approaches

A number of studies have evaluated the efficacy of medications in the treatment of eating disorders, and findings are thoroughly summarized in recent reviews (Crow et al. 2009; Reas and Grilo 2008; Shapiro et al. 2007). An important related area, the psychopharmacological management of obesity associated with mental disorders, is be-

yond the scope of this chapter but has been reviewed (Malhotra and McElroy 2002).

The most widely studied class of drugs for eating disorders is antidepressants, including tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and selective serotonin reuptake inhibitors (SSRIs). For patients with bulimia nervosa, antidepressants are significantly more effective than placebo in reducing binge-eating and purging behaviors. Furthermore, it appears that all antidepressants work equally effectively; however, SSRIs yield fewer side effects than MAOIs and TCAs, and fluoxetine is the only medication approved by the U.S. Food and Drug Administration for the treatment of bulimia nervosa. However, longer-term studies of antidepressant treatment with bulimia nervosa suggest that these medications alone are not sufficient to facilitate long-term remission (Romano et al. 2002; Walsh et al. 1991). In BED, SSRIs have been found to significantly reduce binge frequency relative to placebo in the short term (Reas and Grilo 2008). For patients with anorexia nervosa, antidepressant treatment has, for the most part, not been found to be effective (Crow et al. 2009).

Although they are less well studied than antidepressants, other classes of drugs have been reported to be useful in the treatment of BED and bulimia nervosa. Anticonvulsants (carbamazepine, phenytoin, valproate) and other psychotropic medications (lithium, naltrexone, methylphenidate) have been reported to be effective in reducing binge eating in bulimia nervosa or BED, but their routine use has not been clearly established. Topiramate has been found to curb binge-eating episodes in patients with BED and bulimia nervosa and also to cause weight loss in obese patients, a potentially useful side effect that has not been observed with other medications used for these disorders (Arbaizar et al. 2008). Studies have found sibutramine to be significantly more effective than placebo in reducing binge frequency and decreasing weight in obese patients with BED (Appolinario et al. 2003; Milano et al. 2005; Wilfley et al. 2008). In their review of medication for BED, Reas and Grilo (2008) suggested that antiobesity medications (i.e., sibutramine) and antiepileptic medications (i.e., topiramate) may be more clinically useful than SSRIs, as they have been shown to enhance weight loss in trials of cognitive-behavioral therapy and behavioral weight loss treatments for BED and are associated with greater reductions in binge frequency than are SSRIs. Finally, Grilo et al. (2005a) examined orlistat, a lipase inhibitor, as an adjunct to guided self-help cognitive-behavioral therapy for BED. Results indicated that those taking orlistat experienced significantly greater remission from binge eating at post-treatment than did those taking placebo; this difference did not persist at follow-up. However, at follow-up, those

taking orlistat had experienced significantly, although quite modestly greater weight loss than did those taking placebo. This relatively minimal benefit, along with the gastrointestinal effects of orlistat somewhat limit clinical enthusiasm for its use in this setting.

In general, patients with anorexia nervosa have not responded favorably to pharmacotherapy (Crow et al. 2009). However, recent evidence suggests that the antipsychotic medication olanzapine may be a useful tool in the treatment of anorexia nervosa, both for its ability to target the delusions, anxiety, and obsessions that often characterize those with anorexia nervosa and its documented side effect of weight gain (Bissada et al. 2008; Dunican and Del-Dorto 2007), though the knowledge of the latter effect may heighten fat concern and cause many anorectic patients to decline it. In addition, some earlier studies found fluoxetine to be a useful tool for relapse prevention in weight-restored patients with prior anorexia nervosa (Kaye et al. 1991, 2001); a more recent study however failed to replicate these findings (Walsh et al. 2006). It has recently been suggested that D-cycloserine, an antibiotic, may help facilitate fear extinction in exposure therapy for anorexia nervosa (Steinglass et al. 2007). However, this has yet to be evaluated in a randomized controlled trial.

Psychotherapeutic Approaches

Mental health professionals employ a wide variety of therapeutic techniques in their efforts to treat the symptoms of anorexia nervosa, bulimia nervosa, and BED. However, only a few of these psychotherapies, such as cognitive-behavioral therapy (CBT) and interpersonal therapy, have been systematically studied in randomized controlled trials, and not all forms of psychotherapy have been studied across eating disorder diagnoses.

CBT, the most widely studied method of psychotherapy for eating disorders, targets the two broad areas of eating disorder symptoms: 1) cognitive and attitudinal disturbances, such as low self-esteem and overemphasis on and distortion of weight and shape; and 2) behavioral aspects of eating and weight regulation, such as purging and food intake restriction. The goals of CBT are to challenge rigid rules about eating and weight that patients with eating disorders have imposed on themselves and to help these patients develop healthier behaviors and cognitions. CBT for bulimia nervosa was first put into manualized format in the early 1990s (Fairburn et al. 1993b) and has subsequently been modified for patients with anorexia nervosa and BED (Garner et al. 1997; Marcus 1997). CBT has been administered in an individual format, in a group setting, and via a self-help manual. Most recently, Fairburn, one of the authors of the original CBT manual (Fairburn et al. 1993b) developed a “transdiagnostic” treatment pro-

to be used with all forms of eating disorder pathology. This protocol allows a clinician to flexibly tailor CBT interventions to the specific eating disorder pathology with which a given patient presents (Fairburn 2008).

Most studies of CBT have examined patients with bulimia nervosa. In general, it has been shown that CBT is more effective than minimal treatment, supportive psychotherapy, and purely behavioral interventions in reducing both the behavioral and the cognitive disturbances of patients with bulimia nervosa. Studies assessing the effectiveness of CBT alone, medication alone, and their combination in the treatment of bulimia nervosa have shown that CBT alone is more effective than medication alone and leads to more successful long-term maintenance of change. Antidepressants have not been conclusively shown to confer significant additional benefits to CBT treatment for bulimia nervosa. They are thought to be most useful for targeting comorbid symptoms of depression and anxiety (Walsh et al. 1997; Wilson et al. 2007). Studies of CBT in patients with BED have shown that CBT is significantly more effective than no treatment (American Psychiatric Association 2006) or treatment with antidepressants alone (Grilo et al. 2005b). While an early study indicated that CBT was no more efficacious than a behavioral weight loss program (Agras et al. 1994), more recent findings have suggested that CBT may be superior to behavioral weight loss treatment in terms of binge remission (Grilo and Masheb 2005; Munsch et al. 2007; Wilson et al. 2010). Further, adding an individual CBT component to a group behavioral weight loss treatment enhances reduction in binge frequency and abstinence (Devlin et al. 2005, 2007). Great Britain’s National Institute for Clinical Excellence (2004) assigned an “A” grade to CBT for bulimia nervosa and BED, indicating that there is solid empirical evidence to support the efficacy of these treatments. Studies of CBT for anorexia nervosa have been too small in scope and methodologically unsound to yield firm conclusions about the use of CBT in this population.

As mentioned, Fairburn (2008) recently developed a “transdiagnostic” CBT treatment, which can be flexibly tailored to a patient’s specific eating pathology. This treatment can be implemented in two forms—a “focused” form, which resembles traditional CBT for eating disorders, as well as a “broad form,” in which one or more broad maintaining mechanisms of the eating disorder (mood intolerance, clinical perfectionism, core low self-esteem, and interpersonal problems) are addressed. Treatment length varies according to an individual’s specific eating pathology and the treatment modules that are selected. In the first randomized controlled trial of this treatment (Fairburn et al. 2009), individuals across eating disorder diagnoses exhibited significant improvement in eating disorder pathology relative to a

wait-list control. Further, both forms of CBT (“focused” and “broad”) were equally effective, prompting the authors to suggest that the “broad” form is indicated only when there is significant comorbid psychopathology that could be addressed by one of the “broad” treatment modules.

Several additional nonpharmacological forms of treatment for eating disorders deserve mention. Interpersonal therapy was originally developed as a treatment for depression (Klerman et al. 1984) and was subsequently adapted for use with bulimia nervosa and BED (Fairburn 1997; Wilfley et al. 1993). Interpersonal therapy focuses on a person’s interpersonal relationships rather than on the specific behavioral or attitudinal disturbances of the eating disorder. Studies comparing CBT and interpersonal therapy for bulimia nervosa have shown that although CBT appears to exert its effects more quickly, the two treatments both lead to significant long-term symptom change (Agras et al. 2000b; Fairburn et al. 1993a). In patients with BED, CBT and interpersonal therapy appear to be equally effective (Wilfley et al. 2002).

It has been suggested that the behavioral therapy technique of exposure and response prevention (EX/RP) might be effective for individuals with anorexia and bulimia nervosa (e.g., Leitenberg et al. 1988; Steinglass et al. 2007). In patients with anorexia nervosa, EX/RP entails exposing individuals to feared foods and asking them to eat them, thereby challenging their typical response (i.e., to avoid the food). Patients with bulimia nervosa are exposed to binge foods and are then asked to refrain from vomiting after eating these foods. Data on the efficacy of this approach for bulimia nervosa is mixed (American Psychiatric Association 2006), and data on EX/RP for anorexia nervosa is lacking. Some research has supported the efficacy of dialectical behavior therapy (DBT) for bulimia nervosa (Safer et al. 2001) and BED (Telch et al. 2001). These studies must be replicated before firm conclusions can be drawn.

As mentioned above, one alternative to CBT treatment for BED is behavioral weight loss treatment, which focuses on improving the patient’s diet and exercise regimen and restricting his or her caloric intake. In general, it appears that behavioral weight loss is effective in the short term in reducing episodes of binge eating and yielding modest weight loss; however, as discussed above, CBT may be more effective for decreasing binge frequency (Latner and Wilson 2008). Furthermore, few studies have examined the long-term effects of behavioral programs, a key issue in obesity treatment. Some patients who have BED associated with obesity may also pursue weight-loss surgery, the most common procedure being the Roux-en-Y gastric bypass (see Chapter 30, “Surgery”). For these patients, the long-term prognostic significance of an eating disorder is uncertain and merits further study.

There have been few systematic studies of treatment for anorexia nervosa. Patients with anorexia nervosa can be treated either on an inpatient or an outpatient basis. Often treatment is sequenced, starting out with inpatient therapy or partial hospitalization followed by outpatient therapy aimed at relapse prevention. Inpatient therapy usually involves some combination of individual therapy, family therapy, nutritional counseling, and occupational/recreational therapy, typically with behavioral incentives in place for encouraging weight gain. Outpatient therapies used for anorexia nervosa have been eclectic, ranging from nutritional counseling to supportive psychotherapy to CBT. Recently, researchers have begun to empirically evaluate some forms of outpatient treatment for anorexia nervosa. For example, a group from the Maudsley Hospital in London developed a manualized outpatient family therapy for adolescents with anorexia nervosa that seeks to empower parents to refeed their child at home (Lock et al. 2001). Results from a number of studies suggest that the Maudsley method is extremely effective for long-term weight restoration in adolescents with an early onset of anorexia nervosa and a short duration of illness (Eisler et al. 2007; Le Grange et al. 2005; Russell et al. 1987). Recent evidence suggests that the Maudsley method might also be effective for adolescents with bulimia nervosa (Le Grange et al. 2007).

Involuntary Treatment

A critical issue concerning treatment for eating disorders, particularly anorexia nervosa, is the question of involuntary hospitalization for critically ill patients. Patients with anorexia nervosa often experience their illness as an important component of their identity, and they are therefore quite reluctant to undertake treatment. Many patients are hospitalized against their will by loved ones or health care providers with serious concerns about their medical stability. Some countries (e.g., the United Kingdom) have established clear guidelines outlining the conditions under which compulsory treatment for anorexia nervosa is indicated. However, the United States has no such guidelines, and American clinicians treating patients with anorexia nervosa must therefore consult more general standards for involuntary treatment. (See Thiels [2008] and Thiels and Curtice [2009] for comprehensive reviews of involuntary treatment for anorexia nervosa.)

The question of whether involuntary treatment for anorexia nervosa is ethical is a controversial one (Beumont and Carney 2004; Russell 2001; Thiels 2008; Thiels and Curtice 2009). Supporters of involuntary treatment claim that extremely low-weight patients with anorexia nervosa are incapable of making treatment decisions for themselves, due to both the cognitive effects of semistarvation and their dis-

torted thinking surrounding food and body image. Detractors of involuntary treatment cite a host of concerns. Some believe that conceptualizing anorexia nervosa as an illness meriting compulsory treatment overemphasizes its medical aspects and ignores the many pertinent emotional and social factors that may contribute to the illness. Others argue that prospective patients are generally neither psychotic nor grossly impaired in cognitive function and therefore do not lack capacity to make treatment decisions. An additional concern is that patients who are forced into treatment will not be willing to continue treatment once their dire medical situation is resolved and that clinicians who take action to commit their patients against their wishes will destroy the therapeutic relationship (Russell 2001). The American Psychiatric Association (2006) practice guidelines state the following regarding involuntary treatment: "There is general agreement that children and adolescents who are severely malnourished and in grave medical danger should be re-fed, involuntarily if necessary, but that every effort should be made to gain their cooperation as cognitive function improves" (p. 44). In a recent study of involuntary hospitalization of adults and adolescents with eating disorders, Guarda et al. (2007) found that of the 46 patients who initially denied needing admission to the hospital, 20 patients changed their minds after 2 weeks in the hospital and agreed that hospitalization was indicated. This led the authors to speculate that engagement in treatment changed patients' perceptions of their need for help.

Four studies, only one of which took place in the United States, compared the outcomes of patients who had been hospitalized involuntarily with those of voluntary patients (Ayton et al. 2008; Griffiths et al. 1997; Ramsay et al. 1999; Watson et al. 2000). Results of all studies indicated that, in the short term, voluntary and involuntary patients made equally strong progress in terms of weight gain, although in some cases involuntary patients required a longer hospital stay to achieve their target weights. Based on the examination of a national mortality register roughly 5 years after hospitalization, Ramsay et al. (1999) reported higher mortality rates in involuntary patients. Ayton et al. (2008) followed their adolescent patients for 1 year post-hospitalization and found nonsignificant trends indicating that a larger proportion of involuntary patients had a good outcome and a lower proportion of these patients required rehospitalization. In interpreting studies of involuntary versus voluntary treatment, it is important to note that randomized designs are not feasible; thus, the possibility that observed outcomes might be influenced by unidentified differences in patient characteristics or treatment cannot be dismissed. Further study of both the ethical basis and the practical utility of involuntary treatment is needed.

Conclusion

Disordered eating is an important component of the clinical presentation of a variety of patients with weights ranging from emaciated to severely obese. In some cases, disordered eating is of sufficient severity to warrant an eating disorder diagnosis in its own right, whereas in other cases, eating disorder symptoms may complicate the clinical picture of patients with other medical or psychiatric illness. Although the most common eating disorder diagnosis is eating disorder NOS, it is also the most inadequately studied. However, knowledge of the assessment, differential diagnosis, medical complications, and treatment of the classic eating disorders will aid the psychiatric practitioner in developing a treatment approach for patients with a wide range of eating disorder symptoms and in contributing to the multidisciplinary treatment of severely ill patients who are medically compromised by their eating disorder.

Sleep Disorders

Lois E. Krahn, M.D.

OBTAINING SUFFICIENT quantity and quality of sleep is important for good health. Chronic partial sleep deprivation, also known as insufficient sleep, is common in our society. The consequences include depressed mood, interpersonal irritability, decreased daytime vigilance, and cognitive impairment (Pilcher and Huffcutt 1996). However, determining the appropriate amount of required sleep is difficult for several reasons. Sleep duration gradually decreases from a starting length of 16 hours per 24-hour day as human beings make the transition from infancy to adulthood. Interindividual differences in the optimal amount of sleep range from 6 to 12 hours with a mean of 7.5 hours for adults. When a primary sleep disorder, such as obstructive sleep apnea, is present, the continuity and depth of sleep may be compromised independently of sleep duration. These complexities preclude a simplistic identification of a precise target of sleep duration for any individual. Nonetheless, there is consensus that chronically inadequate sleep is detrimental.

Physiological Mechanisms of Normal Sleep

Sleep can be subdivided into two major components: rapid eye movement sleep (REM), which is characterized by high levels of cortical activation in the presence of muscle atonia to prevent corresponding movements, and non-rapid eye movement sleep (NREM), which is separated into three distinct stages. The international classification of sleep was updated in 2007 with the most significant change relating to NREM sleep which previously had four distinct phases (Iber et al. 2007). Table 15-1 summarizes the characteristics and percentage of time spent in each sleep stage by healthy middle-aged adults.

Normal sleep progresses from wakefulness to stage N1 NREM sleep. From this stage of twilight sleep, a patient can be easily awakened by environmental stimuli. Stage N2 NREM sleep is deeper, and moderate environmental stimuli, such as a crack of thunder, no longer cause arousal but rather result in a distinctive electrophysiological event, the K complex. Sleep spindles and K complexes are used to identify stage N2 sleep. When the electroencephalographic (EEG) tracing slows until at least 20% of the activity consists of higher-voltage slow waves, the sleep is rated stage N3. Previously subdivided into Stage III and IV sleep, stage N3 is also called *delta wave sleep*, *deep sleep*, or *slow-wave sleep*. A person awakes from this sleep only when environmental stimuli are marked, such as the prolonged loud noise of an alarm.

As the normal sleep cycle progresses, the EEG activity gradually returns to the most common stage, N2 sleep. Stage N2 sleep evolves into the first REM sleep episode of the night. REM sleep, now called stage R, consists of high-frequency EEG activity, episodic bursts of vertical eye movements, muscle atonia, and penile tumescence. The first REM episode is often brief and typically occurs 70–100 minutes after the person falls asleep. There is marked interindividual variability in arousal threshold in REM sleep (Carskadon and Dement 1994). The sleep cycle repeats four or five times during the night, subsequent REM episodes being of longer duration. In general, slow-wave sleep is more common early in the night, and REM periods become longer toward morning. Because the last REM episode occurs at the very end of the major sleep period, people recall their dreams, and men experience morning erections.

The data in Table 15-1 are useful as normative data because sleep study reports typically describe the percentage of the night spent in each complete stage, and thus subjects with normal sleep patterns can be compared with sub-

TABLE 15-1. Sleep stages in healthy adults

Stage	Percentage	Polysomnographic characteristics	Physiological changes
Stage N1	2-5	Slow eye movements	Easy to arouse
Stage N2	45-55	Spindles, K complexes	More difficult to arouse
Stage N3	13-23	Slow EEG frequency	Difficult to arouse
Stage R	20-25	Rapid eye movements Muscle atonia Increased EEG frequency	Variable arousal threshold Penile engorgement

Note. EEG = electroencephalographic; REM = rapid eye movement.

jects with pathology. In healthy elderly subjects, the relative percentage of time spent in slow-wave sleep decreases, and sleep is generally more fragmented. Figure 15-1 is based on a meta-analysis of distribution of sleep stages over the life span and shows in the absence of pathology a progressive decrease in total sleep time plus stages N3 and R (Ohayon et al. 2004). Patients with disrupted sleep often spend most of the night in stages N1 and N2 and have little

slow-wave or REM sleep. The exact roles of slow-wave sleep and REM sleep in a refreshing night's sleep are not well understood, but significant reductions in either state can lead to undesirable results, including daytime sleepiness, depressed mood, and cognitive impairment. In animal studies, prolonged absolute sleep deprivation has resulted in death attributed to sepsis because of suspected underlying compromise of immune function (Bergmann et al. 1996).

**FIGURE 15-1. Changes in sleep architecture throughout the life cycle**

Evaluation of Sleep

Office Evaluation

A detailed diagnostic interview and physical examination remain the foundation of the sleep evaluation. Table 15-2 lists the many issues that must be evaluated in an assessment for a possible sleep disorder. The decision to refer for a specialty evaluation and diagnostic testing is based on the findings at the history and physical examination conducted by the primary care provider or referring physician. Sleep studies are not necessary for some disorders (e.g., restless legs syndrome) and can be avoided if the classic symptoms of the disease are identified in the absence of any other factors. Clinicians need to obtain both thorough medical and psychiatric histories because many illnesses and disorders can alter sleep. As people age, sleep complaints become more common, not because of primary sleep disorders but because of comorbid conditions (Vitiello et al. 2002). Tables 15-3 and 15-4 list disorders that may lead to sleep problems. Treatment should therefore stabilize the underlying disease.

An interview with a bed partner is of great value, if feasible, especially in regard to snoring, respiratory pauses, and unusual behaviors. A screening interview is available to help collect data from family members concerning possible REM sleep behavior disorder and other common conditions (Figure 15-2). The more attentive the bed partner, the more likely it is the clinician will be able to obtain a

useful history of what actually happens while the patient sleeps. Presbycusis and sound sleep may limit the ability of a bed partner to provide observations.

Sometimes, even if the patient sleeps alone, a family member can provide useful information if the partner moved out of a shared bedroom because of intolerable snoring or unusual behaviors. Although this interview results in limited specific information about current symptoms, it clearly increases the likelihood that a pathological condition is present.

During the physical examination, the examiner should note the patient's level of alertness (in the waiting room and during the appointment), body mass index, neck circumference, nasopharyngeal abnormalities, protrusion of mandible, thyroid size, pulmonary findings, findings at cardiac auscultation, and cognition. Valuable laboratory tests include measurement of thyroid-stimulating hormone, ferritin, cobalamin, and folate and a complete blood cell count. The findings of these studies are helpful in identifying medical disorders that can enter into the differential diagnosis of several sleep disorders.

Because of the cost and inconvenience of sleep studies, a clear need exists for cost-effective screening tools for determining which patients are good candidates for more definitive diagnostic testing. In children, careful visualization of tonsillar size has been found highly sensitive and specific as a screening test for obstructive sleep apnea (A. Li et al. 2002). In adults, other factors, the most significant of

TABLE 15-2. Essential issues in a sleep diagnostic interview of patients and bed partners

Presenting complaint?	Previous sleep evaluations?
Sleep interruptions—Parenting issues? Caregiver issues?	Work schedule—Rotating shifts? On call?
Preferred sleep time—Early or late bedtime? Sleep position?	Exercise schedule—Late in the evening?
Sleep environment—Bed partner? Comfortable bedding? Bright light?	Insomnia—Early? Middle? Late?
Noisy? Vibrations? Excessive heat/cold? Pets?	Sleep walking? Somnambulism? Sleep eating?
Nap schedule—Frequent or prolonged?	Motor vehicle accident due to sleepiness?
Excessive daytime somnolence?	Alcohol, street drug, or caffeine use, abuse, or dependence?
Cataplexy? Sleep paralysis? Hallucinogenic experiences?	Snoring? Observed pauses?
Nocturnal movements?	Pain—Chronic? Acute? Medications wear off?
Gastrointestinal reflux—Diagnosed? Partially treated?	Hangover effect? Amnesia?
Erectile problems? Urinary frequency? Enuresis?	Vivid dreams, nightmares?
Depression, mania, or panic attacks?	Herbal preparations?
Prescription drug use, abuse, or dependence?	Childhood sleep history?
Family sleep history?

 Sleep state misperception
 Mood disorders (depression, mania)

Primarily environmental

Community noise (traffic, alarms, neighbors, gunshots, etc.)
 Altered temperature (too hot, too cold)

which is body mass index, confound clinical prediction models that rely solely on the findings of the nasopharyngeal examination. In one large-scale study with a community-based sample, investigators found that in adults, male sex, older age, higher body mass index, greater neck circumference, snoring, and repeated respiratory pauses were all independent correlates of moderate to severe breathing-related sleep disorder (Young et al. 2002b).

Because many patients minimize excessive daytime sleepiness or slowly adapt to it, they may lose insight into the degree of their excessive daytime sleepiness. History from other sources, such as family members, may be necessary. Daytime symptoms related to excessive sleepiness can be evaluated with the brief and convenient Epworth Sleepiness Scale (Johns 1991) (Table 15-5). Unfortunately, no similar scale or questionnaire has been used widely in

TABLE 15-4. Selected causes of excessive daytime sleepiness**Primarily neurological**

Idiopathic narcolepsy or hypersomnia
 Delirium
 Kleine-Levin syndrome
 Narcolepsy caused by lesion near the third ventricle

clinical practice to screen for nocturnal sleep symptoms and disorders.

Diagnostic Procedures

Techniques for measuring sleep and body functions during sleep have evolved since the initial description of REM sleep in 1953 (Aserinsky and Kleitman 1953). Currently, most sleep studies are conducted in facilities using sophisticated computerized equipment that is steadily replacing the older paper-and-ink polygraph units. These recording devices typically monitor and store the multiple physiological measurements considered essential for a polysomnographic study (Table 15-6). Trained technologists attend the patient during the study, making adjustments and assisting as needed. Sleep disorders centers designed for the evaluation and treatment of the full spectrum of sleep disorders are free-standing or located in a hospital. Although there is considerable interest in portable systems with which sleep studies can be performed in the patient's home, these systems have not been widely available owing to quality and reimbursement issues. In the United States, Medicare recently approved the use of portable devices that collect no less than three types of physiological data for patients suspected to be at high risk of obstructive sleep apnea. Many patients welcome the availability of portable studies that can be conducted the privacy and comfort of their home. For carefully selected patients where there is a high degree of suspicion about obstructive sleep apnea and the absence of insomnia, the procedure is cost-effective. When the differential diagnosis includes sleep

Mayo Sleep Questionnaire—Informant

Do you live with the patient? ☐ Yes ☐ No (If No, END FORM HERE)

Do you sleep in the same room as the patient? ☐ Yes ☐ No

If no, is it because of his/her sleep behaviors (i.e., snores too loud, acts out dreams, etc.)? ☐ Yes ☐ No

Please mark "Yes" if the described event has occurred at least 3 times.

1. Have you ever seen the patient appear to "act out his/her dreams" while sleeping? (punched or flailed arms in the air, shouted or screamed)
 - ☐ 0 no
 - ☐ 1 yes
 - If Yes,
 - a. How many months or years has this been going on?
 - year(s)
 - months
 - b. Has the patient ever been injured from these behaviors (bruises, cuts, broken bones)?
 - ☐ No
 - ☐ Yes
 - c. Has a bedpartner ever been injured from these behaviors (bruises, blows, pulled hair)?
 - ☐ No
 - ☐ Yes
 - ☐ No bedpartner
 - d. Has the patient told you about dreams of being chased, attacked or that involve defending himself/herself?
 - ☐ No
 - ☐ Yes
 - ☐ Never told you about dreams
 - e. If the patient woke up and told you about a dream, did the details of the dream match the movements made while sleeping?
 - ☐ No
 - ☐ Yes
 - ☐ Never told you about dreams
2. Do the patient's legs repeatedly jerk or twitch during sleep (not just when falling asleep)?
 - ☐ No
 - ☐ Yes
3. Does the patient complain of a restless, nervous, tingly, or creepy-crawly feeling in his/her legs that disrupts his/her ability to fall or stay asleep?
 - ☐ No
 - ☐ Yes
- If Yes,
 - a. Does the patient tell you that these leg sensations decrease when he/she moves them or walks around?
 - ☐ No
 - ☐ Yes
 - b. When do these sensations seem to be the worst?
 - ☐ before 6 pm
 - ☐ after 6 pm
4. Has the patient ever walked around the bedroom or house while asleep?
 - ☐ No
 - ☐ Yes
5. Has the patient ever snorted or choked him/herself awake?
 - ☐ No
 - ☐ Yes
6. Does the patient ever seem to stop breathing during sleep?
 - ☐ No
 - ☐ Yes
 - If Yes,
 - a. Is the patient currently being treated for this (e.g., CPAP)?
 - ☐ No
 - ☐ Yes
7. Does the patient have leg cramps at night? (e.g., also called a "charlie horse" with intense pain in certain muscles in the leg)?
 - ☐ No
 - ☐ Yes
8. Rate the patient's general level of alertness for the past 3 weeks on a scale from 0 to 10.

disorders other than obstructive sleep apnea or when a patient sleeps poorly increasing the chance that monitors get dislodged, portable studies have not been demonstrated to be appropriate. In these cases the sleep study may need to be repeated in a laboratory setting, in effect increasing the overall cost and inconvenience.

In some tertiary-care hospitals, polysomnographic equipment can be transported to the medical-surgical floor or intensive care unit. In selected cases of a primary sleep disorder coexisting with another process, such as severe chronic obstructive pulmonary disease, identifying and treating the sleep disorder may be necessary before a patient can be stabilized and discharged (Olson 2001). Less research has been conducted on how to screen or test for primary sleep disorders in other settings, such as nursing homes. Sleep diaries, completed by patients or caregivers, can be used but often are inaccurate owing to the poor recall of sleep parameters, lack of adherence to daily documentation, or distorted perception (Mercer et al. 2002).

Use of devices such as wrist actigraphs has been studied in the hospital setting, but these devices are used mostly in ambulatory practices (Krahn et al. 1997). Precise determination of sleep-wake status is impossible with actigraphs because the equipment measures limb acceleration and does not record EEG activity. Accordingly, specific sleep stages cannot be identified. One distinct advantage of actigraphy, however, is that the compact device can be worn 24 hours per day for 1–4 weeks. This longitudinal monitoring also allows identification of irregular sleep-wake patterns while the patient is pursuing routine activities.

Other portable monitoring devices, which do not enable the full complement of measures obtained with polysomnography, have been marketed, but all have limitations. Several models monitor only respiratory function without EEG data. Similarly, overnight pulse oximetry measures only oxygen saturation and heart rate. With this equipment, the clinician does not know heart rhythm,

TABLE 15-6. Components of polysomnography

Essentials

- Electroencephalography (typically three channels)
- Electromyography (surface)—chin and lower extremity
- Electro-oculography (two channels)
- Electrocardiography
- Respiratory effort measurement
- Airflow monitoring (nasal pressure or temperature)
- Pulse oximetry

Options

- Videotaping (conventional or digital) with infrared lighting
- Transcutaneous carbon dioxide monitoring
- Esophageal pressure monitoring
- Esophageal pH monitoring
- Additional electromyography (upper extremities, intercostal muscles)
- Additional electroencephalography (seizure detection)

body position, or whether the patient is asleep or awake or in NREM versus REM sleep (Netzer et al. 2001). False-negative results can be obtained from patients with obstructive sleep apnea so severe that they cannot fall asleep. Oxygen saturation looks deceptively normal while patients are lying awake in bed at night. Only after patients fall asleep do they begin to experience significant oxygen desaturation. The setting of the oximeter unit can greatly influence the appearance of the compressed overnight printout and contribute to false-positive and false-negative impressions regarding sleep-related breathing conditions (Davila et al. 2002). The results should specify the time settings. Setting up the equipment to acquire data with briefer time periods—for example, 3 seconds rather than 12 seconds—is preferable in screening for breathing-related sleep disorder.

The multiple sleep latency test is used to identify disorders of excessive daytime sleepiness, including narcolepsy (Krahn et al. 2001a). Patients must first undergo an overnight sleep study for exclusion of other sleep disorders caused by disrupted nocturnal sleep. If the patient has had, at minimum, 6 hours of sleep to preclude sleep deprivation, then a valid multiple sleep latency test can be conducted the next day. Patients are asked to take four or five scheduled naps wearing a simplified set of leads including only EEG, electromyographic, and electro-oculographic leads. The test is used to measure initial sleep latency and initial REM latency, if present, for each nap. Patients are asked to stay awake between naps, to refrain from stimulants such as caffeine and prescribed medications, and to undergo drug screening for occult sedative use. The maintenance of wakefulness test is a similar procedure with slight modifi-

cations. Instead of being asked to fall asleep, patients are asked to stay awake during four or five specified daytime sessions (Mitler et al. 1982). The data can be used to document that a patient with a treated sleep disorder such as obstructive sleep apnea or narcolepsy can sustain wakefulness sufficiently to drive or operate equipment requiring sustained vigilance. The result of this test is sometimes used as a marker of successful treatment outcome.

Sleep Disorders

Several disorders with signs and symptoms closely linked with sleep or the 24-hour sleep-wake schedule are generally classified as sleep disorders. Many other disease states—for example, tumor growth and chemotherapy tolerability—vary according to a 24-hour schedule, but are not classified as sleep disorders because circadian rhythmicity is not the defining feature (Mormont and Levi 2003). The clearest example of this distinction would be restless legs syndrome where periodicity and timing set this condition apart from other painful neurological diseases.

Narcolepsy and Other Disorders of Excessive Daytime Sleepiness

Narcolepsy is an excellent example of a disorder with dysfunction of a specific sleep state, in this case REM sleep. Isolated fragments of REM sleep intrude into wakefulness, and the result is the characteristic symptoms that invariably cause excessive daytime sleepiness. Narcolepsy in humans was first described in 1880 by the French neurologist Gelineau. Since that time, this sleep disorder has been observed in several dog breeds as well as in horses and sheep. These naturally occurring animal models have greatly facilitated investigations into the pathophysiological mechanisms of narcolepsy.

Prevalence

Narcolepsy is a more common disorder than many recognize. As a result, the need to identify and treat it offers a valuable opportunity to prevent medical, occupational, and social complications. When patients present with sleepiness, many other conditions, including insufficient sleep and breathing-related sleep disorder, should be suspected before narcolepsy is considered. The average delay between onset of symptoms and diagnosis is 10 years.

In a U.S. community sample, narcolepsy was observed to have prevalence of 0.06% (Silber et al. 2001). All cases of narcolepsy met the diagnostic criteria on the basis of excessive daytime sleepiness and laboratory findings. In 64% of these cases, the patient had cataplexy. Incidence data from the same study confirmed the long-standing impression

that narcolepsy is slightly more common in men (1.72 per 100,000) than women (1.05 per 100,000). The disease most commonly starts in the second decade of life and is a chronic condition.

Narcolepsy is no longer believed to be a familial disease, although rare cases of familial clusters have been identified (Overeem et al. 2001). When narcolepsy is familial, the mode of inheritance is neither a simple recessive or dominant one. The debate continues about whether narcolepsy is the result of an autoimmune or neurodegenerative process. The association between 85% of cases of narcolepsy with cataplexy and a specific human leukocyte antigen (HLA) allele (DQB1*0602) is the basis of postulation about an autoimmune mechanism; despite several investigations, no confirmatory evidence had been found as of early 2004 (Black et al. 2001). The possibility of the presence of an extremely selective degenerative process stems from the autopsy finding of gliosis in the hypothalamus of narcolepsy patients (Thannickal et al. 2000).

Clinical Features

Narcolepsy is characterized by chronic excessive daytime sleepiness with episodic sleep attacks. Approximately 65%–75% of patients with narcolepsy have cataplexy, which is a condition in which an emotional trigger, most commonly laughter, provokes abrupt muscle atonia without loss of consciousness. Other associated symptoms of narcolepsy include sleep paralysis (isolated loss of muscle tone associated with REM in normal sleep) and hypnagogic and hypnopompic hallucinations (vivid dreaming occurring at the time of sleep onset and awakening that can be difficult to distinguish from reality). When related to the dissociated components of REM sleep, such as muscle atonia (cataplexy and sleep paralysis) and vivid dreams (hypnagogic and hypnopompic hallucinations), these phenomena can intrude into wakefulness. Disturbed nocturnal sleep has been added as a fifth part of this constellation of symptoms.

Pathophysiological Mechanism

In 2000, patients with narcolepsy were reported to have undetectable levels of a newly identified neuropeptide, hypocretin (also known as orexin), in cerebrospinal fluid. Hypocretin is synthesized by a small number of neurons in the anterior hypothalamus that project widely throughout the central nervous system (CNS). After studies of other sleep and neurological disorders, the absence of this neuropeptide appears to be highly specific (99%) for narcolepsy (Mignot et al. 2002). Hypocretin influences sleep, appetite, and temperature. As of early 2004, the relevance of hypocretin as a neuromodulator in diseases other than narcolepsy was

unknown. The genes for the ligands and receptors for hypocretin have been knocked out in mice with the development of excessive sleepiness, cataplexy, and obesity (Smart and Jerman 2002). An autoimmune mechanism has been suspected ever since the association between narcolepsy and a specific HLA allele was recognized 25 years ago. Recent work has demonstrated a strong association between narcolepsy and polymorphisms in the T cell lymphocyte receptors, which may point to a new autoimmune mechanism for neuropsychiatric disease (Hallmayer et al. 2009).

Diagnostic Testing

The most important part of an evaluation for narcolepsy is a careful interview to screen for long-standing excessive daytime sleepiness and spells triggered by emotions. The definitive bedside test for cataplexy is demonstrating the transient absence of deep tendon reflexes during the episode (Krahn et al. 2000). This procedure also aids in differentiating cataplexy from pseudocataplexy (Krahn et al. 2001b). However, cataplexy is difficult to provoke, and the episode is often too brief to allow a physical examination.

In most cases diagnostic testing in a sleep disorders center is necessary to supplement the clinical interview. The diagnosis must be as certain as possible before a life-long course of treatment is begun. An overnight sleep study is important for ruling out other causes of excessive daytime sleepiness. This study is ideally preceded by wrist actigraphy to confirm adequate sleep in the weeks before testing and to eliminate sleep deprivation as the cause. If polysomnography reveals that the patient has obstructive sleep apnea or another primary sleep disorder, these conditions must be stabilized before reliable daytime testing can be conducted. The multiple sleep latency test quantifies the time to fall asleep during daytime naps and confirms the presence of inappropriate daytime REM sleep. Testing for hypocretin in the cerebrospinal fluid is not yet part of clinical practice.

Complications

Narcolepsy is associated with a poorer quality of life than epilepsy (Broughton and Broughton 1994). Without treatment, patients are at risk of motor vehicle accidents and occupational injuries related to sleepiness. Patients with narcolepsy have a higher-than-expected rate of obstructive sleep apnea, REM sleep behavior disorder, and periodic limb movements (Krahn et al. 2001a). New data indicate that patients with narcolepsy have higher rates of obesity, which potentially may be linked to the hypocretin deficiency. Current pharmacological treatments for sleepiness do not appear to have a significant mitigating effect on weight gain (Schuld et al. 2002).

Treatment

Patient education should emphasize the importance of a consistent sleep-wake schedule, the need for adequate sleep, the value of brief daytime naps, and refraining from driving a car when sleepy. Pharmacological treatment options for narcolepsy include methylphenidate or amphetamines, which target excessive daytime sleepiness (Mitler and Hayduk 2002). Extended-release preparations of methylphenidate and amphetamines have the advantage of continuous drug delivery, which reduces the daytime variability in alertness that may occur with the immediate-release forms, which are taken twice or three times a day. Modafinil is a unique wake-promoting medication that was approved by the U.S. Food and Drug Administration (FDA) in 1999. Modafinil, lacking sympathomimetic activity, is not considered a psychostimulant. The mechanism of action is not well understood (U.S. Modafinil in Narcolepsy Multicenter Study Group 1998). Sodium oxybate (also known as gamma-hydroxybutyrate), approved by the FDA in 2002, is a medication indicated for the treatment of narcolepsy. This novel hypnotic was approved initially for the treatment of cataplexy and subsequently permitted for all narcoleptic symptoms. Recently armodafinil, a longer-acting R-enantiomer, was shown to reduce excessive daytime sleepiness in narcolepsy and to be more suitable than modafinil for administration once a day (Keam and Walker 2007).

An endogenous substance, sodium oxybate, increases slow-wave sleep and also improves sleep continuity (Lammers et al. 1993). Although somewhat counterintuitive, clinical trials in narcolepsy have demonstrated that sodium oxybate decreases excessive daytime sleepiness by increasing nighttime sleep (Black and Houghton 2006). Improving the quality of nocturnal sleep also appears to reduce the severity of cataplexy, sleep paralysis, and hypnagogic hallucinations and improve overall quality of life (Weaver and Cuellar 2006). Because of its expense and the inconvenience of taking a liquid medication twice during the night (upon retiring for bed and again 4 hours later), this medication is reserved for patients whose condition is more refractory to treatment. Taken as prescribed, sodium oxybate is well tolerated. Risks arise from combining it with other sedative agents and taking it in excessive amounts. Tricyclic antidepressants and, to a lesser degree, selective serotonin reuptake inhibitors (SSRIs) historically have been used to treat cataplexy. These agents increase the level of norepinephrine in the brain and thus suppress REM sleep-related symptoms. Sodium oxybate needs to be used with caution. Historically known as gamma-hydroxybutyric acid (GHB), it is sought by drug abusers to increase euphoria and libido. Overdoses with illicit use, leading to coma and respiratory depression, are common because of the difficulty in titrat-

ing the dosage. Likely because of the short half-life, fatality with overdose is relatively rare unless GHB is mixed with other substances (Knudsen et al. 2008).

Idiopathic Hypersomnia

Idiopathic hypersomnia is a disorder of unknown etiology characterized by excessive daytime sleepiness in the absence of other specific symptoms. Patients typically have a prolonged duration of nocturnal sleep as well as unrefreshing daytime naps. The prevalence of idiopathic hypersomnia is unknown, but the condition appears to develop at equal rates in both male and female patients. As in narcolepsy, symptoms first appear in adolescence or young adulthood. This condition increases the risk of motor vehicle accidents and occupational or educational problems due to sleepiness. Depression may be another consequence (Bassetti and Aldrich 1997).

The clinical interview should concentrate on the duration of excessive daytime sleepiness, the sleep-wake schedule, and the presence of mood disorders. The presence of a mood disorder complicates the evaluation because both depression and antidepressant medications can alter sleep architecture. Because of the broad differential diagnosis, the evaluation for idiopathic hypersomnia must be in-depth. Ideally the diagnostic testing consists of wrist actigraphy, polysomnography, multiple sleep latency testing, and drug screening. The testing for respiratory arousals must be particularly rigorous, since any degree of upper airway resistance syndrome or subclinical sleep-related breathing disorder can produce persisting excessive daytime sleepiness. The diagnosis of idiopathic hypersomnia is established on the basis of the finding of quantifiable excessive daytime sleepiness on the multiple sleep latency test. Unlike patients with narcolepsy, those with idiopathic hypersomnia have no sleep-onset REM episodes and have normal levels of hypocretin in the cerebrospinal fluid.

There is less consensus on the treatment approach to idiopathic hypersomnia than with other sleep disorders. Patient education regarding adequate sleep is critical. A common strategy is initially to request patients to extend sleep time by at least an hour with the intent to aid patients whose sleepiness may be related to inadequate nocturnal sleep. Long sleepers, who require an hour or more sleep than typical persons to obtain adequate sleep, may be erroneously identified as having idiopathic hypersomnia. Apart from sleep extension, treatment is otherwise similar to that used for narcolepsy. In contrast to narcolepsy, daytime naps are not encouraged because they are not refreshing. If the results at evaluation suggest the presence of a coexisting mood disorder after sleep tests are completed, use of an antidepressant is appropriate and does not cause problems. More stimulating antidepressants are preferred.

Kleine-Levin syndrome, also known as recurrent hypersomnia, is an important part of the differential diagnosis of idiopathic hypersomnia. Patients with recurrent hypersomnia are generally male adolescents who engage in binge eating and have periodic hypersomnia that lasts several weeks (Minvielle 2000). The typical pattern is recurrent episodes, each lasting approximately a week, spanning 8 years. Depressed mood has been reported in 48% of affected patients (Arnulf et al. 2005). In the absence of any randomized controlled trials in Kleine-Levin syndrome, psychostimulants and lithium have been reported to prevent relapses (Oliveira et al. 2009).

Parasomnias

Parasomnias are disorders in which patients have inappropriate intermittent motor behaviors during sleep. REM sleep behavior disorder is arguably of most interest because of the distressing behaviors and the relationship with other neurological conditions. Patients with REM sleep behavior disorder appear to “act out their dreams” by yelling or gesturing during REM sleep. They lack the muscle atonia normally found in REM sleep and move in response to dream imagery. REM sleep behavior disorder appears more common than originally suspected, although the prevalence has not been established. Risk factors for this sleep disorder are male sex (90% of patients described in the literature) and advanced age (most patients have been 50 years or older) (Olson et al. 2000). SSRIs and venlafaxine have been suggested as possible triggers. Patients and their bed partners can be seriously injured by hitting, kicking, rolling, and other more complex behaviors. REM sleep behavior disorder is associated with several neurological disorders, including Parkinson’s disease (15%–33% of patients), multiple system atrophy (69%–90%), and dementia with Lewy bodies (50%–80%) (Boeve et al. 2007; Comella et al. 1998). These neurodegenerative disorders share the pathological finding of cerebral intracellular inclusion bodies containing alpha-synuclein.

Polysomnography optimally with extra electromyographic leads and synchronized videotaping can be useful for documenting increased electromyographic tone during REM sleep. Patients can have an inappropriate degree of muscle tone without reports of disruptive or inappropriate behaviors. These patients are not yet considered to have REM sleep behavior disorder, but the disease is expected to evolve. Polysomnography also helps identify complicating disorders, such as obstructive sleep apnea, which is of particular importance if benzodiazepines are used later. Nocturnal seizures should be excluded from the diagnosis. Treatment includes modifying the bedroom to reduce injury to the patient and bed partner. Bed partners often choose to sleep apart. Clonazepam has become the

medication of choice because it reduces the muscle movement that occurs during REM sleep, reducing the risk of injury (Schenck and Mahowald 1990), but there are no randomized controlled trials of treatment for REM sleep behavior disorder.

NREM parasomnias, unlike REM sleep behavior disorder, are markedly more common in children and adolescents than in adults. Patients act unusually, walk, or eat when not fully alert. Polysomnography is not always needed because the behaviors are often intermittent and therefore difficult to observe with a single night of monitoring. Sleep deprivation, nocturnal arousals, shifting bedtimes, and consumption of alcohol can precipitate episodes in susceptible individuals. In one study sleep deprivation was used as a trigger of sleepwalking.

Treatment of NREM parasomnias includes modifying the sleeping environment to promote safety, adhering to a consistent sleep schedule, reducing nocturnal awakenings, and, if warranted, using medications such as hypnotics to prevent arousal (Pilon et al. 2008). The relationship between parasomnias and posttraumatic stress disorder remains unclear.

Nocturnal panic disorder is increasingly regarded as a rare disorder. However, panic disorder with attacks occurring both during the day and at night is not rare. Treatment of this condition ideally includes a combination of medications and behavioral measures. When panic or anxiety exists exclusively at night, most typically in NREM sleep, a broad differential diagnosis should be used to screen for breathing-related sleep disorder, nightmares, and medical disorders (e.g., arrhythmia, angina, and gastroesophageal reflux) triggering the anxiety. Confirmed treatment of nocturnal panic disorder relies on medications because behavioral measures are less feasible when an attack develops while the patient sleeps. Hypnosis at bedtime has been tried (Hauri et al. 1989).

Whenever a patient presents with unusual behavior at night, the differential diagnosis must include epilepsy. In particular, seizures arising from a locus in the frontal lobe can result in stereotypical but bizarre events during slow-wave sleep (Dyken et al. 2001).

Sleep-Related Breathing Disorder and Snoring

Sleep-related breathing disorder comprises obstructive sleep apnea, central sleep apnea, and obesity hypoventilation syndrome. Obstructive sleep apnea is the most notable of these conditions because of its high prevalence and association with numerous medical conditions if untreated (Walker 2001). Obstructive apnea is defined as cessation of airflow that lasts at least 10 seconds owing to impedance of respiratory effort as the result of airway obstruction. Hypopnea is defined as reduction in airflow resulting in at least a

TABLE 15-7. American Academy of Sleep Medicine diagnostic criteria for obstructive sleep apnea

Essential signs and symptoms

1. Excessive daytime sleepiness
2. Obstructed breathing during sleep

Essential polysomnographic findings

1. More than five episodes of apnea (>10 seconds) per hour of sleep with evidence of respiratory muscle effort and one of the following:
 - a. Apnea causing frequent arousals
 - b. Apnea causing oxygen desaturation $\geq 4\%$
 - c. Bradycardia

Source. Adapted from American Academy of Sleep Medicine 2005.

4% decrease in oxygen saturation. Table 15-7 outlines the diagnostic criteria for obstructive sleep apnea. Apnea and hypopnea both are considered clinically significant markers of disease and as a result are reported together as the apnea-hypopnea index. Since these criteria were published, sleep specialists have recognized that hypopnea with an oxygen desaturation greater than or equal to 4% must be quantified in addition to pure apnea.

Prevalence

Patients with obstructive sleep apnea are the largest subgroup of patients referred to sleep disorders centers. This disorder, which affects at least 2% of women and 4% of men ages 30–60 years (Young et al. 1993), is strongly associated with obesity. Obstructive sleep apnea is more common without marked obesity in several racial groups, including Asians, in whom craniofacial anatomic features can produce a narrower nasopharyngeal airway (K. Li et al. 2000). Advanced age, male sex, and postmenopausal state are all associated with a higher prevalence of this condition (Young et al. 2002a). In subpopulations of patients with hypertension, heart disease, and adult-onset diabetes mellitus, as many as 30%–40% of patients can have obstructive sleep apnea (Partinen 1995).

Clinical Features

Most patients with obstructive sleep apnea snore. Family members may observe disruptive snoring intermixed with quiet periods and reduced respiration. Although essentially all patients with obstructive sleep apnea snore, the reverse is not the case. Snoring is an extremely common phenomenon in the community, affecting 25% of men and 15% of women. For this reason, screening for obstructive sleep apnea must rely on more than simply a history of snoring. Patients may have restless sleep at times, to the point they are suspected to have a parasomnia such as REM behavior

disorder. Excessive sweating and morning headaches can be present. Patients may report choking or being awakened by their snoring. An increased rate of nocturia has been described, possibly because the patient is more aware of bladder fullness when awakened by the breathing disorder (Pressman et al. 1996). Obstructive apnea can lead to respiratory arousals and oxygen desaturation, which can cause transient elevations in blood pressure initially at night (Dart et al. 2003). Hypertension is common, especially in patients with severe obstructive sleep apnea. Initially, blood pressure increases follow each obstructive event, but if apneic or hypopneic episodes are frequent, blood pressure can remain elevated throughout the night and day. Pulmonary hypertension also has been an associated finding, particularly with severe obstructive sleep apnea.

The hemodynamic alterations of obstructive sleep apnea include systemic hypertension, increased right and left ventricular afterload, and increased cardiac output. Earlier reports attributed the association between obstructive sleep apnea and cardiovascular disease to the common risk factors such as age, sex, and obesity. However, newer epidemiological data confirm an independent association between obstructive sleep apnea and these cardiovascular diseases. Possible mechanisms include a combination of intermittent hypoxia and hypercapnia, repeated arousals, sustained increase in sympathetic tone, increased platelet aggregation, reduced baroreflex sensitivity, and elevated plasma fibrinogen and homocysteine levels (Bradley and Floras 2009).

Pathophysiological Mechanism

Patients with obstructive sleep apnea experience intermittent collapse of the upper airway. The most common site of obstruction is the pharynx, a tube unsupported by cartilage or bone that contorts during swallowing and speech. The pharyngeal musculature serves to keep the upper airway open and opposes the subatmospheric pressure in the pharynx itself. The genioglossus muscles also pull forward to keep the upper airway clear of obstruction. This balance is further influenced by anatomic structures (adipose tissue, tongue size, mandible, soft palate, and tonsils) and neuromuscular mechanisms (activity of the pharyngeal muscles affected by sleep state, degree of muscle relaxation, and hypnotic medications) (Rama et al. 2002). The obstructed upper airway leads to cessation or reduction of airflow resulting in a cortical arousal. Snoring or increased effort to ventilate due to narrowing but no actual collapse of the airway is called *upper airway resistance syndrome*, a potentially distressing but subclinical form of obstructive sleep apnea that occurs more often in women than in men (Guilleminault et al. 2001).

Diagnostic Testing

Polysomnographic data generated in a sleep disorders center have been the standard for the diagnosis of breathing-related sleep disorder (Bresnitz et al. 1994). Overnight pulse oximetry has not been demonstrated to be cost-effective, reliable, or sufficiently sensitive but newer multichannel portable monitors are available that are utilized with straightforward cases. Many centers use “split-night” sleep studies. Under these circumstances, patients are monitored while asleep, ideally until they experience both NREM and REM sleep in both the supine and nonsupine positions. Once a diagnosis of breathing-related sleep disorder is established, the technologist introduces nasal continuous positive airway pressure (CPAP). Nasal CPAP is applied through a nasal mask connected to a blower that can be adjusted so that pressurized air is delivered to the upper airway. Having positive pressure keep open the airway is particularly important during expiration, when the airway most commonly collapses in patients with obstructive sleep apnea. The nasal CPAP pressure setting can be carefully titrated in response to airway narrowing during the rest of the sleep study. In the morning, the patient can be asked about comfort and acceptance of this therapy. A split-night study is an opportunity for clinician and patient to compare the untreated versus the newly treated state. The procedure is controversial because of the limited time available for both the diagnostic study and the treatment trial. In most cases, a split-night study eliminates the need for a second night in the laboratory (Strollo et al. 1996).

Complications

The complications of obstructive sleep apnea lead to significant morbidity and mortality. Risk factors for obstructive sleep apnea (see section “Evaluation of Sleep” earlier in this chapter) are male sex, older age, high body mass index, greater neck circumference, snoring, and observed pauses in breathing at night (Young et al. 2002b). Untreated obstructive sleep apnea has been associated with systemic hypertension, right-sided heart failure, cerebrovascular accidents, type 2 diabetes, cognitive impairment and depression (Rakel 2009). The excessive daytime sleepiness that can result from untreated obstructive sleep apnea can put patients at risk of motor vehicle accidents, cognitive problems, and interpersonal difficulties. An association has been described between obstructive sleep apnea and gastroesophageal reflux. Nevertheless, treatment with anti-reflux medication reduces arousals but not apneic episodes, and intervention for obstructive sleep apnea with nasal CPAP does reduce reflux (Ing et al. 2000).

Treatment

Since the early 1980s, the treatment of obstructive sleep apnea has been revolutionized by the use of nasal CPAP. This treatment involves delivering pressurized air (typically 3–18 cm of water pressure) to sites of upper airway collapse (generally the oropharynx and less commonly the nasopharynx) and forcing the airway open. Apnea and snoring are eliminated, allowing the patient to sleep continuously without being aroused to breathe. Nasal CPAP is generally introduced when the patient is sleeping in the sleep laboratory, where staff can adjust the pressure appropriately and assist with mask fit. Newer technology entails the use of self-titrating devices that modify the pressure setting breath by breath without requiring technologist involvement (Berry et al. 2002). The extent to which these more sophisticated machines may replace nasal CPAP titrations conducted in a sleep laboratory is not clear.

Patients with severe obstructive sleep apnea often report marked improvement, within days, in their mood and energy. This improvement provides positive reinforcement that leads to good compliance with nasal CPAP treatment (Sullivan and Grunstein 1994). Patients with mild to moderate obstructive sleep apnea have more adherence problems, the compliance rate being estimated at 10%–50%. Optimizing compliance with CPAP is a challenge but recent studies show that providing a safe hypnotic medication (zolpidem or eszopiclone) short term may be beneficial presumably by increasing sleep duration (Collen et al. 2009). Certain medications, especially long-acting benzodiazepines and opioids, can exert a similar effect and can depress the reticular activating system to reduce the arousal threshold and prevent arousals that effectively interrupt prolonged episodes of apnea (Dolly and Block 1982). Patients with obstructive sleep apnea who consume alcohol close to bedtime pose a challenge, because alcohol has been observed to increase the collapse of the upper airway. These patients often need higher nasal CPAP settings to prevent apnea. In addition, if the sleep study is done when the patient has not been consuming alcohol often, the selected pressure settings are insufficient on nights when the patient has ingested alcohol (Berry et al. 1991).

Another treatment of obstructive sleep apnea is bilevel positive airway pressure. This therapy represents a modification of CPAP whereby the positive pressure fluctuates depending on whether the airflow is inspiratory or expiratory. Bilevel pressure therapy is considerably more expensive than conventional CPAP and is reserved for patients who cannot tolerate CPAP because of discomfort or emergence of central apnea at necessary pressure settings. Supplemental oxygen alone is inadequate for obstructive sleep apnea because the oxygen cannot pass the obstruction to

reach the lungs. Patients with both breathing-related sleep disorder and intrinsic lung disease who have persistent hypoxia despite CPAP can benefit from supplemental oxygen delivered through the nasal CPAP mask.

For patients who have apnea only in the supine position, effective treatment may include preventing them from lying on their backs. Inflatable devices resembling backpacks can serve the same purpose. Few data are available regarding long-term adherence with these interventions. Some patients who refuse CPAP and have severe apnea during REM sleep have been offered a REM-suppressant medication such as a monoamine oxidase inhibitor. No published data are available regarding this practice. Abrupt discontinuation of the pharmacological agent should be avoided because of REM rebound, which can increase the risk of apnea.

Weight loss through diet and exercise is a critical component of the treatment plan for any overweight patient with breathing-related sleep disorder (Flemons 2002). Motivated patients can succeed. Weight loss should be the primary treatment only of patients with mild to moderate disease, particularly if they are not interested in other modalities. Gastric bypass surgery can be especially important for management of medically complicated obesity (see Chapter 30, "Surgery"). In general, a 20-pound weight loss can reduce the required CPAP pressure; however, many patients eventually seem to gain rather than lose weight with the result that CPAP pressure needs to be increased.

Patients with abnormalities of the soft tissue or skeletal structures surrounding the upper airway may consider surgery. Surgical procedures include laser-assisted uvulopalatopharyngoplasty, tonsillectomy, mandibular advancement, and tracheostomy (Littner et al. 2001). Patients must be carefully selected. They must have upper airway obstructions that are resectable, for example, large tonsils, and have no other comorbid conditions, such as a high body mass index that compromises upper airway patency at multiple points. Oral appliances that pull the tongue or mandible forward are also a valuable option (Smith 2007).

Central Sleep Apnea and Obesity Hypoventilation

Central sleep apnea and obesity hypoventilation are two additional breathing-related sleep disorders of interest. Central sleep apnea is more likely to be asymptomatic than is obstructive sleep apnea, given that it is less likely to be associated with sleep disruption. Because the patient's airway is not narrowed and vibrating, snoring is not a typical warning sign. Patients often present with insomnia rather than excessive daytime sleepiness. Patients with central

sleep apnea are often older and have associated cardiac or cerebrovascular disease. Central sleep apnea can be differentiated from obstructive sleep apnea by the absence of snoring, this differentiation being confirmed by the presence of polysomnographic features of the apnea (Quaranta et al. 1997). Treatment can include a hypnotic agent to decrease arousals or supplemental oxygen to reduce hypoxia (Guilleminault and Robinson 1998). When central apnea and obstructive sleep apnea coexist, treatment may include CPAP or bilevel positive airway pressure therapy.

In some patients with marked obesity, obstructive sleep apnea with repetitive desaturation is occasionally absent, but patients still have a sleep-related breathing condition. Particularly during REM sleep, when muscle atonia affects all muscles but the diaphragm, patients may be unable to properly ventilate because of the difficulty in expanding their lungs owing to their body mass. In obesity hypoventilation, polysomnography shows persisting oxygen desaturation without the fluctuating cessation of airflow and oxygen desaturation that occur in obstructive sleep apnea. Arterial blood gas panels typically reveal hypercapnia (Kessler et al. 2002). Obese patients commonly have both obesity hypoventilation and obstructive sleep apnea, in which case CPAP is indicated. Other treatment options include weight loss, avoiding any factor that may aggravate hypoventilation (e.g., discontinuing sedatives), CPAP with supplemental oxygen, and bilevel positive airway pressure therapy.

Restless Legs Syndrome and Periodic Limb Movements

Patients with restless legs syndrome describe subjective discomfort of the lower extremities that worsens at night. Patients can have an irresistible need to move their legs in bed or during prolonged periods of sedentary activity, such as airplane flights. This condition was first described by Ekblom in 1945. As a result of these distressing symptoms, patients can experience insomnia or have unrefreshing sleep.

Prevalence

Restless legs syndrome is often unrecognized but is far from rare. For years, all data about this condition were collected in clinical settings and the prevalence in community samples was essentially unknown. A community-based survey showed a prevalence of restless legs syndrome of 3% in respondents ages 18–29 years, 10% in those ages 30–79 years, and 19% in those age 80 years and older. The overall prevalence was 10% with equal rates for male and female respondents. In the study, risk factors for restless legs syndrome were identified as greater age and high body mass index as well as nicotine dependence, diabetes mellitus, and

lack of exercise (Phillips et al. 2000). Another survey of community-dwelling adults in five European countries had slightly different findings. The prevalence of restless legs syndrome according to the criteria of the International Classification of Sleep Disorders (Table 15–8) was 5.5% and associated with older age, female sex, musculoskeletal disease, hypertension, use of an SSRI, and engaging in physical activities close to bedtime (Ohayon and Roth 2002).

Restless legs syndrome sometimes occurs in association with anemia and iron deficiency. The condition can develop during the third trimester of pregnancy, likely because of the presence of functional anemia (Allen and Earley 2001a). Case reports have shown that patients with restless legs syndrome who donate blood may have an exacerbation of the condition, which warrants more medication. Patients with restless legs syndrome should carefully consider the condition a risk of donating blood (Silber and Richardson 2003).

Restless legs syndrome is known to be secondary to diabetes, peripheral neuropathy, and uremia; 20%–30% of patients with renal failure experience restless legs syndrome (Winkelmann et al. 1996). Familial occurrence of restless legs syndrome has been described. In several large families, an autosomal dominant mode of inheritance has been observed. In a large French Canadian kindred, restless legs syndrome was mapped to chromosome 12q (Desautels et al. 2001). In familial restless legs syndrome, the disorder can have a childhood onset.

Clinical Features

Periodic limb movement disorder is a condition that frequently overlaps with restless legs syndrome. Approximately 80% of patients with restless legs syndrome have intermittent muscle twitches called periodic limb movements (Montplaisir et al. 1997). These movements are involuntary leg jerks that occur at night. They can cause insomnia and, as a result, excessive daytime sleepiness. Almost all patients with restless legs syndrome have periodic limb movements, but many patients with periodic limb movements have no symptoms (Chaudhuri et al. 2001). The periodic limb

TABLE 15–8. Clinical characteristics of restless legs syndrome
Desire to move the limbs because of subjective discomfort
Motor restlessness
Symptoms worse or exclusively associated with sedentary activities
Symptoms at least partially relieved by activity
Symptoms worse in the evening or during the night

movements can affect a variety of muscles in the legs or arms. Periodic limb movements in the absence of subjective symptoms of restlessness are of uncertain clinical significance (Nicolas et al. 1999).

Periodic limb movements must be differentiated from nocturnal leg cramps, which are extremely painful sustained muscle contractions, particularly involving the gastrocnemius and soleus muscles. Predisposing factors include pregnancy, diabetes mellitus, electrolyte disturbances, and prior vigorous exercise. Nocturnal leg cramps are not periodic and usually occur, at most, several times a night. The differential diagnosis of restless legs syndrome and periodic limb movement disorder includes neuropathic pain, arthritis, restless insomnia, and drug-induced akathisia.

Complications

Patients with restless legs syndrome experience irritability, depressed mood, or cognitive disturbance due to disturbed sleep; headache, especially on awakening; depressed mood; social isolation; and reduced libido (Ulfberg et al. 2001).

Pathophysiological Mechanism

Restless legs syndrome is believed to be a condition associated with decreased dopamine levels. Treatment with dopamine antagonists aggravates the symptoms, and this syndrome occurs with increased frequency in Parkinson's disease. Positron emission tomographic studies of restless legs syndrome have shown decreased dopaminergic functioning in the caudate and putamen regions of the brain (Ruottinen et al. 2000). Treatment with dopaminergic agonists, even low dosages, leads to marked improvement. Restless legs syndrome has been strongly associated with anemia. Deficient iron stores appear to play a role in the pathophysiological mechanism because iron is hypothesized to be a cofactor for tyrosine hydroxylase, the enzyme for the rate-limiting step in the synthesis of dopamine (Earley et al. 2000).

Diagnostic Testing

A rating scale for restless legs syndrome has facilitated diagnosis (Allen and Earley 2001b). Attempts to develop a self-administered screening survey for restless legs syndrome in dialysis populations have been less successful because of low specificity and a high false-positive rate (Cirignotta et al. 2002).

An overnight sleep study is not essential, because the diagnosis of restless legs syndrome can be based on the patient's history. Polysomnography is valuable when a patient may have a coexisting sleep disorder, such as obstructive sleep apnea, or if the patient does not respond to

treatment of restless legs syndrome diagnosed on the basis of history alone. Useful laboratory tests include complete blood count to assess for anemia and ferritin, especially when levels are less than 50 µg/L.

Treatment

Treatment of restless legs syndrome is primarily with dopaminergic medications. Direct dopamine receptor agonists, such as pramipexole and ropinirole have become first-line agents (Trenkwalder 2008). These drugs have replaced low-dose, controlled-release carbidopa and levodopa because of a lower incidence of side effects and improved efficacy. There have been encouraging reports about the benefits of gabapentin, although this anticonvulsant lacks an FDA indication for restless legs syndrome (Garcia-Borreguero et al. 2002). Long-acting benzodiazepines, such as clonazepam, and opioids, including codeine and methadone, also have been used. Medications that can lead to physical dependence require careful monitoring for tolerance. As a result, these drugs are not preferred treatment choices. Most clinicians use drug treatment of restless legs syndrome. Nonpharmacological options include physical therapy and exercise consisting of lower body resistance training plus walking on a treadmill (Aukerman et al. 2006). Pneumatic compression devices have recently been demonstrated to improve symptom severity, daytime sleepiness, and quality of life (Lettieri and Eliasson 2009).

Insomnia

As outlined in Table 15-4, insomnia can be caused by a variety of medical, neurological, psychiatric, and environmental conditions. If possible, any factors that cause or exacerbate insomnia, such as gastric regurgitation, should be corrected (Ohayon and Roth 2003). However, many patients have no specific triggers of insomnia, and insomnia is not a symptom of an underlying disorder.

Prevalence

Insomnia is the most common sleep disorder, with 24% of adults reporting that sleep problems affect their daily activities (National Sleep Foundation Web site 2005). The manifestations range from frequent nighttime awakenings (33%) to premature awakenings with inability to return to sleep (23%) and difficulty falling asleep (18%). Women experience even more difficulties, with 67% reporting sleep problems on a weekly basis and 29% using either a prescription or an over-the-counter agent a few nights a week (National Sleep Foundation Web site 2008).

Patients with the classic type of, or psychophysiological (conditioned), insomnia learn to associate sleeplessness with certain circumstances, such as their own bed-

rooms. These patients become progressively more tense as bedtime approaches. The prevalence of this condition is unknown. Polysomnography is not generally useful in establishing the diagnosis. Sometimes a patient's best sleep in years occurs in the unfamiliar setting of the sleep disorders center (Chesson et al. 2000).

Treatment

Treatment of insomnia includes improvement in sleep hygiene with the techniques listed in Table 15-9; behavioral techniques, such as relaxation strategies including tapes, self-hypnosis, and music; and occasional doses of hypnotic medication (Toney and Ereshefsky 2000).

More medications are now available that were specifically developed as hypnotics. The newer nonbenzodiazepine hypnotics zolpidem and zaleplon have a short half-life that reduces the hangover effect. Patients have been shown to have alertness adequate for driving and other activities that require sustained vigilance (Richardson et al. 2001). Unusual sleep behaviors, including somnambulism and sleep eating, have been reported, especially with zolpidem. The dosage is often supratherapeutic or combined with a cross-tolerant substance such as alcohol. The prevalence of these phenomena is unknown (Tsai et al. 2009). Physical dependence has not been reported with the short-term use approved by the FDA. Ramelteon is a novel hypnotic that acts as a selective melatonin agonist which also has been demonstrated to be well tolerated and free of morning residual effects (Devi and Shankar 2008). Benzodiazepines, although less expensive than some nonbenzodiazepine hypnotics, can cause dependence and alter cognition the morning after use. Several antidepressants with prominent sedative side effects, such as mirtazapine and trazodone, are valuable therapeutic options, especially if the patient has a coexisting mood or anxiety disorder. Mirtazapine has prominent antihistaminergic side effects at doses of 15 mg or less; however, undesirable weight gain can occur (Artigas et al. 2002). Tricyclic antidepressants like low-dose doxepin have a role in carefully selected patients, considering their cardiac and anticholinergic side effects. Antihistamines such as diphenhydramine are generally a poor choice because they quickly lose effectiveness and can exacerbate confusion in the medically ill. Hypnotic medications have an important role in the management of short-term or intermittent insomnia, but most sleep specialists prefer a meaningful trial of nonpharmacological interventions in the care of patients with the chronic form of primary insomnia. The intent is to alter the thoughts and behaviors that lead to the development of poor-quality nocturnal sleep.

More specific behavioral studies have produced basic information about sleep habits that can be helpful to pa-

TABLE 15-9. Sleep hygiene

Circadian issues

- Avoid daytime naps
- Limit time in bed to 8 hours
- Get daily exercise, preferably finishing at least 4 hours before bedtime
- Keep regular sleep-wake cycle 7 days per week
- Avoid bright light in the evening or at night
- Seek bright light in the morning

Reduction of sleep disruption

- Avoid large quantities of fluids in the evening
- Minimize caffeine; a hot drink without caffeine may be beneficial
- Avoid alcoholic drinks
- Keep the bedroom quiet, dark, and at a comfortable temperature
- Develop a relaxing bedtime ritual
- Avoid worrying in bed by using tools such as list writing during the day
- Manage stress optimally during the day
- Do not use the bed and bedroom except for sleep and for sexual activity
- Get assistance with pets and children
- Avoid large meals soon before bedtime
- Pursue medical intervention for problems such as gastroesophageal reflux, pain, and nausea

tients who have disturbed sleep. These sleep hygiene factors have been found to have particular efficacy in the care of patients with chronic insomnia. Establishing a regular waking time 7 days a week optimizes biological rhythms. This regimen is particularly helpful for patients who need to keep morning commitments but tend to naturally be "night owls" or have problems falling asleep at the needed bedtime. However, the clock tends to drift rapidly back to the old schedule as soon as there is variability in arising time (Brown et al. 2002). Discipline and consistency are important.

When regular exercise is an option, exercising in the late afternoon several hours before bedtime may improve sleep. One postulated mechanism is that a decrease in body temperature is associated with sleep, and body temperature decreases approximately 4 hours after exercise (Montgomery and Dennis 2002). Avoiding "clock watching" can help reduce the arousal effects of becoming annoyed when tracking the slow passage of time throughout the night. Most people recall only periods of wakefulness at night, so clock watching can reinforce the perception that no sleep

has occurred. Patients should avoid alcohol and stimulants, including nicotine and caffeine, at any time during the day. Patients, particularly patients prone to gastroesophageal reflux, should not sleep on a full stomach. Introducing relaxing routines around bedtime can be helpful to many patients with sleep complaints. Treating gastroesophageal reflux with antacids and histamine₂-blocking medication before sleep can be beneficial.

More specific behavioral evaluation may lead to suggestions that a patient learn relaxation techniques or develop stress management strategies (Morin et al. 1999). Psychotherapy can be helpful for sleep-related anxiety. One of the techniques recommended to those who find that they spend inordinate amounts of time worrying when awake at night is called "worry time" or "thinking time." This technique entails the recommendation that patients take 15–30 minutes in the late afternoon or early evening (not near bedtime) during which there is time to devote attention to worries. Patients are expected to use this time to list their concerns and then identify which they may be able to have some control over and which they do not. When patients awaken at night and begin to worry about a "new" problem, this worry is added to the list, to be included in the next day's session. Eventually the energy and time spent worrying at night diminish, and wakefulness is not perpetuated by anxious thought content (Hauri and Esther 1990).

Stimulus control techniques have been used to help patients with psychophysiological, or conditioned, insomnia (Bootzin and Perlis 1992). These patients find they are sleepy near bedtime, but as soon as they enter the sleeping environment, they become aroused and unable to sleep. This conditioned association between sleeplessness and the bedroom may need to be interrupted by instructing patients to avoid "trying to sleep." Patients who find they are hyperaroused while lying in bed should not try to sleep. They are advised instead to get up and go to a different setting and engage in a different activity (e.g., reading a book, watch relaxing television, or listening to music) until they become sleepy again and return to bed. They should repeat this process as often and as long as needed to extinguish the arousal state conditioned to the bedroom. Some patients find that rather than getting out of bed or leaving the bedroom, they can achieve the same results by watching a monotonous videotape in the bedroom with the VCR set to turn off automatically (Pallesen et al. 2003).

For patients with severe persistent insomnia, a sleep restriction management method may be helpful. In this modality, patients are instructed to allow no more hours in bed than they estimated they slept the previous night. Initially this period may be considerably less than 7.5 hours. When they are able to sleep for essentially all the time in bed

for several nights, patients are advised to increase their time in bed by half-hour increments until they achieve optimal sleep time and sleep efficiency. Although pharmacological and behavioral treatments are effective for insomnia management over the initial weeks of treatment, results of a randomized controlled trial of these treatments in the care of elderly patients suggested that behavioral treatment was associated with more sustained improvement than was pharmacological therapy (Morin et al. 1999). Research has successfully demonstrated that as little as one to two sessions may be beneficial (Morin and Espie 2004). The availability of medication may reduce patients' motivation and confidence in behavioral techniques.

Paradoxical Insomnia

Paradoxical insomnia, previously known as sleep state misperception, is a rare type of primary insomnia. Patients with this disorder describe subjective sleep disturbances that are not consistent with objective data. For the criteria for this diagnosis to be met, polysomnography must demonstrate normal duration and quality of sleep (American Academy of Sleep Medicine 2005). As the understanding of sleep increases, specific sleep disorders may eventually be diagnosed in some of these patients. Treatment involves discussing with the patient the discrepancy between subjective and objective data. Behavioral techniques and hypnotic medications have been used successfully in this group of patients.

Medications and Sleep

Any substance that crosses the blood-brain barrier will very likely have an effect on CNS receptors that affect sleep and wakefulness. Essentially all drugs that have been studied have been found to have some effects, and many that have not been formally studied are known by clinicians to influence sleep and wakefulness. The hypothalamus is a key center for sleep regulation in addition to the classically understood brain stem sleep influences. Sleep mechanisms were previously thought to be predominantly due to the interactions of acetylcholine, dopamine, serotonin, and norepinephrine primarily in the brain stem. More recent research findings indicated that the hypothalamic neurotransmitters adenosine, dopamine, gamma-aminobutyric acid (GABA), histamine, and hypocretin also play an important role in the physiological mechanisms of sleep. The newest observations suggest that connections between the thalamus (cortical activation, sleep spindle formation, and EEG synchronization), hypothalamus (sleep-wake switch), suprachiasmatic nucleus (circadian clock), and the brain stem (ascending cortical activation

and REM sleep-wake switch) organize circadian, ultradian, and intrinsic sleep function (Saper et al. 2005).

Some CNS substances affect intrinsic sleep parameters, such as sleep latency, awakenings, percentage of various stages of sleep, nocturnal wakefulness, and evidence of sleep interruptions manifested primarily at a sleep EEG study. Many drugs have known effects on primary sleep disorders such as restless legs syndrome, obstructive sleep apnea, and insomnia from many causes. The known effects of drugs on sleep are summarized in Table 15-10.

Few drugs have uniformly beneficial effects on sleep. Rather than assume that these various factors are too complex to be useful in the psychiatric care of a medically ill patient, the consultation psychiatrist can learn the few basic groups of drugs with empirically demonstrated significant effects on sleep (see Table 15-11 for a summary of hypnotic effects). Combining this information with knowledge of the physiological mechanisms of sleep will allow the clinician to logically infer the effects of most other drugs on sleep. The interactions of hypnotics with other medications are reviewed in Chapter 38, "Psychopharmacology."

The following general rules about drugs can assist in the application of sleep knowledge to patient care:

1. Most CNS drugs decrease slow-wave and REM sleep, at least acutely. It is reasonable to learn the relatively short list of drugs known to increase REM sleep and to assume that others will suppress or disrupt normal REM sleep function. The medications that increase REM sleep are reserpine, yohimbine (and other α -antagonists), and physostigmine (and other cholinomimetic drugs, perhaps including cholinesterase inhibitors such as donepezil) (Slatkin et al. 2001).
2. Many drugs cause daytime sedation. It is reasonable to learn the short list of drugs that cause increased daytime alertness and perhaps anxiety as well (psychostimulants, modafinil, and caffeine) and to presume that most others will either be neutral or negative toward daytime alertness.
3. Stopping drugs suddenly commonly produces adverse effects. The condition suppressed will likely rebound. Thus, stopping drugs that suppress REM sleep (most CNS agents) will often lead to REM sleep rebound, which can be associated with insomnia, nightmares, and even hallucinations.
4. Stopping drugs that stimulate the CNS (and that have depleted or displaced stimulating neurotransmitters) can lead to temporary depression. This effect is surprisingly uncommon, even in patients who have taken high doses of stimulants for a long time. Depression and decreased alertness are common after stopping stimulants but usually are transient.
5. Many drugs continue their activity on sleep and wakefulness far beyond the intended therapeutic time. Many medications used to promote sleep are associated with some "hangover" experience the next day. The few exceptions are drugs with an ultrashort half-life, such as zaleplon (definitely demonstrated) and perhaps triazolam and zolpidem (less clearly demonstrated) (see Table 15-11).
6. Alternative therapies and herbal preparations may be helpful, but little definitive information is available (although more formal controlled studies are increasingly common). Many of these agents are pharmacologically active in the CNS, and some have interactions with prescribed medications.

Herbal and Alternative Therapies for Sleep Problems

Herbal agents have been used for centuries as traditional remedies for sleep problems. A review of complementary therapies from an Eastern perspective describes in detail an extensive list of Chinese herbal treatments and their potential toxicities (Cheng 2000). Melatonin, 5-hydroxytryptamine, catnip, chamomile, gotu kola, hops, L-tryptophan, lavender, passionflower, skullcap, and valerian are agents that have been used to manage sleep disorders (Cauffield and Forbes 1999). The toxicities of herbal substances most commonly used for sedative or stimulant purposes among consultation-liaison populations are shown in Table 15-12 (Crone and Wise 1998).

Melatonin is a readily available and popular sleep aid. Evaluating clinical trials of melatonin is complicated by the varying bioavailability of oral doses, even in pharmacologically pure preparations, resulting in as much as a 20-fold difference in plasma levels of the agent (Di et al. 1997). Actual doses range markedly, from 0.5 to 10 mg, with lower doses of 1.8–3 mg being more common (Morgenthaler et al. 2007). Some practice guidelines have found support for melatonin's use to promote daytime sleep in night shift workers, to combat jet lag, and to treat sleep phase disorder (advanced or delayed). Research findings for jet lag are somewhat mixed, but on balance, carefully timed administration of melatonin appears to have moderate effectiveness in preventing jet lag (Suhner et al. 2001). The literature on insomnia is replete with contradictory reports concerning the dosage and efficacy of melatonin. There is evidence that a low dose (0.5 mg) of melatonin improves initial sleep quality, for example, in elderly persons with insomnia (Olde Rikkert and Rigaudo 2001). Overall adverse effects of melatonin are rare but include autoimmune hepatitis, optic neuropathy, fragmented sleep, psychosis, nys-

TABLE 15-12. Herbal medications with sleep-wake toxicity

Medication	Toxicity
Herbal medications used as sedatives	
Broom (<i>Cytisus scoparius</i>)	Vomiting, uterine contractions, and bradycardia
Kava kava (<i>Piper methysticum</i>)	Dermatitis, hallucinations, and shortness of breath
Passionflower (<i>Passiflora caerulea</i>)	Seizures, hypotension, and hallucinations
Valerian (<i>Valeriana officinalis</i>)	Dystonic reactions and hepatotoxicity
Miscellaneous herbal preparations with excessive stimulation and insomnia as side or toxic effects	
Echinacea (<i>Echinacea angustifolia</i> or <i>E. purpurea</i>)	Central nervous system stimulation, dermatitis, and anaphylaxis
Ginseng (<i>Panax ginseng</i>)	Hypertension, mastalgia, agitation, anxiety, depression, and insomnia
Goldenseal (<i>Hydrastis canadensis</i>)	Nausea and vomiting, central nervous system stimulation, paralysis and paresthesia, and respiratory failure
Ma huang (<i>Ephedra sinica</i>)	Mania and psychosis, hypertension, and tachycardia
Yohimbine bark (<i>Pausinystalia yohimbine</i> or <i>Corynanthe yohimbe</i>)	Hallucinations and anxiety, hypertension and tachycardia, and nausea and vomiting

tagmus, seizures, headache, skin eruption, and confusion from overdose (Morera et al. 2001). In general, the risks of melatonin appear to be low (Morgenthaler et al. 2007).

Conclusion

Sleep takes up one-third of a typical day. Obtaining adequate quantity and quality of sleep is optimal for good health and the prevention of complications. We have addressed the major sleep disorders by discussing their clinical features, diagnostic testing, and treatment. Sleep medicine is a vibrant medical specialty with recent scientific advances in understanding of the mechanisms of sleep disorders and their treatment. Interventions can prevent undesirable medical, psychiatric, and social consequences of sleep disorders. Patients can benefit from these discoveries when dysfunctional sleep is recognized and carefully assessed. A growing menu of treatment options is available once the diagnosis of a specific sleep disorder is made.

Sexual Dysfunction

Rosemary Basson, M.D.

Peter M. Rees, M.D., Ph.D.

ADVANCES IN SURGICAL and medical treatment have greatly improved survival from a variety of chronic illnesses including many types of cancer. However, frequently, sexual function is negatively affected. Approximately 30% of the general population reports recently acquired sexual difficulties, and about 10% reports long-lasting problems that cause distress, but in some medical conditions, such as end-stage renal disease (ESRD), sexual dysfunction seems almost inevitable: the prevalence of hypoactive sexual desire disorder in men and women may reach 100% (Steele et al. 1996). In contrast, some studies find little increase in sexual dysfunction in women with diabetes compared with control subjects (Basson et al. 2001).

The distress that accompanies sexual dysfunction in the context of illness also varies: a sizable proportion of individuals living with spinal cord injury—regardless of the segmental level of their injury—rate regaining sexual function as either the first or the second priority (Anderson 2004). A recent survey of patients with compensated heart failure in New York Heart Association Classes I–III reported that despite the associated fatigue, some 52% of men and 40% of women still considered sexual activity to be important and felt that their quality of life was reduced by their sexual difficulties (Schwarz et al. 2008). It is important for psychiatrists to routinely address sexual health during their assessments: the attending physician may have avoided this subject entirely. Chronic illness may even increase the need for sexual intimacy (Owen and Tepper 2003). For other persons with chronic illness, for whom sexual activity was never particularly rewarding, being unable to engage may be completely acceptable.

Chronic medical illness can affect sexual function in a

variety of ways, both directly and indirectly (Table 16–1). Disease-related interruption of the neurovascular pathways and the hormonal milieu may not be the major determinant of dissatisfaction. For instance, sexual function in both men and women with ESRD is mostly governed by presence or absence of depression (Peng et al. 2005, 2007). Similarly, depression is the major factor influencing sexual function after bone marrow transplantation (Humphreys et al. 2007) and in women with multiple sclerosis (Zivadinov et al. 1999) or diabetes (Bhasin et al. 2007); this knowledge is important to a psychiatrist.

Chronic illness commonly alters a person's sense of self (Anderson et al. 2007a, 2007b). Qualitative studies have shown that new issues in sexuality emerge as people live with a chronic illness (Kralik et al. 2001), including the need to adapt to and accept changes in the body. The realization that part of sexual intimacy involves meeting the needs of others is a further factor. A third factor is the major importance of being able to communicate one's changed sexual needs and meet those of the partner.

Sexual dysfunction can be a harbinger of otherwise asymptomatic systemic disease. Of 32,616 healthy male participants in a U.S. study reporting erectile dysfunction (ED) in 1986, a fourfold higher risk of developing Parkinson's disease was found over the next 16 years of follow-up, suggesting that erectile difficulties can precede the onset of the classic motor features of parkinsonism by a substantial margin (Gao et al. 2007). In a retrospective cohort study of 26,000 men (mean age = 40) in good general health, and followed up for an average of just 1 year, a twofold increase in the risk of myocardial infarction was identified among the 13,000 men noted to have ED at baseline (Blumentals et al. 2004).

TABLE 16-1. Factors involved in sexual dysfunction associated with chronic disease

Type	Factor	Examples
Direct	Change in sexual desire from disease	Typically reduced (e.g., from high prolactin level and anemia of chronic renal failure) ^a ; may be increased (e.g., from some brain injuries) ^b
	Disruption of genital response from disease	ED from multiple sclerosis, ^c hypertension ^d ; orgasmic disorder from multiple sclerosis ^e
	Disruption of genital response from surgery	Radical prostatectomy and ED ^f ; radical hysterectomy and reduced genital congestion, reduced lubrication ^g ; orgasmic disorder after radical vulvectomy ^h
	Disruption of genital response from radiation	ED from vascular and neurological damage after radiotherapy for prostate cancer ⁱ ; vaginal stenosis and friability from radiation for pelvic cancer ^j
	Dyspareunia and disruption of sexual desire and response from chemotherapy	Ovarian failure after chemotherapy for breast cancer ^k ; testicular failure after intensive chemotherapy for hematopoietic transplantation ^l
	Disruption of sexual desire and response from antiandrogen treatment	GnRH therapy for prostate cancer ^m
	Disruption of genital response from estrogen depletion by aromatase inhibitors	Loss of sexual genital sensitivity, and exacerbation of vaginal atrophy from aromatase inhibition following breast cancer ⁿ
	Disruption of sexual desire and response from pain	Pain from any chronic condition is a potent sexual distraction ^o
Indirect	Disruption of sexual desire and response from nonhormonal medications	Narcotics can depress desire through gonadotropin suppression ^p ; selective serotonin reuptake inhibitors reduce desire and response ^p
	Reduction of self-image	Reduced by disfiguring surgeries, stomas, incontinence, altered appearance (e.g., drooling and altered facies of Parkinson's disease; altered skin color and muscle wasting of renal failure)
	Depressed mood	Depression and mood lability commonly accompany chronic illness; depression is a major determinant of sexual function in men and women with renal failure ^q and women with multiple sclerosis ^r or diabetes ^s ; strong link between ED and subsequent depression ^t
	Impaired mobility	Reduced ability to caress, hug, and hold a partner; to sexually self-stimulate; to stimulate a partner; to move into positions for intercourse; to pelvically thrust after spinal cord injury, Parkinson's disease, brain injury, or postamputation
	Reduced energy	Fatigue may take its toll on sexuality, especially desire (e.g., from renal failure or chemotherapy)
	Partnership difficulties	Difficulties in finding a partner; lack of privacy from institutionalization; dysfunction in the partner who assumes a caregiver role; fears of inability to satisfy partner; fear of becoming a burden to a partner; lack of independence; relationship discord from stressors of living with medicalized lives (e.g., three times weekly hemodialysis)
	Sense of loss of sexuality from imposed infertility	From surgery removing gonads or uterus, or from chemotherapy or radiotherapy causing gonadal failure
	Fear of sexual activity worsening medical condition	Avoiding sexual intercourse because of fear that a pregnancy would provoke cancer recurrence; fearing that a genital cancer could be contagious; fearing that sexual activity will cause another myocardial infarction

Note. ED = erectile dysfunction; GnRH = gonadotropin-releasing hormone.

^aFinkelstein et al. 2007; ^bAbsher et al. 2000; ^cRees et al. 2007; ^dDoumas and Douma 2006; ^eTzortzis et al. 2008; ^fPenson et al. 2005; ^gBergmark et al. 1999; ^hLikes et al. 2007; ⁱIncrocci 2006; ^jBruner et al. 1993; ^kKornblith and Ligibel 2003; ^lSyrjala et al. 2008; ^mBasaria et al. 2002; ⁿFallowfield et al. 2004; ^oHal-linan et al. 2008; ^pClayton et al. 2007; ^qPeng et al. 2005; ^rZivadinov et al. 1999; ^sBhasin et al. 2007; ^tKorfage et al. 2009.

Assessment

The details of assessment of sexual dysfunction are shown in Table 16-2. A holistic approach is needed because sexual disorders in illness and in health reflect the interaction of mind and body. For instance, psychological stress alone can induce hypothalamic amenorrhea or male hypogonadotropic hypogonadism to potentially cause dysfunction from reduced sex hormones. Alternatively, nerve damage from multiple sclerosis or radical pelvic surgery leads to orgasmic dysfunction or ED; these problems undermine sexual self-confidence and mood, thereby compounding the sexual dysfunction. Detailed respectful inquiry is necessary, without assumptions about orientation, but with an acceptance of the range of sexual expression.

The assessment is guided by current models of human sexual response. The traditional model of human sexual response stemming from the research of Masters, Johnson, and Kaplan was of a linear progression from desire to arousal to a plateau of high arousal, culminating in orgasm or ejaculation; a phase of resolution then followed. However, in the past 10 years, empirical and clinical studies have focused on the complexity, variability, flexibility, and more circular nature of human sexual response (see Figure 16-1). In both men and women, the relation between desire and arousal is variable and complex; women are mostly unable to separate the two (Brotto et al. 2009; Janssen et al. 2008). The motivations and incentives for sex are multiple and varied, with a wish to increase emotional intimacy between the partners being important for both men and women (Carpenter et al. 2009; Meston and Buss 2007). Sexual “desire”—as in “lust” or “drive”—is only one of many reasons that people engage in sexual activity. Thus, models have been constructed that reflect the multiple reasons to initiate or agree to sexual activity, the need for sexual stimuli in a context that is conducive to sexual arousal, and a variable order and overlap of the phases of desire and arousal (Bancroft 2008; Basson 2001; Basson and Schultz 2007; Janssen et al. 2000; Meuleman and van Lankveld 2005). The circular nature allows a building of arousal, inviting more intense stimulation, thereby triggering more powerful feelings of both arousal and desire.

Overview of Therapy for Sexual Dysfunction in the Medically Ill

In subsequent sections, we address specific therapies shown to benefit dysfunction precipitated by the particular illness or cancer. However, it is usually necessary first to explain the formulation—that is, the summary of the most

important underlying causes of their difficulties—to the patient or couple. Reference to current models of human sexual response can be particularly helpful. Debility, fatigue, and pain frequently lessen any innate or spontaneous desire, so that a sexual encounter beginning prior to sensing arousal or desire becomes the norm. This may be rather different from that before illness, especially for men: the type of sexual stimulation, context of the encounter, and ability to stay focused all may need to be modified, as well as prescribing a needed medical adjunct (e.g., a phosphodiesterase type 5 [PDE-5] inhibitor or local estrogen therapy). In addition, if the interpersonal relationship is troubled, the chances that the couple will move on to enjoy a newly modified type of sexual interaction are slim. This may need to be explained and a necessary resource found. The knowledge that the partner of the less well person also may have developed major sexual dissatisfaction (Schulzer et al. 2003; Wasner et al. 2004) encourages provision of therapy for both partners.

Standard therapies include psychoeducation, cognitive-behavioral therapy (CBT), and sex therapy. The latter usually involves sensate focus therapy, whereby each partner is encouraged to take turns giving or receiving sensual and later sexual touches, caresses, and kisses. Initially, genital areas and breasts are off limits. Past goals and expectations are put aside. Encouragement to stay in the moment is needed. Couples plan 15- to 20-minute sessions two to three times per week for 3–4 weeks. The clinician guides as to when breast and genital areas are included and when ultimately intercourse (if still possible) is also “on the menu.”

Mindfulness, although practiced for some 3,500 years, is a new addition to therapy for sexual dysfunction. Early studies show benefit for sexual dysfunction in health and after pelvic cancer (Brotto et al. 2008a, 2008b). Randomized wait-list-controlled studies are in progress. CBT can be very helpful in challenging a distorted self-view or catastrophic thinking from the changes imposed by the illness. In clinical experience, sick persons may view their sexual disability as so unattractive to their partner that they do not deserve care and attention. Some may even stay in a relationship in which they experience emotional, physical, or sexual abuse.

Specific themes in therapy are shown in Table 16-3.

When sexual function deteriorates coincident with beginning a medication, the latter may be able to be changed (see Table 16-4). When this is not possible, the patient is advised that at least part of the problem is the needed medication, and adjustments can be suggested. The context might be made more erotic, more intense sexual stimulation may be provided, and specific goals can be removed (e.g., that intercourse or orgasm must necessarily occur).

TABLE 16-2. Assessment of sexual dysfunction associated with chronic illness

Review medical and psychiatric history.

Review current medical status: consider respiratory, cardiac, mobility, and continence requirements for sexual activity, including intercourse, self-stimulation, and orgasm.

Review current medications.

List the sexual dysfunctions and their duration.

Clarify relationship status and quality.

Review the environment for sexual activity: home/institution/"medicalization" (e.g., hemodialysis machines, respirators, lack of independence in daily living).

Review any chronic pain.

Assess current mood

Assess consequences of illness on sexual self-image (concerns regarding attractiveness, physical appearance).

Review dysfunctions in detail; ask what the sexual difficulties are:

For each complaint, clarify if the difficulty is the same with self-stimulation as with partnered sex; for ED, also check erections on waking from sleep.

Clarify motivations for sexual activity, including desire or drive and desire to satisfy partner; identify reasons for avoiding sexual activity.

Clarify subjective arousal or excitement and pleasure.

Clarify genital congestion or erection.

Review variety and usefulness of sexual stimuli and sexual context.

Assess couple's sexual communication.

Inquire about distracting thoughts or negative emotions during sexual intercourse.

Determine whether wanted orgasms are possible, very delayed, nonintense, or painful.

Identify ejaculation difficulties: delayed, too early, painful, or absent.

Determine whether intercourse is possible.

Assess female dyspareunia: introital, deeper, how constant, exacerbation from partner's ejaculation fluid, postcoital burning, postcoital dysuria.

Assess male dyspareunia: immediate, delayed, any physical changes.

Clarify sexual response preillness: any dysfunction, how rewarding and how important sexual activity was, any desire discrepancy or paraphilia.

Review effect of medications on desire and response.

Review treatment of sexual dysfunction to date.

Complete a full physical examination, including genital examination; usually necessary because of the medical condition, particularly important for neurological illness and whenever generalized ED, dyspareunia, or pain with arousal occurs.

Perform laboratory investigations—as necessary, especially when needed to monitor anemia, high prolactin level, thyroid replacement, or testosterone levels (in men). Estrogen levels usually are assessed by the history and the genital or pelvic examination.

Complete specialized testing of genital blood flow (e.g., Doppler studies of cavernosal flow for ED; rarely indicated because results do not alter treatment options).

Note. ED=erectile dysfunction.

FIGURE 16-1. Sexual response cycle.

A circular sexual response cycle of overlapping phases may be experienced many times during any one sexual encounter. Desire may or may not be present initially; it is triggered by the arousal to sexual stimuli. The sexual and nonsexual outcomes influence future sexual motivation. ANS = autonomic nervous system.

Sexual Function in Various Medical Conditions

Cardiac Disease

Factors known to strongly influence sexual function in patients with cardiac disease include the ease of treating any associated ED, concomitant depression, and personal or partner's fears that sexual activity is dangerous (Montorsi et al. 2003). Most patients report reduced frequency of sexual activity after myocardial infarction, and 10%-54% do not resume sexual activity at all (Drory et al. 2000). However, it is important to advise patients that risk of further cardiac damage is low and short-lasting. Energy requirements for sexual stimulation, intercourse, and orgasm are estimated to be 3-4 metabolic equivalents (METs)—similar to climbing a flight of stairs. For a 50-year-old patient with a previous myocardial infarction, the risk of a recurrent myocardial infarction during the 2-hour period after sexual intercourse has been calculated to increase from 10 chances to 20 chances in a million per hour (Muller et al.

1996). The patient can be advised that threatening symptoms are unlikely to occur if no cardiac symptoms arise during exercise testing to 6 METs. Prescribing exercise will increase tolerance for sexual activity. Two consensus panels have developed similar guidelines for the resumption of sexual activity in patients with cardiac disease according to degree of cardiovascular risk (Cheitlin et al. 1999; DeBusk et al. 2000) (see Table 16-5). To date, such guidelines have focused on men. Unfortunately, discussion of sexual activity by patients' physicians is often minimal: for instance, in one study, only 24% of cardiac patients were given information on the safety of sex and erection-enhancing medication before receiving a prescription for such medication (Bedell et al. 2002).

Of patients having symptomatic coronary artery disease (CAD), 44%-65% have ED. Erectile difficulty, as mentioned in the introduction, is now considered a warning symptom of CAD. The associated endothelial dysfunction, structural atheromatous change, and loss of cavernosal smooth muscle from ischemia lead to suboptimal venous trapping of blood within the penis subserving erection.

TABLE 16-3. Themes in management of sexual dysfunction in the context of medical disorders

Treat comorbid depression: consider using "sexually neutral" antidepressants, including mirtazapine, bupropion, and possibly agomelatine (an agonist of melatonin receptors MT₁ and MT₂ and an antagonist at serotonin type 2C receptors^a) in the future.

When current beneficial antidepressants appear to have compounded sexual dysfunction, consider use of PDE-5 inhibitors in men^{b,c}; possible benefit from sildenafil for orgasmic dysfunction induced by SSRIs in women.^d

Address pain relief: suggest planning of sexual encounters at times of better pain control.

Share formulations of sexual dysfunctions with patients (and with partners when possible), referring to the human sexual response model.

Address logistics: privacy, safety from STDs, pregnancy, need of assistance from health care providers, particularly when immobility is a problem.

Encourage openness between the sexual partners: fears of being physically unattractive, that scars are ugly, that the stoma is upsetting to the "well" partner may not be accurate.

Encourage non-goal-oriented sexual activity. Acceptance that sexual activity will not be the same as preillness but need not be less satisfying is a realistic approach.

Note. PDE-5 = phosphodiesterase type 5; SSRIs = selective serotonin reuptake inhibitors; STDs = sexually transmitted diseases.

^aMontgomery 2006; ^bNurnberg et al. 2007; ^cSegraves et al. 2007; ^dNurnberg 2008.

Some 60%–90% of patients with heart failure complain of ED (Al-Ameri and Kloner 2009). Although minimally studied, evidence suggests that sexual function does not always recover after cardiac transplantation. Desire may improve, but both preexisting dysfunction and interpersonal difficulties appear to limit attainment of sexual satisfaction posttransplantation (Basile et al. 2001). One of the immunosuppressive drugs given to prevent rejection, sirolimus, can cause primary gonadal failure (Kaczmarek et al. 2004).

The PDE₅ inhibitors such as sildenafil can be used in men with cardiac disease provided there is no risk of hypotension from concomitant prescription of nitrates or nonselective alpha-adrenergic blockers. Inhibitors of cytochrome P450 (CYP) 3A4 (e.g., cimetidine, efavirenz, erythromycin, ketoconazole, itraconazole, ritonavir) can significantly decrease metabolism of PDE-5 inhibitors to cause unwanted accumulation. All three available PDE-5 inhibitors (sildenafil, vardenafil, tadalafil) improve endothelial function (Al-Ameri and Kloner 2009). Sildenafil does not change the time to 1 mm ST segment depression during stress testing in men

with chronic stable angina but can prolong the time to angina (Jackson 2002). In contrast, vardenafil may prolong the duration of ST depression in such men. The clinical significance of this is unclear. Vardenafil should not be prescribed to persons with the long QT syndrome, nor should it be prescribed to patients taking quinidine, procainamide, amiodarone, or sotalol because of further increase to the QT interval. The PDE-5 inhibitors should not be used in low-cardiac-output states (e.g., severe aortic stenosis). Intracavernosal injection of prostaglandin E₁ (PGE₁; alprostadil injection) by self or partner can be taught if PDE-5 inhibitors are contraindicated.

More than 50% of patients with CAD are depressed. The mutually reinforcing triad of depression, ischemic heart disease, and ED (Goldstein 2000) should encourage screening for the other two conditions if one is present. To date, studies indicate benefit to sexual function and to depression from sildenafil in men with heart failure (Freitas et al. 2006; Webster et al. 2004). Antidepressant-induced ED can be ameliorated with PDE-5 inhibitors (Nurnberg et al. 2007). Cardiac drugs rarely alter depression, although some (e.g., thiazides, spironolactone, digoxin) may reduce erectile function. Contrary to previous belief, a meta-analysis of 35,000 patients (Ko et al. 2002) suggested that beta-blockers cause only minimal ED—and only if nonselective and higher doses are used (Franzen et al. 2001).

Chronic Obstructive Pulmonary Disease

Studies of sexual dysfunction in patients with chronic obstructive pulmonary disease (COPD) are limited. Of 53 men with mostly moderate or severe COPD, 55% had moderate or severe ED (Köseoglu et al. 2005). Although erectile function, orgasmic function, and general sexual satisfaction decreased with COPD severity, desire did not.

One study showed that about one-third of patients with chronic respiratory failure using noninvasive mechanical ventilation were sexually active (Schönhofer et al. 2001). Sexual activity increased in 12% of the patients after the introduction of noninvasive mechanical ventilation and lessened in 36%. Causes of this decline were not investigated, but progression of the disease rather than the inclusion of noninvasive mechanical ventilation was thought to be responsible. For some patients, noninvasive mechanical ventilation allowed intercourse that had been impossible for several years. These men could not come off the ventilator for intercourse, and the ventilator settings for frequency and tidal volume had to be increased for the patients to reach orgasm.

Limited studies are available on supplementing testosterone for men with COPD. Given the debility associated with COPD alongside the weight loss and loss of lean body mass, testosterone was administered in a randomized,

TABLE 16-4. Frequently noted sexual side effects of commonly used medications

Medication	Sexual side effects	Comments
Antidepressants	SSRIs may cause low desire and delayed orgasm in 30%–50% of women and men ^a and new-onset ED in 22%–41% when patients are asked directly. ^a Trazodone may rarely cause priapism.	PDE-5 inhibitors ^{b,c} can reverse sexual side effects in men. Limited evidence of reversal of orgasmic delay in women by sildenafil. ^d Limited evidence that bupropion can reverse SSRI-induced dysfunction. ^e Agomelatine, available in Europe, appears sexually neutral. ^f
Antipsychotics	Low desire in 50%–73%, ^g new-onset ED in up to 70% of patients taking traditional antipsychotics when patients are asked directly ^g ; retrograde ejaculation ^h	Second-generation antipsychotics, which do not raise prolactin level, may be preferable, ⁱ but other mechanisms may still cause dysfunction. ^j
Antihypertensives	Low desire: When compared with ACE inhibitors ^k and angiotensin II antagonists, ^l beta-blockers reduce desire in men. Beta-blockers reduce desire in women when compared with angiotensin II antagonists ^m ; probably applies to agents with selective and nonselective beta-blockade ED: Increased by centrally acting alpha-blockers; beta-blockers (conflicting data); little evidence from meta-analysis of 35,000 patients ⁿ ; probably only if nonselective and higher dose ^o Priapism: rarely from centrally acting alpha-blockers	Use instead ACE inhibitors, angiotensin receptor antagonists, calcium channel blockers, or peripherally acting alpha-blockers.
Diuretics	ED from thiazides, chlorthalidone, spironolactone ^p	Choose nonthiazide alternatives.
Antiandrogens	Agents such as GnRH agonists, flutamide, cyproterone acetate, and spironolactone in high doses will suppress GnRH, LH, and/or antagonism of androgen receptor, inhibiting sexual desire and response. Finasteride may lower desire, delay ejaculation, and cause ED.	Selective androgen receptor modulators not currently available
Anabolic steroids (chronic use)	Low desire, ED, anejaculation, testicular atrophy	
Narcotics	Low desire in men via suppression of GnRH; limited evidence in women	Testosterone supplementation for men but minimal data
Antiepileptic drugs	May increase SHBG and reduce free testosterone ^q	Studies needed to confirm whether there is less sexual dysfunction from enzyme-neutral AEDs (e.g., oxcarbazepine, lamotrigine, levetiracetam)
Antiparkinsonian drugs	Hedonistic homeostatic dysregulation from early use of dopamine agonists ^r with levodopa Paraphilias from dopamine agonists plus levodopa	Reversible side effects if dopamine agonist is discontinued

Note. ACE=angiotensin-converting enzyme; AED=antiepileptic drug; ED=erectile dysfunction; GnRH=gonadotropin-releasing hormone; LH=luteinizing hormone; PDE-5=phosphodiesterase type 5; SHBG=sex hormone-binding globulin; SSRIs=selective serotonin reuptake inhibitors.

^aKennedy et al. 1999; ^bNurnberg et al. 2007; ^cSegraves et al. 2007; ^dNurnberg et al. 2008; ^eClayton et al. 2004; ^fMontejo et al. 2010; ^gMacDonald et al. 2003; ^hDossenbach et al. 2005; ⁱKnegtering et al. 2006; ^jAtmaca et al. 2005; ^kFogari et al. 1998; ^lFogari et al. 2002; ^mFogari et al. 2004; ⁿKo et al. 2002; ^oFranzen et al. 2001; ^pDüsing 2005; ^qRees et al. 2007; ^rKlos et al. 2005.

TABLE 16-5. Management recommendations based on graded cardiovascular risk assessment

Grade of risk	Cardiovascular disease categories	Management recommendations
Low	Asymptomatic, <3 major risk factors for CAD, excluding age and gender	Primary care management
	Controlled hypertension	Consider all first-line therapies
	Mild, stable angina	Reassess at regular intervals (6–12 months)
	After successful coronary revascularization	
	Uncomplicated past MI (>6–8 weeks)	
	Mild valve disease	
	LVD/CHF (NYHA Class I)	
Intermediate	≥3 major risk factors for CAD, excluding gender	Evaluation by a cardiologist prior to initiation of any therapy for erectile dysfunction because of risk of myocardial ischemia during sexual activity and orgasm
	Moderate, stable angina	
	Recent MI (>2, <6 weeks)	Specialized cardiovascular testing (e.g., ETT, Echo)
	LVD/CHF (NYHA Class II)	Restratification into high risk or low risk based on the results of cardiovascular assessment
High	Noncardiac sequelae of atherosclerotic disease (e.g., CVA, peripheral vascular disease)	
	Unstable or refractory angina	Priority referral for specialized cardiovascular management
	Uncontrolled hypertension	Treatment for sexual dysfunction to be deferred until cardiac condition stabilized and dependent on specialist recommendations
	LVD/CHF (NYHA Class III/IV)	
	Recent MI (<2 weeks), CVA	
	High-risk arrhythmias	
	Hypertrophic obstructive and other cardiomyopathies	
	Moderate or severe valve disease	

Note. CAD = coronary artery disease; CHF = congestive heart failure; CVA = cerebrovascular accident; Echo = echocardiogram; ETT = exercise tolerance test; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

double-blind trial and found to increase fat-free mass, decrease fat mass, and improve ED and sexual quality of life (Svartberg et al. 2004).

Rheumatic Disease

Clinical experience confirms that the sexual lives of men and women with rheumatic disease are frequently negatively affected by pain, debility, loss of mobility, comorbid depression, and genital tissue changes in some of the disorders. However, not all studies confirm increased prevalence of sexual dysfunction. When patients with different types of rheumatic disease were studied and long-term couples in which one partner did or did not have rheumatic disease were compared, no differences in sexual satisfaction were found. However, sexual dissatisfaction of both partners was shown to be related to degree of functional impairment (Majerovitz and Revenson 1994).

Impaired mobility can interfere with sexual caressing and specific sexual stimulation of the partner or the self. The movements needed to engage in intercourse may be too painful or impossible. Altered mobility can negatively affect self-image, particularly in adolescents, leading to

difficulties forming relationships. It has been shown that when the hip is substantially involved, as in rheumatoid arthritis, hip replacement has a one in two chance of improving sexual function back to previous levels (Yoshino et al. 1984).

Because pain and depression have major negative effects on sexual function, their control is primary when addressing sexual dysfunction in these patients. Particularly in women, pain, age, and depression have been shown to be important modulators of sexual function in the context of rheumatoid arthritis (Abdel-Nasser and Ali 2006). In a recent survey of 552 men (mostly) and women with ankylosing spondylitis, 38% reported that the disease had “quite a bit” or “extreme” negative effects on their sexual relationships (Healey et al. 2009). Depression, greater disease activity, unemployment, and poor self-efficacy were independently associated with a greater impact on sexual function.

Interestingly, the degree of early-morning articular stiffness has been related to both the degree of sexual dissatisfaction in women with rheumatoid arthritis (Gutweniger et al. 1999) and the degree of ED in men with ankylosing spondylitis (Pirildar et al. 2004).

Aside from changes to the joints, other tissue changes may interfere with sexual function. Sjögren's syndrome is associated with vaginal dryness and dyspareunia such that these complaints are at least twice as common as in control subjects (Marchesoni et al. 1995). Moreover, in women with systemic sclerosis, loss of vaginal elasticity is common, as is vaginal dryness and even ulcerations (Bhadauria et al. 1995). ED from associated vasculitis is common in systemic sclerosis, with a prevalence of up to 80% (Tristano 2009). PDE-5 inhibitors are shown to be effective in some but not all studies when the context is systemic sclerosis.

Neurological Disease

Neurological disease can alter sexual motivation, sexual self-image, sexual desire, and ability to communicate sexual needs between partners. Its presence can increase vulnerability to sexual exploitation or coercion. Moreover, neurological disease frequently causes disruption of the sexual response system at brain, spinal cord, and peripheral nerve levels.

For the most part, neurological deficit leads to sexual deficit, but problematic increases can occur, such as hypersexuality from dopaminergic agonists given to treat Parkinson's disease or disinhibited hypersexuality from severe trauma to the prefrontal lobes or bilateral amygdaloid damage in the Klüver-Bucy syndrome.

Ironically, sometimes the imposed neurological deficits can lead to a more rewarding and more intimate sexuality compared with preillness (e.g., after spinal cord injury) (Owen and Tepper 2003).

Brain Injury

Whether from trauma or from stroke, brain injury is frequently associated with sexual problems, the prevalence of which can be difficult to estimate when the patient has extensive bodily injuries other than to the brain or when the patient who has had a stroke has comorbid impairment of genital blood supply because of vascular disease. Depression affecting sexuality is common in both vascular injury and traumatic injury to the brain. Published prevalence levels of depression in the chronic phase following moderate and severe brain injuries are as high as 50% (Kelly et al. 2006). Depression is the most sensitive single predictor of sexual outcome after mechanical injury to the brain (Hibbard et al. 2000).

Damage to the deeply located limbic structures or to their connections is the main cause of organic sexual dysfunction following stroke (Rees et al. 2007). Middle cerebral artery stroke causes injury to multiple limbic and paralimbic areas. Anterior cerebral artery ischemia damages the medial frontal cortex and adjoining cingulate gyrus receiving massive projections from limbic areas. Anterior

choroidal artery strokes cause injury to the medial temporal limbic structures.

No clear relation has been found between the focality of brain injury or the duration of coma and the degree of sexual impairment (Sandel et al. 1996). Prevalence figures range from 36% to 54% for more severe head injuries compared with 15% for healthy control subjects (Ponsford 2003). Most studies lack input from the sexual partners, thereby probably lowering the true prevalence of dysfunction, especially when the patient has frontal lobe damage and distorted sense of reality. The most common dysfunctions are ED, premature or delayed ejaculation, and loss of lubrication leading to dyspareunia. At least one-quarter of cases of ejaculatory failure are related to psychotropic medication (Glass and Soni 1999).

Severe head trauma can lead to pituitary injury. This is suspected when a basal skull fracture involves the sphenoid bone that surrounds the pituitary gland or when diffuse cerebral edema compresses the third ventricle with pressure on the hypothalamus and the connecting portal veins alongside the pituitary stalk. Published rates of pituitary hypogonadism after brain injury have shown a wide range of up to 22%, but these studies did not assess sexual symptoms (i.e., the diagnosis was based on only biochemical results). Although brain trauma can induce hyperprolactinemia, which reduces sexual interest and sexual response in both sexes, the most common cause of hyperprolactinemia in the head-injured population is the use of antidepressants (Lieberman et al. 2001) and antipsychotics (Bancroft 2005). Clinicians should screen for pituitary injury at 3 and 12 months following severe brain injury (Ghigo et al. 2005). If the patient has early diabetes insipidus, serious panhypopituitarism may already be present.

The brain trauma also may have led to impaired insight and cognition, causing difficulties in social interaction (Sandel et al. 1996). Many survivors of brain trauma are young men; engaging in the subtleties involved in forming and maintaining a sexual relationship may be particularly challenging.

Parkinson's Disease

Given that Parkinson's disease involves components of the autonomic, limbic, and somatomotor systems, sexual dysfunction rates are high. Further dysfunction from dopamine replacement therapy is possible. Traditionally, dopamine has been thought to play a major role in promoting sexual motivation, sexual arousal, and reward. Recent reviews support the idea that dopamine is important not only for motor function but also for general arousal, thereby explaining most of the effects observed on sexual behavior in parkinsonism (Paredes and Agmo 2004). Prevalence rates of sexual dysfunction in Parkinson's disease vary from 40% to

68% in men and 30% to 88% in women (Meco et al. 2008), including problems with erections and ejaculations (both premature and delayed); difficulties with arousal, lubrication, and orgasm in women; and impaired sexual satisfaction and desire in both sexes. Despite the documented interruption of dopaminergic pathways in Parkinson's disease, it has been found that for men and women, attitudes about their sexuality and Parkinson's disease can be more important to their sexual functioning than are biomedical factors (De La-mater and Sill 2005). Some studies have suggested that healthy female partners of patients with Parkinson's disease are more sexually dissatisfied than are women afflicted with Parkinson's disease (Basson 1996).

Sexual dysfunction is almost invariably present in the parkinsonian variant of multiple system atrophy. The most frequent first symptom of multiple system atrophy in men is ED. Some 50% of women with multiple system atrophy report reduced genital sensitivity compared with only 4% of women with idiopathic Parkinson's disease (Oertel et al. 2003). It is recognized that symptoms of disruption of the autonomic nervous system can occur at any stage of Parkinson's disease or can predate it, so that sexual symptoms do not by themselves indicate the presence of multiple system atrophy.

Some authors have attributed a negative effect on desire and sexual function to L-dopa and dopamine agonists (Bronner et al. 2004). On the contrary, these same agents may increase sexual function and motivation through direct stimulation of the dopamine type 2 (D_2) receptors in the medial preoptic area. Also, prolactin is inhibited and oxytocin is increased at the lumbar sacral spinal cord to potentially facilitate erections. Thus, there is a theoretical reason that dopaminergic therapy allows resumption of sexual activity in some patients but perhaps leads to hypersexuality in others. An open-label, prospective 6-month follow-up study showed that pergolide, 3 mg/day, improved sexual function in young men with Parkinson's disease (Pohanka et al. 2004).

Aberrant sexual behavior has been reported in patients with Parkinson's disease. The term *hedonistic homeostatic dysregulation* has been coined to signify exhibitionism and excessive use of phone-sex lines, prostitution services, and sex shops. Eventually, there can be a vicious cycle of dysregulation of brain reward systems resulting in compulsive use of dopamine agonist medications promoting other behavior disorders such as pathological gambling, obsessive shopping, and aggression (Giovannoni et al. 2000). Hedonistic homeostatic dysregulation may not be rare in milder forms of Parkinson's disease: retrospective case-control studies suggest that a history of mood disorder, alcohol intake, personal traits of novelty seeking, early onset of Parkinson's

disease, and early use of dopamine agonists are risk factors for this syndrome (Evans et al. 2005; Pezzella et al. 2005). Of 300 patients with Parkinson's disease taking dopamine agonists, including ropinirole and pramipexole, 25 had sexual compulsions and 28 had comorbid or separate compulsive gambling, of whom 17 met criteria for pathological gambling. These concerns were more common in men than in women (Singh et al. 2007). In several case reports, paraphilias were clearly iatrogenic from use of high-dose dopamine agonists (pergolide, ropinirole, bromocriptine, pramipexole) or use of the monoamine oxidase-B (MAO-B) inhibitor selegiline. It is currently thought that administration of dopamine agonists, especially if combined with L-dopa, may cause these disorders through excessive stimulation of D_2 receptors, particularly the D_3 subclass (Klos et al. 2005). Sexual compulsions can be completely resolved by discontinuing the dopamine agonist despite continuing L-dopa therapy (Klos et al. 2005).

It is interesting that positron emission tomography scans of healthy volunteers experiencing orgasm and ejaculation show strong activation in the dopamine-rich mesodiencephalic and ventral tegmental areas that are also activated during the orgasmlike rush experienced by heroin-addicted persons (Park et al. 2001). The sad irony is that this potential hypersexuality in Parkinson's disease is so diametrically opposed to the disrupted genital function brought about by the neurodegenerative process. The combination of heightened desire with impaired genital function can be enormously problematic for a couple or in a nursing home environment.

Multiple Sclerosis

The prevalence of sexual dysfunction in men and women with multiple sclerosis is high, with the disease eventually affecting 75% of men because of ED predominantly and up to 62% of women because of loss of genital sensation (Rees et al. 2007). Even at diagnosis, when symptoms of MS averaged 2.7 years, sexual dysfunction was present in 35% of women compared with 21% of healthy control subjects (Tzortzis et al. 2008). Fatigue, spasticity, pain, and incontinence all contribute to sexual dysfunction in both men and women. Sexual dysfunction can be a presenting symptom of MS: reduced sensation in the genital area was a presenting symptom in 4 of 63 women with early disease (Tzortzis et al. 2008).

PDE-5 inhibitors are effective for ED. One small study in women showed that these inhibitors improved vaginal lubrication (Dasgupta 2004) but without benefit to the women's overall sexual response. Baclofen, tizanidine, botulinum toxin, and sclerosing agents can lessen spasticity that interferes with sexual activity.

Amyotrophic Lateral Sclerosis

Published data on amyotrophic lateral sclerosis (ALS) are few. Patients with ALS have intact nerve supply to the genitalia because the sensory and autonomic nerve pathways are spared. Consequently, the effect of ALS on sexuality is largely by way of motor incapacity through damaged efferent pathways of brain stem and spinal cord.

Wasner et al. (2004) evaluated sexuality in 62 persons with ALS and found that 62% of the patients and 75% of their partners reported sexual difficulties, compared with 19% and 20%, respectively, before onset of the disease, yet sexual interest and activity remained. Fear of rejection and inhibition by physical limitation were important. The topic of sexuality was rarely discussed with medical personnel. Restricted pulmonary function made penetrative sexual intercourse difficult or impossible; however, five of the six ventilated patients in the study reported having intercourse at least once per month, which is consistent with an unexpectedly high importance of sexuality even in advanced disease.

Spinal Cord and Cauda Equina Injury

Data suggest that some 86% of patients with spinal cord injury retain sexual desire (Anderson et al. 2007a, 2007b), but such injuries are associated with the highest rate of sexual dysfunction from any neurological condition. Depending on the level and completeness of the spinal cord injury, the sexual dysfunction is variable. Very low lesions involving S2, S3, and S4 allow mental excitement to cause a degree of erection and vaginal lubrication and vulval swelling, but reflexive erection of the penis and vulval swelling are lost. The T10–L2 sympathetic outflow from the spinal cord is thought to signal sexual excitement.

In men and women with complete lower motor neuron dysfunction, orgasms are usually lost (Anderson et al. 2007a, 2007b). However, women with complete lesions at any level of the cord still may experience orgasm from cervical vibrostimulation, possibly mediated through an intact neural supply to the cervix traveling separately in the vagus nerve outside of the spinal neuraxis (Komisaruk et al. 2004). Injuries to the medullary cone or to the cauda equina will interrupt the innervation to the genitalia from the autonomic nerves. Trauma to the cauda equina (e.g., from spinal fracture below L1 or severe stenosis of the central canal below L1) can cause complete loss of genital sensation together with loss of voluntary control of the bladder and bowel.

As time progresses postinjury, it is thought that neuroplasticity (Anderson et al. 2007a, 2007b; Duggal et al. 2010) occurs in the ascending pathways of the spinal cord with the result that body areas, including the torso, shoul-

ders, and neck, can be highly sexually arousing when stimulated, even in injuries that have precluded any sensation in the anal or genital areas and any motor function below the lesion level.

PDE-5 inhibitors and intracavernosal PGE₁ are effective to augment reflex and psychogenic erections. Tadalafil has shown benefit in erectile and ejaculatory function at all spinal levels (Giuliano et al. 2007). Similarly, vardenafil has resulted in a significant increase in awareness of orgasm and in ejaculation success (Giuliano et al. 2008). Ejaculation is also facilitated by midodrine combined with penile vibratory stimulation and is more effective than penile vibratory stimulation alone (Soler et al. 2007). Injuries below T10 show less improvement. Sildenafil has been shown to produce a minor increase in vaginal lubrication (Sipski et al. 2000).

Epilepsy

Hyposexuality commonly follows but does not predate the onset of epilepsy and is particularly common in temporal lobe epilepsy (Rees et al. 2007). Epilepsy also can provoke involuntary sexual gestures during a seizure. This occurs when the seizure arises in the mesolimbic temporal structures or the interhemispheric parietal cortex subserving genital sensation. Also, an erotic aura can precede a seizure. Given that automatisms typically occur during the amnesic phase of the seizure, their frequency is probably underreported: video-electroencephalography detected sexual automatisms in 11% of 200 selected patients having medically refractive seizures (Dobesberger et al. 2004). Characteristically, women who have reflex orgasms with their seizures are profoundly hyposexual.

Enzyme-inducing antiepileptic drugs, including phenytoin, barbiturates, and carbamazepine (but not oxcarbazepine), increase the level of sex hormone-binding globulin by an unknown mechanism. Although the total (free plus bound) serum concentration of testosterone is generally unchanged by these anticonvulsants, the increase in sex hormone-binding globulin raises the proportion of bound testosterone and reduces the level of free or bioavailable testosterone. These older antiepileptic drugs impair male sexuality, but data on women are inconclusive. The CYP enzyme-inhibiting antiepileptic drug valproic acid may increase serum androgen levels and estradiol level in both men and women. At least in theory, enzyme-neutral antiepileptic drugs are less likely to cause sexual side effects. The latter include oxcarbazepine, gabapentin, pregabalin, levetiracetam, and lamotrigine. Some evidence indicates that lamotrigine has the lowest profile of sexual side effects (Devinsky 2005).

Dementia

Patients with dementia may lose the normal inhibitory control of sexual behavior. Inappropriate sexual gestures to caregivers or to other patients when institutionalized, or public self-stimulation, may occur. These difficulties can be compounded by frustration with inability to have sexual release. The typical patient is male, and self-stimulation is ineffective in producing orgasm because of ED. Although such behavior is not usually dangerous, it can cause immense distress to all concerned. It is important to confirm that what appears to be inappropriate or disinhibited sexual behavior is not simply a result of frustration or lack of privacy to be alone to self-stimulate or to be with the intimate partner. Still, in some health care facilities, there is no recognition and acceptance of the sexual needs of the institutionalized patient. Psychiatrists may well be consulted not only to assess the problematic sexual behavior but also to negotiate a necessary environment and willingness of hospital staff to allow their patients sexual expression.

When medical treatment is necessary to prevent harm to the patient or others, antiandrogen therapy is considered. Scientific study is very limited, but spironolactone, medroxyprogesterone acetate (MPA), and gonadotropin-releasing hormone agonists are of some benefit. When spironolactone is prescribed, caution is necessary to avoid hyperkalemia and hypotension. Gonadotropin-releasing hormone agonists will cause a brief increase in testosterone level before it declines, which may produce a temporary increase in sexual behaviors. When decisions concerning the use of pharmacological therapy for limiting sexual behavior of demented patients are made, the inclusion of health care team members, the family, and possibly legal advice is recommended.

Diabetes

Diabetes poses risk for sexual dysfunction in both men and women. In diabetic men, diabetic control and length of disease correlate with the incidence of ED, but generally no such correlations between diabetes and sexual dysfunction are observed in women. However, one recent study indicated that longer duration of diabetes did correlate with sexual dysfunction in women (Abu Ali et al. 2008). Insulin resistance and increased adiposity are associated with low levels of testosterone in men, whereas insulin resistance in women is associated with high testosterone levels (Ding et al. 2006).

Some studies suggest that ED may affect some 75% of men with diabetes; both type 1 and type 2 are mixed in many sampled cohorts. In uncomplicated type 2 diabetes without other risk factors for CAD, ED can signal silent cardiac ischemia (Gazzaruso et al. 2004). Etiology of the ED is

multifactorial, including endothelial and smooth muscle dysfunction, autonomic neuropathy, and interpersonal or psychological issues. Men with both diabetes and ED tend to have poor metabolic control, untreated hypertension, peripheral neuropathy, micro- and macroalbuminuria, retinopathy, cardiovascular disease, diuretic treatment, obesity-related testosterone decrease, and psychological vulnerability (Bhasin et al. 2007). Peyronie's disease is an important comorbid disorder in older diabetic men with ED (Bhasin et al. 2007).

PDE-5 inhibitors are the first-line treatment in diabetes; however, these drugs are less effective in some men with diabetes than in others (Bhasin et al. 2007). Calculation of free testosterone concentrations recently has been advocated for patients whose ED is not improved with PDE-5 inhibitors (Traish and Guay 2006).

Ejaculatory problems are common. Retrograde ejaculation consists of propulsion of all or some seminal fluid into the bladder as a result of autonomic nerve damage to the internal urethral sphincter. Sometimes emission happens, but the expulsion phase is completely inhibited so that semen seeps out of the penis, and orgasmic intensity may be less.

Case studies show that ejaculatory dysfunction in diabetes can benefit from treatment with methoxamine, imipramine, or midodrine. When infertility is an issue, sperm can be retrieved by bladder washing after either sexual stimulation or electrostimulation of the prostatic nerve plexus per rectum, prior to intrauterine insemination (Gerig et al. 1997).

A recent review of women's sexual dysfunction in the context of diabetes noted that differentiation between type 1 and type 2 diabetes was often neglected (Bhasin et al. 2007). In addition, most studies did not separate pre- and postmenopausal women, and estrogen status was not controlled. Importantly, sexual dysfunction was linked consistently to comorbid depression. The rates of decreased desire were similar in women with diabetes (17%–85%) and control subjects (16%–90%). However, decreased arousal was high in women with diabetes (76%) compared with control subjects (41%). About twice as common in women with diabetes were reduced lubrication, dyspareunia, orgasmic difficulty, and sexual dissatisfaction in some but not all series. A recent study differentiated the generalized blunting of desire and of all phases of response in women older than 50 years compared with control subjects from the apparently unaffected sexual responses of younger women with diabetes, who showed increased problems only with low desire (Abu Ali et al. 2008).

In another recent study of women enrolled in the long-term Epidemiology of Diabetes, Interventions and Complications (EDIC) study, 35% of participants in a follow-up

assessment met criteria for sexual dysfunction (Enzlin et al. 2009). Among these women, low desire was reported by 57%; problems with orgasm, arousal, and lubrication by 38%; and pain by 21%. In a multivariate analysis, only depression and marital status predicted sexual dysfunction.

As in prior research, no association between sexual function and glucose control, duration of diabetes, or hypertension was found in a very recent study of 595 women with type 2 diabetes (Esposito et al. 2010). Moreover, both depression and marital status were again found to be independent predictors of sexual dysfunction. This particular study did show some association between sexual dysfunction and presence of metabolic syndrome and dyslipidemia.

Because of cardiovascular risk, systemic estrogen is generally avoided in diabetes. Topical estrogen can be prescribed via a vaginal ring, tablet, or cream. One small study showed improved genital congestion with sildenafil (Caruso et al. 2006). Screening for treatable comorbid depression is strongly recommended.

Male Hypogonadism

Investigating and treating the primary pathology in secondary hypogonadism is vital. The underlying disease may be life threatening, as in hemochromatosis or a prolactinoma, and the presenting symptoms are typically sexual. Once the underlying disorder leading to secondary hypogonadism is addressed, as well as in cases of primary testicular failure, testosterone replacement usually improves sexual desire and the delayed ejaculation, diminished ejaculate, low sperm count, and variable ED. Transdermal, as opposed to parenteral, preparations are recommended to avoid peaks and troughs in testosterone levels, which tend to cause both erythrocytosis and mood changes. Addressing the vaguer symptoms of late-onset hypogonadism in older men is less straightforward. All levels of the hypothalamic-pituitary-gonadal axis are blunted, and sexual benefit is not seen unless definite clinical symptoms and clear, repeated biochemical deficit are evident (Bhasin et al. 2007). See also Chapter 22, "Endocrine and Metabolic Disorders."

End-Stage Renal Disease

Sexual dysfunction is extremely common in men and women with ESRD. The etiology is complex because of comorbidities, including diabetes, hypertension, CAD, and depression (Peng et al. 2005, 2007). Associated symptoms relevant to sexual activity include pain in bones and joints from osteodystrophy, fatigue, anorexia, nausea, stomatitis, pruritis, and malnutrition. Reported prevalence of ED is as high as 85%, with anemia, endothelial dysfunction, uremia, and autonomic nerve dysfunction all contributing (Basson et al. 2010). PDE-5 inhibitors can be used if no

contraindications are identified; the dose is reduced in renal insufficiency but not during dialysis. Transplantation may improve ED, and sildenafil is both effective and safe posttransplant (Basson et al. 2010). Recombinant human erythropoietin therapy is guided by hemoglobin levels and can improve ED in men who are receiving dialysis but not when uremia is present. Low desire is present in up to 100% of men with ESRD; low testosterone, high prolactin, anemia, depression, chronic pain, and psychosexual factors, including altered self-image and medicalization of the bedroom in home hemodialysis, all contribute. Testosterone therapy has been of limited benefit, in part because of the anemia and high prolactin level. Erythropoietin partially corrects low testosterone levels (Basson et al. 2010).

Low sexual desire is present in up to 100% of women with ESRD and those undergoing hemodialysis and is as high as 80% posttransplantation (Basson et al. 2010). Multiple factors are involved, including anemia, negative outcomes to sexual interactions, estrogen deficiency with vaginal atrophy, high prolactin level, depression, chronic pain, and psychosexual and interpersonal issues. In addition, 40% of women with ESRD are totally amenorrheic, and fewer than 10% have regular menstrual periods. Premature menopause is common.

Children with ESRD will face many obstacles when it comes time to form sexual relationships. Their lives have been medicalized, which limits social interaction. Puberty may have been delayed, reducing sexual self-confidence. Their situation is compounded by the negative effects of medical interventions on sexual responsiveness.

Cancer

Advances in the management of malignant disease have allowed more lives to be saved, so now the emphasis is also on the quality of those lives. Negative sexual sequelae are present in most cancer patients, 50% of whom would definitely seek treatment for sexual dysfunction were it available (Huyghe et al. 2009). The most pertinent causes of sexual dysfunction are shown in Tables 16-6 and 16-7.

Nerve Damage

Surgical or tumor-induced damage to the inferior hypogastric plexus and cavernous nerves interrupts genital congestion, leading to ED, decreased lubrication, and reduced pain, together with impoverished genital sensitivity, which delays or prevents orgasm. Enhancement of orgasm is possible (for instance, with a vibrator) because sympathetic fibers to the genital structures take multiple routes. Nerve-sparing techniques in radical hysterectomy are in their infancy, but early studies confirm a conservation of genital congestion in response to erotica (Pieterse et al. 2008). ED

TABLE 16-6. Possible direct effects of malignant disease and its treatment on sexual function

Insult	Dysfunction
Loss of sexual organs: breast, vulva, penis	Reduced desire and response; intercourse possibly precluded
Chemotherapy-induced gonadal failure	Reduced desire and response
Surgical section of pelvic autonomic nerves causing failure of erection, vulval and vaginal congestion	Reduced desire and arousal, ED, dyspareunia
Retroperitoneal lymph node dissection for testicular cancer or lymphoma	Failure of emission
Pelvic radiation damage to tissues, including vagina, to autonomic nerve and vascular supply of penis, vagina, vulva; higher doses causing neurogenic orgasmic disorder	Reduced desire and arousal, ED, dyspareunia or inability to accommodate penis or dildo, orgasmic disorder
Hormonal manipulation depleting testosterone, as in androgen deprivation therapy, and estrogen, as with aromatase inhibitors, bilateral oophorectomy, withdrawal of estrogen therapy	Reduced desire and arousal, ED, orgasmic and ejaculatory disorder, dyspareunia

Note. ED=erectile dysfunction.

TABLE 16-7. Indirect effects of malignant disease on sexual function^a

Knowledge of potentially terminal disease
Pain and depression
Fear of inability to satisfy partner, especially when vagina is stenosed from radiation or when ED from radical pelvic surgery or radiation is not improved by PDE ₅ inhibitors or intracavernosal PGE ₁
Fear of transmitting cancer through intercourse
Fear that sexual intercourse was causative of the cancer (e.g., anal or cervical cancer)
Feeling "neutered" from loss of sexual organs
Feeling asexual because no longer fertile after chemotherapy
Perception of premature aging with premature menopause
Feeling unattractive from presence of stoma, ileal conduit, surgical disfigurement

Note. ED=erectile dysfunction; PDE₅=phosphodiesterase type 5; PGE₁=prostaglandin E₁.

^aAll may lower sexual motivation and response.

is still in the range of 53%–86% following attempts at bilateral nerve sparing during radical prostatectomy (Penson et al. 2005). "Penile rehabilitation" with daily or intermittent PDE-5 inhibitors is frequently advocated. However, a recently published randomized controlled trial of vardenafil did not show benefit (Montorsi et al. 2008). Nerve sparing for rectal and colon cancer is also being pursued (Liang et al. 2008; Rees et al. 2007).

Abrupt Loss of Gonadal Hormones

Although studies have confirmed premature ovarian failure from chemotherapy to be a major factor influencing sexual outcome, it has not yet been shown that hormonal changes per se are responsible. A pilot study of women with past breast cancer and complex endocrine status as a result of ongoing antiestrogen therapy used multiple regression analysis to determine what influenced the sexual outcome (Alder et al. 2008). The study found that relationship factors predicted desire, but a history of chemotherapy predicted problematic arousal, lubrication, orgasm, and pain. However, no relation was seen between sexual function and androgen levels, including androgen metabolites. The researchers concluded that the chemotherapy-associated decline in sexual function was mediated by androgen-independent pathways.

Androgen deprivation therapy for prostate cancer may be continuous or intermittent. In the latter group, desire improves when patients are in the "off" phase of therapy (Tunn 2007); ED can be treated with PDE-5 inhibitors.

Preservation of fertility in patients with cancer is now sometimes possible (Jeruss and Woodruff 2009). Whereas sperm banking for men is relatively straightforward, for women, delaying cancer treatment to allow one cycle of hormone stimulation followed by cryopreservation of either a mature oocyte or an embryo may be a very difficult decision. Moreover, in some situations (e.g., after hormone receptor-positive breast cancer), pregnancy may increase the risk of recurrence. It is helpful for psychiatrists to have some understanding of the current and emerging options to preserve fertility for their patients as they prepare for definitive cancer treatment.

Positive Sexual Sequelae in Cancer Survivors

Positive effects on sexuality also can be seen. For example, when therapy for the cancer has been extreme, as in bone marrow transplantation, survivors have described how they treasure life and focus on each moment, including the sexually intimate moments. Sexual "performance" is no longer a goal; indeed, sexual dysfunction may remain some 5 years after marrow transplantation, especially in women (Syrjala et al. 2008), but closeness and sharing erotic touches can be reported as more rewarding than sexual intercourse was before cancer.

Surgeries Resulting in Ostomies

Sexual difficulties associated with stomas range from hesitancy to even begin a relationship to fear that a current partner will now be offended by odor, leakage, or noise from passing flatus. Sexual self-image is vulnerable, particularly in adolescents who already may be feeling unattractive. However, limited study suggests that by young adulthood, marked adaptation may occur such that sexual confidence nevertheless emerges (Erwin-Toth 1999). For older patients, one case-control study suggested that male veterans with stomas had a higher prevalence of ED and less sexual activity than did those requiring major intestinal surgery that did not involve stoma creation (Symms et al. 2008). Of men with stomas, those discontinuing sexual activity adapted less well generally, reporting more isolation and interference with social activities.

Lower Urinary Tract Symptoms in Men and Women

Various urinary symptoms are common and are associated with an increased prevalence of sexual dysfunction in both men and women.

In men, symptoms include urgency, frequency, and nocturia; benign prostatic hyperplasia is often present. ED and lower urinary tract symptoms co-occur and likely share the same etiology. Surgery for benign prostatic hyperplasia precipitates ED in some 10% of cases, and the risk of delayed ejaculation is approximately 20% (Miner et al. 2006).

Pharmacological therapy for lower urinary tract symptoms (traditionally, alpha-adrenergic antagonists and 5-alpha-reductase inhibitors, and more recently, antimuscarinics and PDE-5 inhibitors) may negatively or positively affect sexual function. Combination treatment with alpha-adrenergic receptor antagonists and 5-alpha-reductase inhibitors produces cumulative risks of sexual side effects (Roehrborn et al. 2008). By contrast, treatment of sexual

dysfunction with PDE-5 inhibitors can improve lower urinary tract symptoms.

In women, symptoms of lower urinary tract infection include frequency, urgency, nocturia, urinary incontinence, hesitancy, and postvoiding dribbling. When infection is absent, the combination of urinary urgency, frequency, and nocturia, with or without incontinence, constitutes the overactive bladder syndrome. Urinary urgency, frequency, nocturia, pelvic pain, and dyspareunia constitute painful bladder syndrome or interstitial cystitis. Well-designed studies are lacking, and the pathophysiology of sexual dysfunction is unclear. Data are sparse on the effects of medications (oxybutynin, tolterodine, and solifenacin) for lower urinary tract symptoms on women's sexual function. Pelvic floor muscle training is effective for lower urinary tract symptoms and can benefit sexual function (Giuseppe et al. 2007). The effect of urogynecological therapy, including suburethral slings and prolapse surgeries for lower urinary tract symptoms, on women's sexual function is variable.

Simple Hysterectomy for Benign Disease

Prospective studies have now confirmed that most women report improved sexual function after hysterectomy for benign disease, regardless of operative method (Kuppermann et al. 2004; Roovers et al. 2003). The autonomic nerves traveling to the vulva in the cardinal and uterosacral ligaments are spared in a simple hysterectomy because the incisions in those ligaments are near the midline, whereas the autonomic nerves are in the more lateral portions of the ligaments. Probably underlying the postoperative improvement in sexual function is the lessening of dyspareunia and better sexual self-image resulting from the relief of prolapse or chronic menorrhagia.

Bilateral Salpingo-Oophorectomy

Three recent prospective studies have shown that perimenopausal women receiving bilateral salpingo-oophorectomy along with a simple hysterectomy for benign disease did not develop negative sexual effects when followed up over the next 1–3 years (Aziz et al. 2005; Farquhar et al. 2006; Teplin et al. 2007). A recent large national survey of 2,207 American women found an increased prevalence of *distress* about low sexual desire in women with relatively recent bilateral salpingo-oophorectomy but not an increased prevalence of low desire per se (West et al. 2008). The indications for undertaking bilateral salpingo-oophorectomy in this large survey were not given; almost certainly, some would have been for malignant disease.

Conclusion

Neither the debility nor the interruption of sexual response caused by disease or iatrogenesis removes the sexual needs of most persons with chronic illness. When physicians treating the disease or cancer avoid the subject of sexual health, patients may be reluctant to initiate this discussion, an all-too-common situation. By routinely addressing sexual health, psychiatrists are well suited to assess, diagnose, and direct the management of sexual disorders while treating comorbid depression or other psychiatric disorders (Stevenson 2004).

Substance-Related Disorders

Michael Weaver, M.D., F.A.S.A.M.

PSYCHIATRIC CONSULTANTS in hospital settings often encounter patients with alcohol or drug addiction. Patients who are intoxicated are more likely to be injured in traumatic accidents, and there is a significant association between having a substance use disorder (SUD) and injury from physical trauma (Soderstrom et al. 1997). Risk-taking behavior associated with drug use can lead to sexually transmitted diseases and other infections, including those acquired through injection drug use (e.g., cellulitis, endocarditis, HIV, hepatitis C virus [HCV]). Several terms are used to distinguish different patterns of drug use (Table 17-1). Illicit drug abuse is more prevalent in patients who have depression or anxiety disorders or other psychiatric comorbidities (including personality disorders) and in those who use tobacco or abuse alcohol. Patients with a dual diagnosis (i.e., both an SUD and another major psychiatric disorder) may present with complex clinical histories and symptoms that make diagnosis challenging. Intoxication and withdrawal symptoms may be mistaken for other psychiatric or medical symptoms. Hospitalization may be prolonged by delirium due to intoxication or withdrawal.

Assessment

The prevalence rate for alcohol and substance abuse among hospitalized patients is 15%–30% (Katz et al. 2008; Kouimtsidis et al. 2003; McDuff et al. 1997), and this is even higher among trauma or psychiatric inpatients. With rates this high, it is important to be alert for an SUD in inpatients. However, even careful assessment by clinicians looking for an SUD may not identify all current users. A combination of universal questionnaire screening and urine toxicology for those at high risk is more effective than either alone (Christmas et al. 1992). Findings from physical examination and laboratory studies can provide

important clues to an SUD (Tables 17-2 and 17-3). Although many of these findings can be caused by other diseases, the differential diagnosis should include SUD, and additional information can help verify this.

A good general health history can elicit risk factors for SUD. Erratic occupational history, relational problems with partners and children, accidents, burns and fractured bones, and charges for driving under the influence may be clues to probe further into possible SUD. A simple screening tool for problems of alcohol use is the CAGE questionnaire, which has been modified for screening for drug use and is known as the CAGE-AID (Adapted to Include Drugs) questionnaire (Brown and Rounds 1995). The more responses that are affirmative, the more likely that the person answering has an SUD warranting further investigation by the clinician (Buchsbaum et al. 1991). The CAGE-AID is especially useful in settings where there is a high likelihood of an SUD, such as emergency departments, sexually transmitted disease clinics, and student health centers.

Asking directly about alcohol and drug use is important and even therapeutic for the patient. Often, the clinician should ask first about socially accepted substances, such as nicotine and caffeine (coffee, tea, soda, and energy drinks). This will establish an initial level of comfort for the patient in addressing questions about use of substances. The clinician should inquire next about alcohol use. Specifically, the clinician should ask about beer, wine, and whiskey because many patients do not consider beer to be “alcohol,” which they equate with hard liquor. Then the clinician should ask about misuse of over-the-counter and prescription medications. Finally, the clinician should ask about illicit drugs. By this time, the patient will have a sense that the practitioner is soliciting information in a nonjudgmental fashion for the purpose of helping. The clinician should ask about marijuana first because it is

TABLE 17-1. Definitions

Term	Definition
Use	Sporadic consumption of alcohol or drugs with no adverse consequences of that consumption
Abuse	Frequency of consumption of alcohol or drugs may vary, although some adverse consequences of that use are experienced by the user
Physical dependence	State of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation or rapid dose reduction of a drug or by administration of an antagonist (American Society of Addiction Medicine 2003)
Psychological dependence	Subjective sense of a need for a specific psychoactive substance, either to experience its positive effects or to avoid negative effects associated with its abstinence (American Society of Addiction Medicine 2003)
Substance use disorder	Incorporates both abuse and dependence (American Psychiatric Association 2000)
Substance-induced disorder	Incorporates effects such as intoxication and withdrawal (American Psychiatric Association 2000)
Addiction	A primary chronic neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations; it is characterized by behaviors that include impaired control over drug use, compulsive use, continued use despite harm, and craving (American Society of Addiction Medicine 2003)
Dual diagnosis	Patients with co-occurring psychiatric and addiction diagnoses, which often carry a worse prognosis than either disorder alone (Oscher and Kofoed 1989)

Source. American Psychiatric Association 2000; American Society of Addiction Medicine 2003; Oscher and Kofoed 1989.

considered less problematic by users, its use is prevalent, and it carries less social stigma. Inquiries should then be made about cocaine and heroin use, as well as other illicit substances. The amount of money spent on a daily, weekly, or monthly basis for drugs also may be used to quantify drug use. It is important to ask whether the patient has ever injected drugs in the past or shared needles.

Hospitalized patients frequently will be using more than a single drug. Polysubstance abuse is the norm rather than the exception. Patients with one SUD diagnosis often will have another. Of the patients with an alcohol use disorder (AUD), 13% also have a drug use disorder, and patients with a drug use disorder are highly likely to have an AUD, from 23% of those with sedative dependence to 100% of those with hallucinogen dependence (Stinson et al. 2005). Approximately 22% of adults in the United States use both alcohol and tobacco (Falk et al. 2006).

Recreational drug use is often opportunistic. Users will have a specific drug of choice but will use other drugs when presented with the opportunity or when they do not have access to their drug of choice. Certain drug combinations are more common. Users coadminister drugs to offset unpleasant side effects of one drug by another. Heroin is used with stimulants such as cocaine (this combination is known as a *speedball*) to enhance euphoria and to diminish overstimulation and anxiety (Weaver and Schnoll 1999). Alcohol is used with drugs such as marijuana or

stimulants to lessen anxiety during the "high" (euphoria) or to induce sleep during the "crash" (withdrawal). Ethylcocaine (cocaethylene) is a metabolite of cocaine formed by the liver only in the presence of alcohol; this metabolite has a potency equal to cocaine, which allows users to have a longer period of euphoria but also heightens the risk of toxicity (severe hypertension or vasoconstriction leading to myocardial infarction or cerebrovascular accident) from cocaine when it is taken with alcohol (Benowitz 1993; Farooq et al. 2009).

In the United States, many states require hospitals to report pregnant women suspected of heavy alcohol or other drug use to local public health authorities when the women present for delivery. Fifteen states consider substance abuse during pregnancy to be child abuse under civil statutes, and three consider it grounds for civil commitment. Fourteen states require physicians to report suspected substance abuse in pregnant women, and four require drug testing if abuse is suspected (for a specific listing, see Guttmacher Institute 2009). This reporting may cause women to be even more wary of acknowledging that they have a problem (Weaver 2003). Indeed, in 1988, some hospitals in South Carolina started testing pregnant women for drug use without their consent and turning them over for criminal prosecution. The practice was ultimately ended by a ruling of the U.S. Supreme Court that it constituted an unconstitutional search (*Ferguson v. City of Charleston* 2001). Therefore,

TABLE 17-2. Physical examination indications of substance use disorders

Body system	Examination finding	Medical indication	Substance(s)
Eyes	Scleral icterus	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
	Conjunctival injection		Marijuana
	Pinpoint pupils	Opioid intoxication	Opioids
	Horizontal nystagmus	Acute intoxication	Alcohol
	Vertical nystagmus	Acute phencyclidine intoxication	Hallucinogen
Head and neck	Smell of alcohol on breath	Recent ingestion	Alcohol
	Nasal septal perforation	Snorting drugs	Stimulants
	Poor dentition	Inadequate oral hygiene	Stimulants, opioids
Cardiac	Irregular heart rhythm	Atrial fibrillation ("holiday heart")	Alcohol
	New murmur	Endocarditis from injection drug use	Opioids, stimulants, other injected drugs
	Tachycardia	Intoxication	Stimulants, marijuana
		Acute withdrawal	Alcohol
Abdomen	Enlarged, tender liver	Acute hepatitis (alcoholic or viral)	Alcohol, any injected drug
	Shrunken, hard, or nodular liver	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
	Caput medusae	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
	Epigastric tenderness	Pancreatitis, gastritis	Alcohol
	Enlarged colon	Constipation	Opioids
Extremities	Tremulousness, hyperreflexia	Acute withdrawal	Alcohol
	Ataxia	Acute intoxication	Alcohol
		Wernicke's encephalopathy	Alcohol
	Reduced light touch sensation	Peripheral neuropathy	Alcohol
	Reduced strength	Muscle atrophy	Alcohol
Skin	Jaundice	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
	Spider angiomas	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
	Track marks, fresh needle marks	Injection drug use	Opioids, stimulants, other injected drugs

it is important to assess pregnant women in a nonjudgmental manner for possible SUD. Some studies have shown that comprehensive treatment programs for addicted pregnant women can be successful (Mondanaro and Reed 1987), but the data are insufficient to support any specific intervention (Lui et al. 2008; Stade et al. 2009; Terplan and Lui 2007). Some women may relapse as they near the end of pregnancy. They may confuse early signs of labor with signs of acute withdrawal, so they may medicate themselves during the early hours of labor and arrive at the hospital in labor with high serum levels of drugs from recent use. This increases the chances of fetal stress and distress.

Some patients are able to use illicit substances while hospitalized. They may bring in drugs and paraphernalia at admission in clothing, or visitors may bring drugs to a

patient during the inpatient stay. Occasionally, a patient may obtain drugs from another patient or from hospital personnel. Intoxication may present with altered mental status, unexpected resolution of withdrawal symptoms, or a change in patient behavior. Drug use while in the hospital may be verified by urine drug testing, especially confirmatory testing for specific substances not prescribed. Hospital security personnel may be able to search the room and possibly the patient's belongings. The hospital's risk management department should be notified of any illicit drug use on the premises by a patient. Depending on circumstances, this need not result in a drastic response such as immediate discharge of the patient but may be used as an opportunity for brief intervention to address the seriousness of the patient's addiction.

TABLE 17-3. Laboratory indications of substance use disorders

Laboratory test	Change in result	Medical indication	Substance(s)
Albumin	Reduced	Malnutrition, cirrhosis	Any
Blood alcohol level	Alcohol present	Recent alcohol ingestion	Alcohol
Folate	Reduced	Malnutrition	Alcohol
International normalized ratio, prothrombin time	Increased	Cirrhosis (alcoholic or viral)	Alcohol, any injected drug
Mean corpuscular volume	Increased	Bone marrow suppression, B ₁₂ deficiency	Alcohol
Thiamine	Reduced	Wernicke-Korsakoff syndrome	Alcohol
Transaminases (alanine aminotransferase, aspartate aminotransferase)	Increased	Acute hepatitis (alcoholic or viral)	Alcohol, any injected drug
Urine drug test	Positive	Recent drug use	Any
White blood cell count	Reduced	Bone marrow suppression, human immunodeficiency virus	Alcohol, any injected drug

Alcohol and Sedatives

In the United States, 90% of men and 70% of women consume alcohol (Johnston et al. 2002) in the form of beer, wine, or liquor. AUDs result in 25,000 deaths per year from accidents and 175,000 deaths annually from heart disease, cancer, and suicide (Schuckit and Tapert 2004).

In addition to alcohol, sedative drugs include benzodiazepines, barbiturates, and other sleeping pills. The newer medications zolpidem, zaleplon, and eszopiclone act on the benzodiazepine subtype 1 receptor (Richardson and Roth 2001) and thus are similar to typical benzodiazepines (e.g., diazepam, alprazolam). Zolpidem and eszopiclone abuse is relatively rare when compared with benzodiazepine abuse, but patients with a history of SUD or psychiatric comorbidity are at higher risk for abuse of these medications (Hajak et al. 2003; Victorri-Vigneau et al. 2007).

Intoxication

The clinical features of acute sedative intoxication (including alcohol) are slurred speech, incoordination, unsteady gait, and impaired attention or memory; severe overdose may lead to stupor or coma. Psychiatric manifestations include inappropriate behavior, labile mood, and impaired judgment. Physical signs include nystagmus and decreased reflexes.

A benzodiazepine antagonist, flumazenil, is available for the treatment of acute benzodiazepine intoxication. Nausea and vomiting are its most common side effects. It may not completely reverse respiratory depression and may provoke withdrawal seizures in patients with benzodiaz-

epine dependence. In a mixed overdose with tricyclic antidepressants, flumazenil can precipitate arrhythmias that had been suppressed by the sedative (Weinbroum et al. 1997). Flumazenil appears safe in patients with stable ischemic heart disease (Croughwell et al. 1990). Flumazenil should be withheld in patients with a history of or current seizures and in patients who have overdosed on drugs that lower the seizure threshold. Flumazenil should not routinely be administered to comatose patients when the identity of ingested drug(s) is not certain. Repeat doses should be administered slowly in patients who are physically dependent on benzodiazepines. Flumazenil is short acting, and sedation may recur after an initial awakening. This can be treated by repeating doses at 20-minute intervals as needed.

Withdrawal

Patients may develop an acute alcohol withdrawal syndrome when chronic alcohol use is interrupted by hospital admission. An identical syndrome occurs in patients chronically taking benzodiazepines or other sedatives if the medication is not continued during inpatient admission. Acute withdrawal is most safely managed in an inpatient setting if the patient has been using high doses of sedatives, has a history of seizures or delirium tremens, or has unstable comorbid medical or psychiatric problems (Saitz 1998). The severity of the withdrawal syndrome is affected by concurrent medical illness. Up to 20% of patients develop delirium tremens if left untreated (Cross and Hennessey 1993). Recognition and effective treatment of alcohol withdrawal are important to prevent excess mortality or prolonged hospitalization resulting from complications.

Even when patients acknowledge heavy drinking, they often underestimate the amount, which may be because of minimization or because alcohol is an amnesic agent, and drinkers quickly lose count of how much they have had to drink. It is simplest to ask all patients admitted to the hospital in a nonjudgmental manner about drinking and to be alert for signs of acute alcohol withdrawal in all patients. Individual variability in the threshold at which a patient may develop withdrawal is significant, and those who drink most days of the week are more likely to develop withdrawal as a result of tolerance. Not all daily drinkers will develop withdrawal, but it is difficult to predict who will and who will not. The best predictor of whether a patient will develop acute withdrawal while hospitalized is a history of acute alcohol withdrawal.

The alcohol withdrawal syndrome has two phases: early withdrawal and late withdrawal (Table 17-4). The signs and symptoms of early withdrawal usually develop within 48 hours of the last drink. This time frame may be prolonged if the patient has taken long-acting sedatives or accelerated in extremely heavy users such that patients may begin to withdraw while still mildly intoxicated. The initial indication of withdrawal is an elevation of vital signs (heart rate, blood pressure, temperature). Tremors develop next: first, a fine tremor of the hands and fasciculation of the tongue, sometimes followed by gross tremors of the extremities. Disorientation and mild hallucinations (often auditory, occasionally visual) may develop as the syndrome progresses, accompanied by diaphoresis. Seizures are an early sign of alcohol withdrawal and may be the presenting symptom. However, a large case-control study found that 16% of first seizures in drinkers occurred outside the conventionally defined withdrawal period, and

the timing after the last drink of the other 84% seemed random (Ng et al. 1988).

Late alcohol withdrawal is also known as *delirium tremens* ("the DTs") and consists of worsening autonomic dysregulation that is responsible for much of the morbidity and mortality attributed to alcohol withdrawal. It begins after early withdrawal, usually 72 hours or more after the last drink, and peaks around 5 days (Blondell et al. 2004).

Some patients do not progress from early to late withdrawal, and the symptoms simply subside after a few days with or without treatment, but it is impossible to predict which patients will progress. The signs of late withdrawal consist of worsening diaphoresis; nausea and vomiting (which may result in aspiration pneumonia); delirium with frank hallucinations; and rapid, severe fluctuation in vital signs (Monte Secades et al. 2008). Sudden changes in blood pressure and heart rate may result in complications such as myocardial infarction or a cerebrovascular event, and increased QT variability elevates the risk for serious cardiac arrhythmias (Bar et al. 2007). Hyperthermia is also associated with higher mortality (Khan et al. 2008). Progression to late withdrawal results in significant morbidity and even death (Monte Secades et al. 2008), but adequate treatment of early withdrawal helps prevent progression to late withdrawal.

The revised Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar) is commonly used to assess severity of withdrawal (Sullivan et al. 1989). The CIWA-Ar is just as useful for evaluation and treatment of withdrawal in hospitalized patients on general medical wards and emergency departments as it is in chemical dependency units. It also can be used to determine appropriate pharmacotherapy dose for patients in withdrawal who also have other med-

TABLE 17-4. Alcohol withdrawal signs

Sign	Early withdrawal	Late withdrawal (delirium tremens)
Time of onset	<48 hours after last drink	After onset of early withdrawal
Heart rate	80–110 beats/minute	>120 beats/minute
Temperature	<101.5°F	>101.5°F
Blood pressure	Slight increase (especially systolic)	Significant hypotension and hypertension
Respiratory rate	12–20 breaths/minute	>20 breaths/minute
Tremors	Fine tremor of hands and tongue	Gross tremors, all extremities
Consciousness	Agitated	Delirious
Orientation	Mildly disoriented	Completely disoriented
Hallucinations	Mild auditory and/or visual	Visual, auditory, tactile
Seizures	Possible	Unusual

ical illnesses (Weaver et al. 2006). Regular assessment should continue until the withdrawal syndrome has come under control (CIWA-Ar score <6) for at least 24 hours. If no withdrawal signs have manifested after 48 hours, then it is usually safe to discontinue monitoring for withdrawal. Standardized algorithms with frequent assessment for signs of withdrawal also facilitate efficient treatment of postoperative patients at risk for withdrawal (Lansford et al. 2008).

Pharmacotherapy is indicated for management of moderate to severe withdrawal, and any cross-tolerant medication may be used. It is inappropriate to give beverage alcohol to prevent or treat alcohol withdrawal. Use of intravenous alcohol infusion is reserved for poisoning with methanol, isopropanol, or ethylene glycol and should not be given for treatment of acute alcohol withdrawal because of complications such as intoxication with delirium or development of gastritis (Weaver 2007). Both benzodiazepines and barbiturates effectively treat alcohol withdrawal (Mayo-Smith 1997). In the United States, it is most often managed with benzodiazepines, but barbiturates also have been used successfully to treat acute alcohol withdrawal syndrome in general medical inpatients, and phenobarbital has been used most commonly (Weaver et al. 2009). Several alternative non-sedative-hypnotic medications are available for the treatment of acute alcohol withdrawal. Beta-adrenergic blockers (atenolol, propranolol), clonidine, and anticonvulsant agents (carbamazepine, valproate) decrease alcohol withdrawal symptoms and have been used successfully in treatment of mild withdrawal. However, they are not cross-tolerant with alcohol and may result in progression of the withdrawal syndrome. These alternative medications are not appropriate as single agents to treat moderate or severe withdrawal.

In addition to pharmacotherapy for alcohol withdrawal, some patients need intravenous glucose because many individuals with AUD are hypoglycemic as a result of poor diet and hepatic dysfunction. It is essential to administer thiamine and folate (see discussion below), as well as magnesium and phosphate, before or concurrently with glucose.

Severe withdrawal (delirium tremens), manifested by abnormal and fluctuating vital signs with delirium, should be treated aggressively in an intensive care environment with sufficiently large doses of medication to suppress the withdrawal (Weaver 2007). Medications with a rapid onset of action should be used intravenously for immediate effect. Lorazepam and diazepam have a rapid onset of action when given intravenously, although the duration of action is shorter than when given orally. For example, lorazepam, 1–4 mg every 10–30 minutes, should be given until the patient is calm but awake and the heart rate is less than 120

beats/minute (Weaver 2007). A continuous intravenous infusion may be warranted to control withdrawal symptoms, and the infusion rate can be titrated to the desired level of consciousness. After stabilization, the clinician can substitute an equivalent dose of a long-acting sedative-hypnotic that will be tapered.

Nearly 10% of intensive care unit (ICU) admissions are alcohol related (Baldwin et al. 1993), and 5% will develop severe withdrawal, which carries a mortality rate of 15% (Turner et al. 1989). Prevention strategies include screening ICU patients for SUD and assessment for development of acute withdrawal syndromes (De Wit et al. 2008). The key to treating withdrawal syndromes in the ICU is to anticipate when they may occur and treat vigorously to prevent new problems in critically ill patients (Weaver and Schnoll 1996). No specific benzodiazepine is superior to any other for alcohol withdrawal treatment in the ICU, although longer-acting benzodiazepines may allow for a smoother withdrawal course (Ritson and Chick 1986). Severe alcohol withdrawal that is refractory to high-dose benzodiazepines has been treated successfully with the addition of phenobarbital (Gold et al. 2007) or propofol (McCowan and Marik 2000).

Patients who abuse alcohol often have some degree of liver dysfunction when admitted to the hospital, either from acute alcohol-induced hepatitis or from cirrhosis due to long-term consumption. Hepatically metabolized sedatives such as benzodiazepines and barbiturates may worsen hepatic encephalopathy in patients with cirrhosis. These types of medications should be used with caution to avoid adverse outcomes from accumulation of metabolites requiring liver metabolism. Lorazepam and oxazepam are intermediate-acting benzodiazepines that have no active metabolites (hepatic metabolism of these involves only glucuronidation for excretion), unlike other benzodiazepines, which makes them safer in severe liver disease. Despite the long half-life and metabolism by the liver, phenobarbital is still safe to use for patients with liver disease who are not at risk for hepatic encephalopathy because approximately 30% is excreted unchanged in the urine (Hadamada et al. 2001) and not metabolized by the liver. This is an advantage over most long-acting benzodiazepines (e.g., chlordiazepoxide and diazepam), which undergo extensive liver metabolism to additional active metabolites (Olkola and Ahonen 2008).

Effects on Medical Disorders

An individual with AUD reduces his or her life span by 10–15 years. Chronic alcohol use causes many potential medical problems (Table 17–5). Alcohol use disorders are independent risk factors for the development of community-acquired pneumonia (De Roux et al. 2006). Magnesium

TABLE 17-5. Long-term effects of alcohol use

Cardiovascular	Gastrointestinal	Obstetric
Hypertension	Malnutrition	Sexual dysfunction
Arrhythmias	Gastritis	Intrauterine growth retardation
Cardiomyopathy	Peptic ulcer disease	Fetal alcohol syndrome/fetal alcohol effects
	Gastrointestinal bleeding	
Central nervous system	Acute hepatitis	Other

Diuresis	Mouth, pharynx, larynx	
Hyperglycemia	Esophagus	
Male feminization	Pancreas	
	Liver	

excretion is increased by alcohol intake, so magnesium repletion is important to prevent hypokalemia, which can lead to acute cardiac arrhythmias and muscle weakness (Elisaf et al. 2002). Alcohol dependence is also associated with persistent vascular endothelial damage leading to atherosclerosis with complications such as hypertension and other cardiovascular diseases; this heightened cardiovascular and metabolic risk persists even after 2 years of abstinence (Di Gennaro et al. 2007). Behavior problems may occur in hospitalized patients with AUD, including surgical patients. These may include agitation, sleep disturbances, and verbal abuse (G. Williams et al. 2008). Alcohol also interacts with many different medications in many ways (Table 17-6).

Patients with AUD have longer surgical ICU length of stay, higher rates of ICU readmission, and increased risk of death (Delgado-Rodriguez et al. 2003). A history of alcohol use is an important independent risk factor for delirium and other neurocognitive complications in an ICU setting (Dubois et al. 2001). Acute intoxication or withdrawal from illicit substances may result in delirium and can be easily missed by failing to obtain appropriate history of substance abuse from the patient or family members or by failing to use urine or blood toxicology testing on admission. Even patients admitted with minor injuries have higher morbidity with significantly longer hospital length of stay, including ICU stays with days on mechanical ventilation (Bard et al. 2006), when they have AUD. Alcohol abuse results in postoperative complications, especially from development of alcohol withdrawal syndrome

TABLE 17-6. Interactions between alcohol and medications

Medication	Clinical interaction
Warfarin, oral anticoagulants	Acute: increased anticoagulant effect Chronic: decreased anticoagulant effect
Disulfiram Chlorpropamide Griseofulvin Metronidazole Quinacrine	Nausea and vomiting, flushing, palpitations, dyspnea, hypotension, headache, and sympathetic overactivity
Diazepam	Increased sedation (increased absorption)
Antihistamines Benzodiazepines Opioids	Increased sedation
Chloral hydrate Chlorpromazine Cimetidine	Increased intoxication (decreased alcohol metabolism)

(Chang and Steinberg 2001), so patients at risk for alcohol withdrawal should have elective surgical procedures postponed until they have achieved 7–10 days of abstinence (Bard et al. 2006); if this is not feasible, adequate prophylaxis for alcohol withdrawal should be provided.

Alcohol dependence leads to vitamin deficiency states as a result of reduced transport across the intestinal lining, reduced capacity of the liver to store vitamins, and low vitamin content in alcoholic beverages (Thomson 2000).

Vitamin repletion, especially thiamine and folate, is important for all patients with AUD. Wernicke's encephalopathy results from thiamine deficiency and consists of ophthalmoplegia, ataxia, and altered mental status; this may be difficult to differentiate from acute alcohol intoxication. It is a medical emergency requiring immediate treatment with parenteral thiamine (250–500 mg/day for 3–5 days) to prevent development of Korsakoff's syndrome, the irreversible form of thiamine deficiency consisting of chronic loss of working memory accompanied by confabulation (Sechi and Serra 2007). Thiamine must be given before or concurrently with intravenous glucose because giving glucose alone to a thiamine-deficient patient can precipitate Wernicke's encephalopathy due to thalamic neuronal damage (Thomson et al. 2002).

Pharmacological Treatment

Three medications have been approved by the U.S. Food and Drug Administration (FDA) for treatment of alcohol dependence. Disulfiram has been used for 60 years. It does not reduce craving for alcohol but acts as an aversive agent by inhibition of aldehyde dehydrogenase, which prevents metabolism of alcohol to acetaldehyde. When alcohol is ingested, this results in accumulation of acetaldehyde in the blood with unpleasant effects. The drinker experiences nausea and vomiting, flushing, palpitations, dyspnea, hypotension, headache, and sympathetic overactivity. This reaction to alcohol consumption discourages further drinking. However, disulfiram may have serious side effects, including hepatotoxicity, depression, and psychotic reactions (O'Shea 2000). These potential toxicities limit its utility in medically ill patients, including long-term drinkers who may have developed liver damage over time, as well as patients with major depression or psychotic disorders. It is contraindicated in patients with severe cardiac disease or cirrhosis and during pregnancy because of its association with specific birth defects (Jessup and Green 1987). Ingestion of even small amounts of alcohol, such as that in over-the-counter cough medicines or mouthwash, can result in aversive symptoms; oral liquid medications dissolved in alcohol (elixirs) can also trigger the reaction. Alcohol is present in hundreds of oral, parenteral, and topical (including inhalational) prescription and nonprescription drugs (Parker 1982–1983). Metronidazole has been reported to cause a disulfiram-like effect when alcohol is consumed while taking it, but this has been disputed; however, current recommendations are that patients avoid alcohol while taking metronidazole and for at least 48 hours after stopping it (C.S. Williams and Woodcock 2000).

Naltrexone affects alcohol consumption through blockade of opioid receptors because some reinforcing effects of alcohol are mediated through the endogenous

opioid system. Naltrexone reduces the pleasurable effects of alcohol, which reduces the risk of relapse, especially among those with a family history of alcoholism and those with strong cravings (Johnson 2008). Naltrexone is available as a daily pill or as a monthly intramuscular depot injection given in a physician's office. The primary side effect is nausea, which occurs somewhat less with the depot version. Naltrexone has been reported to cause transaminase elevation and potential hepatotoxicity, with recommendations to monitor this periodically. Although this has been disputed (Brewer and Wong 2004), an FDA black-box warning now states that naltrexone is contraindicated in severe hepatic disease and may cause hepatotoxicity above the recommended dose. Depot naltrexone provides a lower total exposure to naltrexone and bypasses first-pass hepatic metabolism and thus has potential for improved hepatic safety (Dunbar et al. 2006). Naltrexone should be used with caution in patients with hepatic dysfunction, but this is not an absolute contraindication. Because naltrexone is an opioid blocker, treatment of acute or postoperative pain can be challenging in a patient who is using naltrexone for treatment of AUD. For unexpected severe pain such as trauma, nonopioid analgesics should be considered, including nonsteroidal anti-inflammatory agents, or local anesthesia with a nerve block or epidural catheter can be used (Vickers and Jolly 2006). It also may be feasible to titrate typical opioid analgesics upward to patient comfort under medical observation without causing oversedation or significant respiratory depression.

Acamprosate antagonizes *N*-methyl-D-aspartate glutamate receptors, restoring balance between excitatory and inhibitory neurotransmission that was deregulated by chronic alcohol consumption (De Witte et al. 2005), which reduces negative affect and craving during abstinence (Spanagel and Zeiglgansberger 1997). The primary side effects are diarrhea and nervousness, usually only at high doses. This drug has no contraindication to use with liver damage, but the dose should be reduced in patients with renal impairment (Mason et al. 2002); it is contraindicated in renal failure. Acamprosate has no known drug interactions. Compared with disulfiram and naltrexone, which have multiple drug interactions and potential complications (hepatotoxicity), acamprosate may be a good choice for patients with medical and/or psychiatric comorbidities, especially those taking other medications.

Timely follow-up after hospitalization is essential to monitor effectiveness and adverse effects of medications for abstinence. For patients who are motivated to remain abstinent, one of these medications may be started in the inpatient setting. These medications should be started only if a practitioner is identified to continue them in the outpatient setting.

Opioids

The most commonly used illicit opioid is heroin, with more than 2 million chronic users in the United States (Substance Abuse and Mental Health Services Administration 2006). The all-cause mortality rate of heroin dependence is more than 60 times that expected for nonusers of the same age and sex (Gronbladh et al. 1990). Prescription opioid analgesic abuse is the fastest-growing form of drug abuse in the United States (Cicero et al. 2005) and is predominantly localized in rural, suburban, and small urban areas (Cicero et al. 2007).

Pseudoaddiction is an iatrogenic syndrome of aberrant medication-taking behaviors that occurs when pain is undertreated with opioid analgesics (Weissman and Haddox 1989). This may revert to normal behavior when pain is adequately treated. The best course of action to differentiate addiction from pseudoaddiction is to titrate the dose of medication upward rapidly to control pain quickly (Weaver and Schnoll 2002). Opioid abuse can be differentiated from pseudoaddiction by continuing inappropriate behavior, such as oversedation despite complaints of severe pain and requests for additional opioids despite multiple upward titrations of the opioid dose.

Intoxication

Acute opioid intoxication is characterized by decreased level of consciousness, substantially decreased respiration, miotic pupils, and absent bowel sounds. Prescription opioid analgesics may be abused and can lead to intoxication or overdose. Oral controlled-release oxycodone has been abused by crushing the tablets and then snorting the powder; when taken in this way by people who have no tolerance to the drug, a single 80-mg dose (the highest strength available in a single tablet) can be fatal. Propoxyphene, meperidine, or tramadol can cause seizures in overdose. Meperidine, in particular, can cause an agitated delirium due to accumulation of normeperidine, which is a neuroexcitatory toxic metabolite; this is most prevalent in patients with acute or chronic renal impairment and results in reduced clearance of normeperidine (Adunsky et al. 2002).

Opioid overdose is treated with naloxone. It is given intravenously as an initial dose of 0.4 mg, but if no response is seen in 3–5 minutes, an additional dose of 1–2 mg is given. The duration of action of naloxone is 20–40 minutes, so repeated doses or a continuous infusion may be necessary for patients who have taken long-acting opioids such as methadone. It is advisable to restrain patients prior to administration of naloxone because patients may become agitated and even violent when awakened in acute withdrawal in an unfamiliar setting.

Withdrawal

Opioid withdrawal has very apparent physical symptoms (Table 17–7) and fairly consistent time to onset from the last use (about 8 hours for short-acting opioids such as heroin or oxycodone), which is a prominent factor in repeated administration after development of tolerance. This is in contrast to delirium tremens from alcohol and sedatives, in which minor signs of acute withdrawal often do not progress to severe withdrawal; onset and severity of opioid withdrawal are consistent and predictable for the vast majority of daily users. Opioid withdrawal is treated with substitution of a long-acting opioid (methadone or buprenorphine) for detoxification over several days.

Hospitalization is usually unnecessary for opioid withdrawal alone unless the patient has concurrent medical or psychiatric illness that warrants hospitalization (e.g., unstable angina, brittle diabetes mellitus, suicidality). Methadone is frequently used to treat acute withdrawal from opioids, but current U.S. federal regulations restrict the use of methadone for treatment of opioid dependence. Methadone may be used by a physician for temporary maintenance or detoxification when an opioid-dependent patient is admitted to a hospital for an illness other than opioid addiction. A method of titrating the amount of methadone based on symptoms has been used extensively to titrate methadone for opioid withdrawal, without causing oversedation or severe patient discomfort (Weaver et al. 1999). The severity of 11 symptoms (see Table 17–7) is rated with a score of 0 to 2 points (0=symptom is absent; 1=symptom is present; 2=symptom is severe). The total score for all symptoms is determined; each point is equiv-

TABLE 17–7. Opioid withdrawal signs

Sign	None	Mild	Severe
Nausea/vomiting	0	1	2
Abdominal cramps	0	1	2
Diarrhea	0	1	2
Chills/hot flashes	0	1	2
Myalgias/arthralgias	0	1	2
Piloerection	0	1	2
Restlessness	0	1	2
Twitching/jerks	0	1	2
Lacrimation	0	1	2
Rhinorrhea	0	1	2
Yawning	0	1	2

alent to a requirement of 1 mg of methadone, but no methadone is given for a score of less than 5 points because such a low score indicates only mild withdrawal. The patient should be evaluated and the symptom score reassessed every 6 hours for the first 24 hours. After 24 hours, the total dose of methadone administered is calculated; this dose is approximately equivalent to the dose of opioid the individual was taking. After being stabilized on this dose of methadone for 24 hours, the patient can be tapered off by approximately 10%–20% per day. The duration of action of methadone allows it to be given once daily as a single dose (when treating opioid withdrawal in contrast to pain treatment). Most patients do not experience euphoria with methadone administration. Buprenorphine is also used to treat opioid withdrawal.

Clonidine is not approved by the U.S. FDA for the treatment of opioid withdrawal, although it is commonly used for this purpose. A transdermal clonidine patch is effective for mild withdrawal symptoms and can be left on the skin for 7 days. Typical clonidine protocols use 0.1–0.3 mg of clonidine every 2–4 hours for the first 24 hours, usually 0.8–1.2 mg/day. Subsequently, clonidine is given three to four times a day, with the total daily dose reduced by 0.1 or 0.2 mg on each subsequent day. The total duration for this regimen is 10–14 days. It is important to monitor for hypotension during clonidine therapy and then to taper clonidine gradually to avoid a hypertensive rebound (Gowing et al. 2004). Clonidine should be avoided in hypotensive patients (systolic blood pressure < 100 mm Hg). In addition to orthostatic hypotension, side effects of clonidine include sedation, dry mouth, and constipation; these are more likely at higher doses.

Certain medications may be given for relief of other symptoms of opioid withdrawal: muscle relaxants reduce spasms and twitching; nonsteroidal anti-inflammatory drugs treat aches; antiemetics are used for nausea; an anti-diarrheal agent such as bismuth subsalicylate may be useful; and a sleeping medication that has low abuse potential (such as trazodone) will help insomnia.

Opioid withdrawal syndrome during pregnancy can lead to fetal distress and premature labor as a result of increased oxygen consumption by both the mother and the fetus (Cooper et al. 1983). Even minimal symptoms in the mother may indicate fetal distress because the fetus may be more susceptible to withdrawal symptoms than is the mother. Buprenorphine is not recommended for pregnant women yet. Naloxone should not be given to a pregnant woman except as a last resort for severe opioid overdose because withdrawal precipitated by an opioid antagonist can result in spontaneous abortion, premature labor, or stillbirth.

Effects on Medical Disorders

Chronic infection with HCV can lead to cirrhosis and need for liver transplant, and the rate of HCV infection among methadone maintenance (MM) patients is 70% (Weaver et al. 2005). Accurate data about drug and alcohol use among patients with liver disease or liver transplant candidates are difficult to obtain because patients underreport this use because they believe that divulging this information will harm their chances of receiving further care, especially access to a liver transplant (Weinrieb et al. 2000). The standard of care for patients with severe liver disease receiving MM is to continue methadone during evaluation, transplant surgery, and thereafter rather than attempting to taper the patient off methadone (Lucey and Weinrieb 2009). Continuation of MM has superior outcomes in terms of relapse to heroin use when compared with tapering off methadone (Ball and Ross 1991). Therefore, it is inappropriate to require patients who are stable on methadone (or buprenorphine) to discontinue this treatment before any surgical procedure or other intervention.

Individuals admitted to the hospital with opioid dependence may have pain from various sources, including trauma or infection. Acute opioid withdrawal syndrome also may be painful because of myalgias and intestinal cramping. Adequate treatment of pain with opioid analgesics will also ameliorate opioid withdrawal signs. It may be difficult to distinguish pain due to opioid withdrawal from pain due to other causes; the best course of action is to give the patient the benefit of the doubt and provide appropriate amounts of opioid analgesics to treat complaints of pain adequately (Weaver and Schnoll 2002). Sedation and mild reduction in respiratory rate are indicators that the pain and withdrawal are adequately being treated; additional requests for opioids despite these signs may indicate that the patient is seeking higher doses in an attempt to achieve euphoria beyond just relief of pain and withdrawal symptoms. Narcotic bowel syndrome is a form of bowel hyperalgesia that has been proposed but not well studied. Patients have chronic or recurring abdominal pain that is worsened with continued or escalating dosages of opioids (Grunkemeier et al. 2007); improvement in symptoms is observed following gradual tapering off opioids.

Some opioids, including tramadol, meperidine, dextromethorphan, and methadone, are weak serotonin reuptake inhibitors (Gillman 2005). When given—especially at high doses—with monoamine oxidase inhibitors (such as phenelzine, tranylcypromine, selegiline, and even the antibiotic linezolid), this can result in serotonin syndrome (see “Serotonin Syndrome” in Chapter 38, “Psychopharmacology”). Opioids that do not have serotonin activity are morphine, codeine, oxycodone, and buprenorphine;

these would be better choices to use for patients taking other serotonergic medications.

Pharmacological Treatment

Methadone may be used for chronic addiction only by a licensed opioid treatment program. Prescribing methadone for withdrawal or long-term treatment of drug dependence requires a special state and federal license; however, methadone can be prescribed in the United States for treatment of acute or chronic pain by any physician with a Drug Enforcement Administration (DEA) license, similar to laws for other Schedule II medications. If an MM client is hospitalized, such as for a traumatic injury or medical illness, the maintenance dose should be continued throughout hospitalization. The hospital physician should contact the MM program to verify the client's current dose and arrange for dosing to resume after discharge.

Acutely ill or injured hospital patients often experience pain; MM clients experience the same pain despite receiving methadone because methadone reaches steady-state levels in the body and does not provide additional analgesia. Patients receiving MM with acute pain should be treated for pain with opioid or nonopioid medications, as would be appropriate if they were not receiving MM. The patient's usual MM dose should be continued and short-acting opioid analgesics administered additionally. These should be given on a schedule and not ordered as needed. Higher-than-usual opioid analgesic doses may be required because of opioid cross-tolerance (Alford et al. 2006). If the patient cannot take oral medication, methadone can be given by the intramuscular or subcutaneous route. The parenteral dose should be given as one-half to two-thirds of the maintenance dose, divided into two to four equal doses per day. Mixed agonist and antagonist opioid analgesics, such as pentazocine, nalbuphine, and butorphanol, should not be administered because they precipitate acute withdrawal and block the analgesic effects of agonist opioids. Combination products with fixed doses of acetaminophen and an opioid should be avoided for most patients because higher opioid dose requirements may expose patients to potentially hepatotoxic doses of acetaminophen.

Many different medications affect methadone metabolism primarily because it is metabolized by cytochrome P450 3A4. Risperidone, rifampicin, and many antiretrovirals can lower serum methadone levels, resulting in opioid withdrawal symptoms. These interactions usually do not have life-threatening consequences for patients, other than acute discomfort and risk of relapse to opioid abuse (Ferrari et al. 2004). Diazepam, fluoxetine, and erythromycin can elevate methadone serum levels and increase the risk of opioid intoxication. Methadone use can prolong the QTc interval. A dose relation has been observed be-

tween methadone and QTc interval (Martell et al. 2005), with most problems occurring at dosages greater than 40 mg/day (Ehret et al. 2006). Torsade de pointes has been reported with very high doses of methadone in outpatient settings, occurring in a few patients who had risk factors for arrhythmias (Krantz et al. 2002). The risk of QTc prolongation is increased when methadone is given intravenously; is used in conjunction with other QTc-prolonging drugs (e.g., antipsychotics, amiodarone, erythromycin) or drugs that inhibit cytochrome P450 3A4; and is administered to patients with hypokalemia, hypocalcemia, hypomagnesemia, or impaired liver function (Ehret et al. 2006).

Buprenorphine, a partial opioid agonist, reduces illicit opioid use with long-term therapy (Kakko et al. 2003). Buprenorphine is taken sublingually. It is available alone or in a combination preparation with naloxone, an opioid antagonist that has poor oral absorption. Buprenorphine has a lower potential for causing respiratory depression than does methadone, and the typical treatment dose (16–32 mg) can be tolerated by opioid-naïve users. It does not appear to prolong the QTc interval (Wedam et al. 2007), unlike methadone. Buprenorphine does have the potential to be misused as an injectable agent. It is less restricted than methadone but may be used in the United States only by certified and specially trained physicians who have registered with the Substance Abuse and Mental Health Services Administration. Administration of buprenorphine or buprenorphine/naloxone may precipitate an acute opioid withdrawal syndrome in patients with opioid dependence (Walsh and Eissenberg 2003).

As with MM, patients taking buprenorphine who develop acute pain should be given appropriate pain medications. Short-acting opioid analgesics should be used in higher-than-usual doses, on a set schedule, and mixed agonist-antagonist opioid analgesics should be avoided. Buprenorphine has fewer drug interactions than methadone does, so it is safer when used for patients with medical comorbidities such as HIV who are taking antiretroviral medications. However, buprenorphine may cause elevation of liver transaminase levels in patients with chronic HCV infection (Petty et al. 2000), which has a very high prevalence among patients who have injected opioids and are receiving maintenance treatment, and monitoring of liver enzymes may be necessary. Buprenorphine toxicity has been linked to use of benzodiazepines (Tracqui et al. 1998), so patients who require chronic benzodiazepine therapy for anxiety disorders or who have a history of sedative dependence may not be appropriate candidates for buprenorphine maintenance.

MM is the treatment of choice for opioid-addicted pregnant women (Center for Substance Abuse Treatment 1993; Winklbaur et al. 2008), although other opioids have

been used (Minozzi et al. 2008). Illicitly bought heroin is adulterated with other compounds that may be harmful to the fetus, so elimination of heroin use with adequate doses of methadone prevents harm to the fetus from exposure to these other compounds. Pregnant women who are opioid dependent should be referred for prenatal care and to a local MM program, if available. Most programs assign high priority to pregnant women, so the patient may be able to enter treatment sooner than if she were not pregnant. Split dosing of methadone rather than the standard once-a-day dose appears to have fewer neurobehavioral effects on the fetus (Jansson et al. 2009). Women can breast-feed while receiving MM as long as they are not abusing any drugs (McCarthy and Posey 2000) and are not HIV positive. Sublingual buprenorphine is not yet approved for use in pregnancy but has been used successfully for opioid maintenance in pregnant women (Fischer et al. 2000). This medication has been well tolerated by mothers, and the newborns have had a similar incidence of neonatal abstinence syndrome compared with newborns of mothers receiving MM (Jones et al. 2005).

Naltrexone is also used as a medication to assist with maintaining abstinence in patients with opioid addiction. Daily oral dosing or monthly intramuscular injections result in blockade of opioid effects if opioids are used. The intramuscular formulation has been approved by the U.S. FDA for the treatment of alcohol dependence but not for the treatment of opioid dependence. Naltrexone causes immediate withdrawal symptoms if administered prior to detoxification. Patients who discontinue antagonist therapy and resume opioid use should be made aware of the risk of serious overdose. This risk may be a result of loss of tolerance to opioids and a resulting misjudgment of dose at the time of relapse (Strang et al. 2003).

Stimulants

Stimulants are drugs that stimulate the central nervous system (CNS) to produce increased psychomotor activity. Amphetamines, including methamphetamine, and cocaine are the most prevalent abused stimulants, but this class also includes prescription stimulants such as methylphenidate and dextroamphetamine, as well as "designer drugs" such as methylenedioxymethamphetamine (MDMA; Ecstasy). More than 40 million people worldwide have used methamphetamine (United Nations Office on Drugs and Crime 2003).

Caffeine is a mild stimulant found in coffee, tea, soda, and energy drinks. Reports of caffeine intoxication have been rising because of the availability of energy drinks with high caffeine content, and this can mimic symptoms of anxiety disorders. Compelling evidence indicates that caf-

feine can produce a substance dependence syndrome in some individuals (Reissig et al. 2009). Energy drink consumption is associated with progression to nonmedical use of prescription stimulants, and caffeine increases the reinforcing effects of nicotine and may increase the rate of alcohol-related injuries (Reissig et al. 2009). It is important to ask all patients about consumption of caffeine and use of other drugs.

Khat is a plant with psychostimulant properties that has been long used socially and in religious ritual in some African and Middle Eastern countries and more recently by immigrants from them. Although the psychoactive compounds in khat leaves are much less potent than amphetamines, addiction does occur in a minority of its users. Adverse medical effects are uncommon with low-level use, but high levels may cause hypertension, arrhythmia, insomnia, and anorexia. In addition, khat users appear to be at increased risk for gastrointestinal cancers (Manghi et al. 2009; Pennings et al. 2008).

Intoxication

Stimulant intoxication includes behavior changes such as hypervigilance, psychomotor agitation, grandiosity, and impaired judgment. People should approach acutely intoxicated stimulant users in a subdued manner, avoid speaking in a loud voice or moving quickly, not approach the patient from behind, and avoid touching the patient unless absolutely sure that it is safe to do so (Weaver et al. 1999). Treatment of acute toxicity includes acute stabilization of airway, breathing, and circulation; administration of activated charcoal; seizure control with benzodiazepines; aggressive management of hypertension; and management of hyperthermia.

Many experts advise that beta-blockers should not be considered first-line agents for controlling chest pain or hypertension in patients using cocaine because that would leave alpha-adrenergic stimulation unopposed, but this remains controversial (Dattilo et al. 2008; Page et al. 2007).

Effects on Medical and Psychiatric Disorders

Use of stimulants may result in many health consequences that can bring users into the hospital or complicate existing medical and/or psychiatric conditions (Table 17-8). Known psychiatric disorders may be exacerbated by stimulant use. Schizophrenia is more susceptible to relapse, and panic attacks may increase in intensity and frequency. Chronic use of MDMA can lead to paranoid psychosis that is clinically indistinguishable from that in schizophrenia, but this usually abates after a prolonged period of abstinence (Buchanan and Brown 1988). Several studies suggest that MDMA use can lead to cognitive decline in otherwise healthy young people (Gouzoulis-Mayfrank et al.

2000); this neurotoxicity occurs at typical recreational doses. Patients presenting with these signs should be suspected of stimulant abuse and screened carefully.

Stimulants are used therapeutically for multiple conditions and are prescribed appropriately for attention-deficit disorder, narcolepsy, fatigue in multiple sclerosis, refractory depression, and palliative care. Stimulants potentiate arrhythmias (Wilkerson 1988), and long-term use can lead to cardiomyopathy (Virmani et al. 1988). When prescribed stimulants such as methylphenidate or dextroamphetamine are abused by patients who have valid prescriptions for them, clinicians may see unintended side effects such as elevation in resting heart rate or other cardiovascular complications; these effects may be a clue to the prescriber that unauthorized dosage escalation is occurring. Patients prescribed stimulants who also have cardiovascular disease are at higher risk for complications. Cocaine is the most frequent drug-related cause of emergency department visits (Drug Abuse Warning Network 2003), and chest pain is the

most common reason to seek emergency care. Stimulant abuse is a major cause of cerebrovascular and cardiovascular disease in young adults (O'Connor et al. 2005). In numerous case reports, MDMA (Ecstasy) use resulted in rhabdomyolysis, hyperthermia, serotonin syndrome, hyponatremia with cerebral edema, fulminant hepatic failure, and stroke (Hall and Henry 2006). Both prescribed and illicit stimulants interact with other medications, which may result in serious adverse reactions, often cardiovascular in nature (Table 17-9).

Pharmacological Treatment

Abrupt discontinuation of stimulants does not cause gross physiological sequelae, so they are not tapered off or replaced with a cross-tolerant drug during medically supervised withdrawal (Weaver and Schnoll 1999). Most pharmacological agents have not proven significantly better than placebo for long-term management of abstinence for stimulant-dependent patients (Schuckit 1994).

Nicotine

Around the world, 57% of men and 10% of women smoke tobacco products, primarily cigarettes (Mackay and Erikson 2002). In the United States, about 21% of the adult population smokes cigarettes (Centers for Disease Control and Prevention 2005). Clinically significant medication interactions with smoking include reduced levels of estradiol, haloperidol, imipramine, pentazocine, propranolol, and theophylline (Smith 2009).

Withdrawal

Symptoms of nicotine withdrawal are similar with all tobacco products, whether cigarettes, chewing tobacco, or snuff. Withdrawal symptoms include irritability, difficulty concentrating, restlessness, anxiety, depression, and increased appetite (Karan et al. 2003). Reaction time and attention are also impaired. Withdrawal symptoms peak around 48 hours after the last use, then gradually diminish over several weeks. Symptoms of dysphoria, anhedonia, and depression may continue for several months after cessation. The withdrawal syndrome from nicotine is similar to that of other stimulants.

Nicotine replacement therapy (NRT) is used in hospitalized smokers to treat acute nicotine withdrawal symptoms and to promote smoking cessation (Rigotti et al. 2008). Recent research supports including NRT in interventions for hospitalized smokers, along with counseling, because pharmacotherapy and counseling may be synergistic. Nicotine replacement products include a patch, gum, lozenge, nasal spray, and inhaler; all provide similar relief from withdrawal symptoms and efficacy for smoking ces-

sation (Hajek et al. 1999). Even patients with hypertension and/or cardiovascular disease benefit from NRT, including those in an inpatient hospital setting (Joseph and Fu 2003). However, NRT is not routinely recommended for smokers with acute coronary syndromes because safety has not been established, and most of these patients have minimal nicotine withdrawal symptoms when they are hospitalized in a tobacco-free environment (Joseph and Fu 2003). Counseling for smoking cessation is appropriate for smokers hospitalized with acute cardiovascular complications. Clinically significant drug interactions of NRT include reduced analgesia from opioids and reduced sedation from benzodiazepines (Kroon 2006).

Pharmacological Treatment

Varenicline is a partial nicotinic receptor agonist (Mihalak et al. 2006) that signals dopamine release and creates reinforcing effects similar to those of nicotine but not to the full extent because of its partial binding of the receptor, and it acts as a physical antagonist by binding to the nicotine receptor and blocking the effects of nicotine. Varenicline is recommended as monotherapy because it blocks the effects of NRT as well as nicotine from tobacco. Varenicline's psychiatric side effects, including depression, agitation, hostility, and suicidality, have prompted an FDA black-box warning. Varenicline is renally excreted, so dose reductions are recommended in patients with renal insufficiency. It is without significant drug interactions. Varenicline's side effects of nausea and vomiting may be problematic in some medically ill patients.

Sustained-release bupropion increases smoking cessation rates by inhibiting dopamine uptake in the mesolimbic dopamine system (reward center) of the brain (Hurt et al. 1997). Bupropion may cause insomnia and may lower the seizure threshold (Dunner et al. 1998), so it is relatively contraindicated in patients with epilepsy or a recent seizure and should be used with caution in patients at risk for seizures (such as those at risk for acute alcohol withdrawal).

Both varenicline and bupropion exert their beneficial effects on smoking cessation over time and are usually started around 10 days prior to quitting smoking, so they may not be appropriate to start in hospitalized patients who are only beginning to consider smoking cessation.

Cannabis

Marijuana is the most frequently abused drug in the United States, with a prevalence of approximately 4% of the adult population that uses regularly. This rate has remained relatively steady since the early 1990s (Compton et al. 2004).

Intoxication

The onset of acute marijuana intoxication is within minutes when smoked, and the effects last for 3–4 hours (American Psychiatric Association 2000). Impairment of concentration and motor performance lasts for 12–24 hours as a result of accumulation of marijuana in adipose tissue, with slow release of tetrahydrocannabinol from fatty tissue stores and enterohepatic recirculation. Thus, a marijuana user may think that he or she is no longer impaired several hours after use when the acute mood-altering effects wear off. However, impairment of cognition, coordination, and judgment lasts much longer than the subjective feeling of being “high.” Impairment is intensified by combination with other drugs, especially alcohol. This explains why fatal traffic accidents occur more often among individuals who have positive test results for marijuana use (Laumon et al. 2005).

Acute intoxication with marijuana alone rarely requires medical treatment, although dysphoria may result in distress that causes the user to seek help. First-time users, older persons, users of high-potency marijuana, and those predisposed to psychiatric illness are at higher risk for experiencing unpleasant effects during intoxication. Unpleasant effects of acute intoxication, such as anxiety, paranoia, or palpitations, are managed with supportive treatment. Placing the distraught user in a quiet environment and maintaining gentle contact is often sufficient until the acute effects subside; more severe paranoia or psychosis may require close observation with possible administration of a benzodiazepine or haloperidol for sedation.

Withdrawal

Heavy marijuana use for more than 3 weeks results in a withdrawal syndrome after abrupt cessation (Wiesbeck et al. 1996). Marijuana withdrawal begins within 10 hours of the last dose and consists of irritability, agitation, depression, insomnia, nausea, anorexia, and tremor. Most symptoms peak in 48 hours and last for 5–7 days. Some symptoms, such as unusual dreams and irritability, can persist for weeks (Budney et al. 2004). Marijuana withdrawal is uncomfortable but not life-threatening. Thus, treatment is entirely supportive and nearly always accomplished without the need for adjunctive medications.

Effects on Medical Disorders

Chronic marijuana use results in multiple psychiatric and medical consequences (Table 17–10). Marijuana use results in cognitive deficits that persist for at least hours after acute intoxication. Very heavy use is associated with persistent decrements in neurocognitive performance, even after 28 days of abstinence (Bolla et al. 2002). Marijuana abuse results in measurable health consequences and increases in

health care costs (Pacula et al. 2008). A 1999 Institute of Medicine report (Watson et al. 2000) concluded that marijuana has potential therapeutic value for pain relief, control of nausea and vomiting, and appetite stimulation, but smoking it is a poor delivery system. Better alternatives are now available for nausea and vomiting caused by cancer chemotherapy. Data do not support its use for glaucoma. The literature to date suggests the plausibility of an association of marijuana smoking with lung cancer and head and neck cancer, but the data to date have not established it as a risk factor for either cancer (Berthiller et al. 2009; Mehra et al. 2006).

Hallucinogens

Drugs considered hallucinogens are a diverse group of compounds, including lysergic acid diethylamide (LSD), designer drugs, and many others (phencyclidine [PCP; angel dust], ketamine). Hallucinogens produce perceptual distortions and cognitive changes with a clear sensorium, without impairment in level of consciousness or attention (Abraham et al. 1996). Use of LSD dropped off in the 1980s but has increased in the 2000s, with a lifetime prevalence of use of 13% among young adults (Wu et al. 2006).

Intoxication

In general, acute physiological complications of hallucinogen intoxication rarely require medical treatment. However, malignant hyperthermia and seizures may occur with hallucinogen intoxication. Warning signs for hallucinogen hyperthermia are agitation, dry skin, and increased muscle tension. Intoxication with PCP causes a characteristic vertical nystagmus (it can also cause horizontal or rotatory nystagmus), which helps to identify it as the cause when a patient presents with intoxication by an unknown drug (Weaver and Schnoll 2007).

Effects on Medical and Psychiatric Disorders

Hallucinogen use may result in long-term psychiatric consequences, such as anxiety, depression, or psychosis. The risk of a prolonged psychiatric reaction depends on the user's underlying predisposition to develop psychopathology, the amount of prior hallucinogen use, the use of other drugs, and the dose and purity of the hallucinogen taken (Strassman 1984). Patients may present with apathy, hypomania, paranoia, delusions, hallucinations, formal thought disorder, or dissociative states. Treatment of prolonged anxiety, depression, or psychosis is the same as when these conditions are not associated with hallucinogen use.

Hallucinogen use also may result in medical consequences. Up to a third of frequent ketamine users experi-

TABLE 17-10. Effects of marijuana use

ence severe gastrointestinal cramping known as “k-cramps,” but the cause is unknown, and no treatment exists currently (Meutzfeldt et al. 2008). PCP may cause hypertensive encephalopathy or life-threatening hyperthermia (Weaver and Schnoll 2008).

No pharmacological treatment is available for hallucinogen abuse (Abraham et al. 1996). Treatment settings for hallucinogen abuse focus on behavioral components such as individual and group counseling.

Gamma-Hydroxybutyrate

Gamma-hydroxybutyrate (GHB) is a sedative that is both a precursor and a metabolite of gamma-aminobutyric acid (GABA). It has been used as a sleep aid and for treatment of narcolepsy; it also increases episodic secretion of growth hormone, so some bodybuilders use it to promote muscle growth. After reports of GHB's toxicity resulted in its regulation by the U.S. government, 1,4-butanediol and gamma-butyrolactone, another precursor of GHB and an industrial solvent, began to be marketed as dietary supplements, both of which have similar effects and risk for abuse as GHB (Zvosec et al. 2001).

Intoxication

GHB's effects have been likened to those of alcohol, with mild euphoria, mild numbing, and pleasant disinhibition. GHB is not detectable by routine drug screening. The dose-response curve for GHB is exceedingly steep, so small increases in the amount ingested may lead to significant intensification of effects and onset of CNS depression. Con-

current use of sedatives or alcohol may increase the risk of vomiting, aspiration, or cardiopulmonary depression; use with stimulants may increase the risk of seizure. In cases of acute GHB intoxication, physicians should provide physiological support and maintain a high index of suspicion for intoxication with other drugs. Most patients who overdose on GHB or related compounds recover completely if they receive proper medical attention, but there have been deaths (Zvosec et al. 2001). Management of GHB ingestion in a spontaneously breathing patient (Li et al. 1998) includes oxygen supplementation, intravenous access, and comprehensive physiological and cardiac monitoring. Atropine can be used for persistent symptomatic bradycardia. Patients whose breathing is labored should be managed in the ICU.

Withdrawal

The symptoms of GHB withdrawal include anxiety, tremor, insomnia, and “feelings of doom,” which may persist for several weeks after stopping the drug (Galloway et al. 1997). Severe withdrawal involves agitation, delirium, and psychosis (McDaniel and Miotto 2001). The treatment of GHB withdrawal is with benzodiazepines, which may require very high doses (Dyer et al. 2001). Antipsychotics or pentobarbital (Sivilotti et al. 2001) may have some utility in treatment of severe GHB withdrawal.

Inhalant Abuse

Inhalants are volatile substances that produce chemical vapors that can be inhaled for psychoactive effects. Examples

of abused inhalants include glue, dry-cleaning fluids (carbon tetrachloride), gasoline, aerosol propellants from whipped cream cans or deodorant sprays, amyl nitrite, butyl nitrite, nitrous oxide ("laughing gas"), and some industrial solvents. Inhalants are second only to marijuana in likelihood of use by adolescents in the United States (Johnston et al. 2003), and about 10% continue to use beyond adolescence for more than 6 years (Neumark et al. 1998).

Many of the inhalants are similar to general anesthetics and sensitize the myocardium to catecholamines; fatal arrhythmias have been reported resulting from inhalant abuse (Shepherd 1989). Antiarrhythmic medications can be given as needed, and supplemental oxygen is administered for hypoxia and to enhance clearance of the inhalant. Chronic inhalant use by industrial workers has caused peripheral neuropathies (Lolin 1989), as well as hepatic, renal, and bone marrow damage (Marjot and McLeod 1989). Cases of methemoglobinemia have been reported secondary to butyl nitrite abuse (Bogart et al. 1986). Chronic complications of abuse usually clear if the patient remains abstinent, but impairment of working memory and executive cognitive function may persist. (See also Chapter 37, "Medical Toxicology.")

Linkage to Addiction Treatment

A psychiatric consultant can address acute issues of intoxication and withdrawal in the inpatient setting. Hospitalization affords an excellent opportunity ("teachable moment") for advising patients to decrease their substance use and for engaging them in treatment (Martins et al. 2007). Brief interventions with trauma patients who have a positive blood alcohol concentration at the time of injury can reduce their future alcohol intake and risk of trauma recidivism (Gentilello et al. 1999). Several inpatient substance abuse consultation services have been described in the literature, but there has been little formal assessment of their efficacy (Fleming et al. 1995; Fuller et al. 1995; McDuff et al. 1997; Murphy et al. 2009).

Acute and long-term treatments are necessary once the diagnosis of SUD is made (McLellan et al. 2000). Recovery from SUD is possible, and those who receive treatment have less disability than do those who do not receive treatment (Hasin et al. 2007). Hospitalized patients identified with SUD should be provided with information linking them to local community addiction treatment resources. In the United States, physicians certified in treatment of addictive disorders can be found through the American Society of Addiction Medicine (www.asam.org) or the American Academy of Addiction Psychiatry (www.aaap.org). At times,

it may be more expedient and cost-effective to refer the patient to a nonphysician counselor, which can be found through the Association for Addiction Professionals (www.naadac.org). Nonpharmacological interventions such as stepped care interventions, contingency management (incentive-based interventions), and needle exchange programs are an essential part of treatment programs for substance abuse. However, for the medically ill, they are usually not a primary focus during hospitalization and consequently are beyond the scope of this chapter.

Impaired Health Care Providers

Some health care workers are at increased risk for addiction because of high-stress occupations and access to controlled substances. Rates of SUD among physicians are 10%–12%, approximately equivalent to the prevalence in the general population (DuPont et al. 2009). Anesthesiologists, emergency department physicians, and psychiatrists have higher rates of identified SUD (Berge et al. 2009). Health care practitioners have higher rates of abuse of opioids and benzodiazepines because of familiarity with and availability of these drugs in a health care setting. Impaired physicians usually have a history of substance abuse that began before medical training (McAuliffe et al. 1987). Initial problems usually affect personal relationships, but deterioration in clinical performance is often one of the last signs of an SUD (Table 17–11). Professionals often have the resources to conceal the addiction for a long time and so may have advanced disease by the time they seek treatment. Impaired performance as a result of drug use may have a significant effect on patient care (Baldisseri 2007).

A definitive diagnosis of SUD in a colleague is not required in order to take action by reporting. There are 49 active physician health programs in 48 states and the District of Columbia (DuPont et al. 2009). These programs are an alternative pathway to disciplinary action by state boards of medicine and are not designed to be punitive unless the physician refuses to comply with recommendations. Most European countries lag behind on national or hospital policies to deal with impaired physicians (Magnavita 2006). Basic elements of treatment for impaired physicians are similar to addiction treatment for nonphysicians, including detoxification, psychiatric and medical evaluation, group counseling, and 12-step attendance, but is often more intensive. Physicians have better outcomes than the general population and other impaired health care workers, with abstinence rates of 75% and successful return to work in 95% of those who complete monitoring (Ganley et al. 2005; McLellan et al. 2008).

TABLE 17-11. Signs of physician impairment

Behavioral	Physical	Workplace	Patient care	Other
Mood swings	Fatigue	Disorganized schedule	Missed appointments	Vague letters of reference
Defensiveness	Change in sleep pattern	Missed deadlines	Inaccessible	New jobs in different geographic areas
Impulsiveness	Weight loss or gain	Decreased work performance	Rounds at odd hours	Unexplained time off between jobs
Anxiousness	Pupil dilation	Frequent breaks	Inappropriate behavior	Prescriptions for family members
Personality changes	Conjunctival injection	Frequent lateness	Inappropriate orders	Heavy drinking at hospital functions
Strained communication	Stumbling	Frequent absences	Conflicts with patients	
Social isolation	Tremulousness	Inappropriate behavior with colleagues		
Changes in long-term relationships	Frequent colds and infections	Inaccessible to staff		
	Deterioration in physical fitness	Conflicts with staff and colleagues		
	Deterioration in personal hygiene	Ordering of large quantities of drugs		

Conclusion

The hospital setting is a good place to identify an SUD and initiate a brief intervention. Treating an SUD patient is not a hopeless process, and the long-term treatment of any chronic disorder can be challenging. Addiction treatment is cost-effective (Harwood et al. 2002), and even multiple episodes of treatment are worthwhile. It can be very rewarding for any health care practitioner to assist a patient who was impaired by addiction to return to normal functioning in society.

PART III

Specialties and Subspecialties

Heart Disease

Peter A. Shapiro, M.D.

CARDIOVASCULAR DISEASE is the cause of death for one-third of American adults (Lloyd-Jones et al. 2009) and the leading cause of death in the developed world. Although some patients experience sudden fatal illness, many have a disease with chronic course that has a marked impact on their life experience. The interface between psychiatry and cardiovascular disease is complex, including both the effects of psychosocial factors on the heart and vascular system and the effects of cardiovascular disease on the brain, psychological function, and psychopathology. Many psychological states and traits have been identified as contributing to risk for the development or exacerbation of heart disease, especially coronary disease, including anxiety, panic, anger, Type A behavior pattern, depression, stress, Type D personality, and sleep disorders. Treatments for psychiatric disorders may also increase cardiovascular disease risk. Behavioral disorders, some associated with psychiatric illness, such as sedentary lifestyle, overeating, smoking, and alcohol abuse also add to the risk of heart disease, especially coronary disease. Conversely, the experience of heart disease seems to contribute to risk for numerous psychiatric problems, especially depression, anxiety, and cognitive disorders. Not only are the psychological effects of dealing with cardiac illness complicated and profound, but also medications and other treatments for heart diseases often have psychiatric effects. Because heart disease is so common, psychiatrists must expect to deal with the effects of cardiovascular comorbidity in the care of their patients, evaluating the role of medical factors in their mental health and recognizing the potential impact of psychiatric interventions on the cardiovascular system (Birkenaes et al. 2006; Rathore et al. 2008). Unfortunately, patients with serious mental disorders tend to receive insufficient screening and treatment for heart disease (Albert et al. 2009; Kisely et al. 2009; Laursen

et al. 2009; Osborn et al. 2006; Rathore et al. 2008), and many patients with heart disease rely on untested complementary and alternative medicine techniques to address emotional stress, depression, and anxiety (Yeh et al. 2006).

Coronary Artery Disease

Aggressive attention to primary prevention measures has reduced the incidence of coronary artery disease (CAD) in the United States over the past 20 years, and early mortality after acute coronary events (Lloyd-Jones et al. 2009). Traditional CAD risk factors include hypertension, smoking, dyslipidemia, diabetes mellitus, male sex, and family history. Increased public awareness about modifiable coronary risk factors and dissemination of effective treatments have resulted in reduction in the prevalence of some of these factors. Nevertheless, the incidence of first acute myocardial infarction (MI) is about 650,000 cases per year in the United States, and of recurrent MI about 350,000 per year (Lloyd-Jones et al. 2009). One-third of patients die within the first hour after the onset of symptoms, before receiving any treatment. Aggressive use of thrombolysis and revascularization procedures, beta-adrenergic blockers, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers, statins, and aspirin and other antiplatelet agents has reduced mortality in those who survive long enough to receive acute care. Estimated 28-day survival after acute MI for patients who survive to hospital admission is over 90%.

Congestive Heart Failure

The prevalence of congestive heart failure (CHF) in the United States is over 2%—a figure essentially unchanged

over the past two decades. In individuals older than 65 years, the incidence of heart failure approaches 1% per year. By and large, heart failure is characterized by an inexorable if gradual downhill course. The 5-year mortality of CHF is 50%, generally within 1 year after the onset of advanced symptoms, although rescue therapies such as ventricular assist devices may alter this trajectory. The primary modes of death in heart failure are pump failure and cardiac arrhythmias (Jessup and Brozena 2003). Treatment with beta-adrenergic blockers, ACE inhibitors, angiotensin II receptor blockers, spironolactone, and implantable cardiac defibrillators reduces the risk of death, whereas inotropic agents have largely failed to do so, although they improve functional status in severely ill patients (Cohn 1996; Jessup and Brozena 2003). New treatments in heart failure include the use of biventricular pacing and long-term ventricular assist devices, which hold the promise of improving survival and quality of life (Cazeau et al. 2001; Jessup and Brozena 2003; Rose et al. 2001; Slaughter et al. 2009).

Psychiatric Disorders in Heart Disease

The development of cardiac disease in a previously well individual is associated with a variety of psychological reactions. Perhaps most fundamentally, it is difficult to maintain denial about one's mortality after a cardiac event. Viewing oneself as having heart disease has effects at every level of psychological development: increasing concerns about dependency, autonomy, control, and ability to provide for others; provoking loss of self-esteem and concern about loss of love; and inciting fears about vitality, sexuality, and mortality. The maintenance of denial has been associated with mental well-being (Levenson et al. 1989; Levine et al. 1987) and may manifest as minimizing the severity of the event ("I just had a small attack") or attributing symptoms to a noncardiac source ("gas pains"), but excessive denial can be detrimental to health because of delay in seeking treatment or failure to accept the need to maintain a treatment regimen (Cassem 1985). In contrast, inadequate denial, or exaggeration of the illness, can lead to invalidism or mental disorder in the cardiac patient.

Attention to one's heartbeat, conscious experience of twinges of chest pain or palpitations, and other preoccupations with minor physical symptoms may result in hypochondriacal avoidance of activity and increased visits to the doctor and emergency room. Research with hypochondriacal, somatizing, and panic disorder patients, who make up a large portion of patients presenting to emergency rooms with noncardiac chest pain, has demonstrated the high level of somatic awareness common in such patients (Barsky 1992; Barsky et al. 1994b, 1996).

Depression

Depression in Coronary Artery Disease

Depression appears to be the most common psychiatric disorder in CAD patients (Barth et al. 2004; Glassman and Shapiro 1998; Rugulies 2002; van Melle et al. 2004; Wulsin and Singal 2003). Numerous surveys of patients with established coronary disease, acute MI, and unstable angina consistently indicate a point prevalence of depression in the range of 15%–20% (Barth et al. 2004; Shapiro et al. 1997; van Melle et al. 2004). In a study of 200 patients interviewed after diagnostic coronary angiography confirmed a diagnosis of CAD, 16% met the criteria for major depressive disorder, and 17% met the criteria for minor depression. Most patients with major depression and about half of those with minor depression were found to have major depression at 1-year follow-up (Hance et al. 1996). Studies in post-MI patients in Europe, Canada, and the United States also converge on a point prevalence of depression of about 15% (Barth et al. 2004; Frasure-Smith et al. 1993; Ladwig et al. 1991; Schleifer et al. 1989; van Melle et al. 2004). This figure is remarkable in light of national surveys indicating a lifetime prevalence of depression of approximately 16% in the general population (Kessler et al. 2003). Three studies of patients following coronary artery bypass graft surgery also demonstrate a point prevalence of depression in the range of 20%–30% (Blumenthal et al. 2003; Connerney et al. 2001; Shapiro et al. 1998). Elevated symptom scores on depression rating scales such as the Beck Depression Inventory are even more common and may predict subsequent major depression (Frasure-Smith et al. 1995a, 1995b).

Many studies indicate a widespread failure to diagnose and treat depression in CAD patients (Frasure-Smith et al. 1993; Luutonen et al. 2002). In a Finnish study (Luutonen et al. 2002) of 85 consecutive post-MI patients with 18-month follow-up, the prevalence of Beck Depression Inventory scores of 10 or greater was 21% in the hospital, 30% at 6 months, and 33.9% at 18 months. Only 6 patients received mental health treatment; 2 received benzodiazepines; none received adequate antidepressant therapy. In the Montreal Heart Institute sample, none of 35 patients identified with major depression by research interviews in the post-MI hospital stay received antidepressants (Frasure-Smith et al. 1993). In another study of patients with newly diagnosed CAD, one-sixth of the sample met the criteria for major depression; at 1-year follow-up, only one-sixth of those who were depressed had received treatment (Hance et al. 1996). The availability of good social support reduces the likelihood of persistent depression after an acute coronary event (Frasure-Smith et al. 1995b, 2000). Current guidelines (Davidson et al. 2006; Lichtman et al. 2008) recommend screening for depression in patients

with CAD, but the added value of screening is not established (Thombs et al. 2008).

Depression in Congestive Heart Failure

Fewer studies have examined the prevalence of depression in patients with CHF, but as in patients with coronary disease, a point prevalence of major depression around 20% is suggested by available data (Faris et al. 2002; Freedland et al. 2003; Jiang et al. 2001; Rutledge et al. 2006; Westlake et al. 2005). An additional 30%–35% of patients have subsyndromal or mild depression symptoms (Jiang et al. 2001; Westlake et al. 2005). Patients with more severe depression symptoms tend to have worse New York Heart Association (NYHA) functional class and exercise tolerance (Westlake et al. 2005). In the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial, a study comparing left ventricular assist device (LVAD) implantation with medical therapy for patients with chronic, end-stage CHF, the mean baseline Beck Depression Inventory score was over 16, indicating moderate to severe depression symptoms, and more than two-thirds of patients had a score over 10 (mild depression) (Rose et al. 2001).

Anxiety

Anxiety in Coronary Artery Disease

The prevalence of anxiety disorders in CAD has not been as well studied as that of depression, but anxiety symptoms are clearly elevated in patients with acute coronary disease and in more than 5%–10% of patients with chronic heart disease (Sullivan et al. 2000). A study of more than 800 patients with stable CAD found a prevalence of generalized anxiety disorder of 5.3%, and elevated anxiety symptoms in 41% (Frasure-Smith and Lesperance 2008). Intense subjective distress and fear of dying immediately after an acute coronary event increase the risk for clinically significant anxiety 1 week to several weeks after the event (Whitehead et al. 2005). Some patients with coronary disease have a family history of death of the parent of the same sex as a result of the same illness. This history is often associated with the conscious fantasy that the patient's death at the age at which the parent died is inevitable, leading to considerable vigilance, avoidance, and other anxiety behaviors.

Anxiety in Congestive Heart Failure

Until recently there have been very few studies of the prevalence of anxiety disorders in CHF patients (MacMahon and Lip 2002). In a survey of ambulatory outpatients with dilated cardiomyopathy, anxiety symptoms rated by the Hospital Anxiety and Depression Scale were significantly increased in comparison with population norms, suggesting

a substantial prevalence of anxiety disorders, but no diagnostic information was obtained (Steptoe et al. 2000). A 2009 review (Yohannes et al. 2009) identified only 8 studies, all from 2005 to 2009, assessing anxiety in samples of only 50–208 CHF patients. The prevalence of elevated anxiety symptoms was 12%–45%. Only one of the reviewed studies, which included 100 ambulatory CHF patients, reported prevalence of anxiety disorders; 11% had generalized anxiety disorder, and 8% had panic disorder (Haworth et al. 2005). Another recent study reported a 10% prevalence of panic disorder in CHF patients treated in cardiology clinic practice (Muller-Tasch et al. 2008). Predictors of anxiety disorder in CHF patients were previous history of mental illness, diabetes, angina, and NYHA functional class. Both anxiety symptoms (Tsuchihashi-Makaya et al. 2009) and diagnosed anxiety disorders (Cully et al. 2009) have been associated with increased health care utilization in CHF patients.

Panic Disorder and Mitral Valve Prolapse

An association of mitral valve prolapse with panic disorder was proposed in the past on the basis of symptoms associated with prolapse (fluttering or palpitation experiences) in patients with panic disorder and echocardiographic findings of prolapse (R. M. Carney et al. 1990; Gorman et al. 1988). Depending on the echocardiographic criteria employed, 5%–20% or more of patients with panic disorder have mitral valve prolapse (Dager et al. 1986; Liberthson et al. 1986; Margraf et al. 1988). Individuals with mitral valve prolapse may be asymptomatic or may experience occasional palpitations or “fluttering” sensations in the precordium, and it has been proposed that these sensations give rise to catastrophic cognitions that stimulate panic attacks in predisposed individuals (Barlow 1988). The link has been questioned, however, because panic attacks do not occur at higher-than-expected rates in patients with echocardiographic mitral valve prolapse, and because mitral valve prolapse occurs in many other psychiatric disorder populations. Confusion has been created by varying criteria for mitral valve prolapse, small sample sizes, and poorly controlled studies. A 2008 systematic review found the evidence of association inconclusive at best (Filho et al. 2008). A possible link, in at least some cases, comes from genetic studies in panic disorder that have identified a syndrome of joint hyperlaxity, bladder and renal abnormalities, mitral valve prolapse, and panic attacks that is linked to chromosome 13 (Hamilton et al. 2003; Martin-Santos et al. 1998).

Anxiety and Automatic Implantable Cardioverter-Defibrillators

Malignant ventricular arrhythmias account for a substantial fraction of fatal events in patients with ischemic heart disease and CHF. The use of automatic implantable cardio-

verter-defibrillators (AICDs) reduces mortality (DiMarco 2003; Epstein et al. 2008), but the experience of defibrillation is unpleasant, likened to being “kicked in the chest.” Implantable defibrillator discharges are associated with iatrogenic anxiety, particularly in patients who experience repetitive, frequent, or early discharges after device implantation (Heller et al. 1998). Early experience indicated a 50% incidence of psychiatric disorders after AICD implantation (adjustment disorders, major depression, and panic disorder) (Morris et al. 1991), but the incidence of psychopathology has apparently diminished over time (Crow et al. 1998). However, significant anxiety and depression symptoms are still present more than 12 months after implantation in 15%–30% of AICD patients (Magyar-Russell et al. 2009).

Although anxiety symptoms, anxiety disorders, and impaired quality of life are more common in patients who have received shocks (Irvine et al. 2002; Jacq et al. 2009; Schron et al. 2002), the likelihood of developing anxiety is also associated with predisposing personality traits such as social inhibition, negative affectivity, and sensitivity to anxiety (Bostwick and Sola 2007; van den Broek et al. 2008). In one study, individual psychological trait factors such as optimism, past history of depression, trait anxiety, and perceived social support accounted for 25%–40% of the variance in self-reported quality of life of patients 9–18 months following AICD implantation, while the experience of having been shocked accounted for only 1%–7% of the variance (Sears et al. 2005). Anxiety is more common in women than in men (Spindler et al. 2009). Although full-fledged post-traumatic stress disorder (PTSD) appears to occur in fewer than 5% of AICD patients, symptoms of the disorder such as avoidance, hypervigilance, and reexperiencing are common, especially if patients experience multiple sequential shocks while conscious, which they endure with a sense of helplessness. A variety of other reactions to implanted defibrillators have been described, including feelings of invulnerability, dependency, and withdrawal (Fricchione et al. 1989; Morris et al. 1991). Despite the potential for unpleasant experiences, most patients with implanted defibrillators report satisfaction with their experience with the device (Bostwick and Sola 2007).

In patients with atrial fibrillation, a trial of defibrillator-delivered pacing and shock therapy for atrial fibrillation found improvement in quality of life at 6-month follow-up after implantation. In patients in whom the device fired during the follow-up period, there was no decrement in quality of life compared with that of patients who did not experience defibrillator discharges (D.M. Newman et al. 2003).

Anxiety and Supraventricular Tachycardia

Patients with supraventricular tachycardia often experience anxiety, especially with paroxysmal arrhythmias (e.g.,

paroxysmal supraventricular tachycardia; see the section “Diagnostic Issues” later in this chapter).

Posttraumatic Stress Disorder in Cardiac Disease

PTSD rates ranging from 0% to 38% have been reported for patients with cardiac disease (Spindler and Pedersen 2005; Wiedemar et al. 2008). Proposed risk factors include personality traits such as repressive coping, alexithymia, and neuroticism, history of depression or of previous trauma, younger age, female gender, limited social support, dissociative symptoms and acute stress reactions immediately during index cardiac events, and subjective factors related to the experience of the event. Changes in the diagnostic criteria for PTSD in DSM-IV (American Psychiatric Association 1994) compared with DSM-III (American Psychiatric Association 1980) made it easier to diagnose PTSD in patients who experienced frightening events in the course of illness (Spindler and Pedersen 2005).

Anxiety and Cardiac Surgery

Heart-focused anxiety increases before cardiac surgery but tends to return to normal levels within 1–6 months after surgery. About 20% of patients continue to experience clinically significant heart-focused anxiety 6 months after surgery (Hoyer et al. 2008). A 10-year retrospective study of 440 coronary artery bypass graft (CABG) patients found increased anxiety symptoms before surgery to be associated with increased mortality risk, after adjusting for other known mortality risk factors (Tully et al. 2008).

Delirium and Neurocognitive Dysfunction

In the cardiac surgery intensive care unit (ICU), delirium, like beauty, is very much in the eye of the beholder. After coronary bypass graft surgery and open-heart procedures, it is evident that many patients have altered mental status with an impaired level of consciousness for some days. Whether these patients are identified as experiencing delirium appears to depend on the sensitivity of the observer and on the degree to which the patient's obtundation or agitation interferes with the clinical management of the postoperative state. Even with the use of structured diagnostic criteria (ICD-10, DSM-IV) and various validated rating scales, incidence rates for delirium in post-cardiac surgery patients range from 6% to over 50% (Detroyer et al. 2008; Kazmierski et al. 2008; Koster et al. 2009; Rudolph et al. 2009). Pioneering studies in the 1960s of the psychiatric aspects of heart disease included observations of the psychiatric complications of mitral commissurotomy and mitral and aortic valve replacement (Kornfeld et al. 1965). These studies documented a high prevalence of delirium in early open-heart surgery patients, which led to changes in ICU design and attention to preservation of sleep-wake

cycles and appropriate use of narcotic analgesia in open-heart surgery. Studies demonstrating the importance of emboli from valvular structures or intracardiac thrombus, and from the cardiopulmonary bypass circuit, for subsequent cognitive impairment led to alterations of surgical technique and bypass circuit filters (S. Newman 1989; S. Newman et al. 1988; Willner and Rodewald 1991).

Frequency of adverse cerebral effects after CABG was estimated at 6% at hospital discharge in a multicenter study of 2,104 patients, with about half of these events being focal neurological events; other problems included persistent cognitive impairment, diminished level of consciousness, and seizures (Roach et al. 1996). Risk factors included advanced age, history of alcohol abuse, systolic hypertension, pulmonary disease, and aortic arch atherosclerosis. A longitudinal study of 261 patients found that 53% of post-CABG patients demonstrated neurocognitive impairment 1 week after surgery; the prevalence of impairment fell to 24% at 6 months (M.F. Newman et al. 2001). Predictors of delirium after open-heart surgery include older age, cerebrovascular disease, prolonged sedation, metabolic derangement, and narcotic use (Giltay et al. 2006; Kazmierski et al. 2008; Norkiene et al. 2007). Off-pump coronary bypass surgery has been studied as a means of reducing delirium and neuropsychological impairment after surgery (Diegeler et al. 2000). Avoidance of the heart-lung bypass machine reduces the production of inflammatory cytokines and reduces emboli to the brain; these fac-

tors appear to correlate with at best modestly improved neuropsychological outcome (Lee et al. 2003; Van Dijk et al. 2002, 2007). Delirium after heart surgery is commonly related to the duration of postoperative sedation with narcotics and benzodiazepines. Substitution of dexmedetomidine for fentanyl, midazolam, or lorazepam sedation reduces the incidence of delirium (Maldonado et al. 2009; Pandharipande et al. 2007).

Psychiatric Side Effects of Cardiac Drugs

A few cardiac medications have psychiatric side effects. These include digoxin, ACE inhibitors, amiodarone, lidocaine, and beta-blockers. Beta-blockers are often blamed for depression, fatigue, and sexual dysfunction; however, it has been demonstrated that fatigue, but not depression, is likely to be exacerbated by beta-blockers (Ko et al. 2002). An exhaustive review is available (Brown and Stoudemire 1998) (Table 18-1).

Psychogenic Cardiac Disability Syndromes

A psychogenic disability syndrome with overvalued ideas or convictions about the severity of one's cardiac illness sometimes occurs after a patient experiences symptoms attributed to heart disease, whether or not actual heart disease exists. In some patients, apparent clinging to symptoms of disease and the resulting disability serve as an unconscious face-saving means to escape otherwise intolerable life stress related to work, troubled intimate rela-

TABLE 18-1. Selected psychiatric side effects of cardiac drugs

Drug/class	Effects
Digoxin	Visual hallucinations (classically, yellow rings around objects), delirium, depression
Beta-blockers	Fatigue, sexual dysfunction
Alpha-blockers	Depression, sexual dysfunction
Lidocaine	Agitation, delirium, psychosis
Carvedilol	Fatigue, insomnia
Methyldopa	Depression, confusion, insomnia
Reserpine	Depression
Clonidine	Depression
ACE inhibitors	Mood elevation or depression (rare)
Pressors (dobutamine, milrinone, dopamine)	Psychiatric effects (rare)
Angiotensin II receptor blockers	Psychiatric effects (rare)
Amiodarone	Mood disorders secondary to thyroid effects
Diuretics	Hypokalemia, hyponatremia resulting in anorexia, weakness, apathy

Note. ACE = angiotensin-converting enzyme.

tionships, or other demands. Remaining in the sick role provides respite from negative affects related to one's previous psychosocial role. Such patients may have a previous history of hard work; denial of dependent needs; and relatively poor capacity for introspection, psychological insight, and verbalization of affects (alexithymia). In other patients, preexisting hypochondriasis, somatization, or panic is directed toward awareness of cardiac symptoms after an initial episode of symptoms. Less commonly, a patient with depression or a chronic psychosis becomes fixated and delusional about cardiac disease. Factitious illness and malingering must also be considered in the differential diagnosis for patients who appear to cling to cardiac disability (Rief et al. 2004).

Sexual Dysfunction

Sexual dysfunction after the onset of heart disease occurs as a consequence of both physical and psychological factors. Physical factors include medications, comorbid medical conditions such as peripheral vascular disease and diabetes mellitus, endothelial dysfunction, and low cardiac output (Kapur et al. 2007). Psychological factors include depression, anxiety, and fear of inducing a heart attack. Coital angina makes up 5% of angina attacks, but it is rare in patients who do not have angina during strenuous physical exertion. The metabolic demand of coitus is about 2–4 metabolic equivalents in men age 33 years, about equal to the demand of walking 2–3 miles/hour. The metabolic demand may be less in older men (DeBusk 2003) (see Chapter 16, "Sexual Dysfunction"). Erectile dysfunction in men with CHF can often be treated with phosphodiesterase type 5 (PDE-5) inhibitors, with appropriate precautions about contraindicated concurrent treatment with nitrates and alpha-adrenergic blockers, which may result in concomitant improvement in mood (Mandras et al. 2007; Webster et al. 2004). Avoidance of intercourse due to fear is associated with greater anxiety and depression in CAD patients, but not with the extent of coronary disease (Kazemi-Saleh et al. 2007).

Effects of Psychological Factors on the Heart and Heart Disease Risk

Depression and Risk of Coronary Heart Disease

Community prospective studies of several different populations demonstrate that a history of depressive disorder or elevated symptoms of depression as evaluated by questionnaire ratings are associated with increased risk for the subsequent development of ischemic heart disease and for coronary disease death. In studies of American, Danish, and Swedish populations, the estimated magnitude of the risk

of incident disease associated with depression is 1.5- to 2.0-fold (Anda et al. 1993; Barefoot and Schroll 1996; Barefoot et al. 1996; Herbst et al. 2007; Rugulies 2002; Wulsin and Singal 2003). Meta-analyses have converged on an estimated 1.6-fold increased relative risk of coronary disease for those with a history of depression (Rugulies 2002; Wulsin and Singal 2003). The risk is probably higher in individuals with major depressive disorder (Surtees et al. 2008). Depression also heightens risk of defibrillator shocks for ventricular tachycardia/ventricular fibrillation and of cardiac arrest, independent of other established CAD risk factors (Empana et al. 2006; Whang et al. 2005, 2009). In patients with preexisting CAD, the risk of death for patients with depression is three- to fourfold higher than that for nondepressed coronary patients (R.M. Carney et al. 2003; Barth et al. 2004; Frasure-Smith et al. 1993, 1995a; Ladwig et al. 1991; van Melle et al. 2004). The association cannot be explained by confounding of depression with severity of heart disease (Kronish et al. 2009). Onset of depression after an acute coronary syndrome, severity of depression measured shortly after the acute coronary syndrome, and persistence of depression (with or without active treatment) all increase risk for long-term mortality after acute coronary syndromes (R.M. Carney and Freedland 2009; R.M. Carney et al. 2009; de Jonge et al. 2006, 2007; Dickens et al. 2008; Glassman et al. 2009; Grace et al. 2005; Kaptein et al. 2006; Parker et al. 2008). Although trends in recent years toward decreased mortality and better outcome after MI and more recognition and treatment of post-MI depression may have diminished the effect of depression on prognosis (Spijkerman et al. 2006), recent studies continue to demonstrate the importance of depression as a risk factor after MI (R.M. Carney et al. 2009).

Depression following CABG surgery predicts recurrent cardiac events at 12 months (Connerney et al. 2001), and both moderate and severe depression symptoms before surgery, and even mild depression persisting from baseline to 6-month follow-up after surgery, are predictors of mortality over several years of follow-up, with hazard ratios of more than 2.0 (Blumenthal et al. 2003).

Vital exhaustion, defined as a mental state of unusual fatigue, feelings of dejection or defeat, and increased irritability, has been associated with increased risk of incident coronary disease in European studies, and a psychotherapeutic intervention to reduce exhaustion has been reported to reduce angina complaints, but not recurrent cardiac events, after angioplasty (Appels and Mulder 1989; Appels et al. 2005, 2006). Although the entity has been conceptualized as distinct from depression (e.g., it does not include self-critical thoughts, and hypothalamic-pituitary-adrenal (HPA) axis activity is diminished rather than increased) (Appels et al. 2005), its overlap with depression

is substantial, and the independent effect of nondepression components of vital exhaustion on CAD risk is uncertain (McGowan et al. 2004).

In contrast to depression, positive emotional characteristics such as optimism and “emotional vitality” have been associated with reduced incidence of CAD (Davidson et al. 2010a). Investigators have tended to view these positive characteristics as independent of depression, rather than simply an absence of depression (Giltay et al. 2004; Kubzansky and Thurston 2007). Absence of positive emotion, independent of other depression symptoms, was associated with increased death and recurrent MI in a 2-year follow-up of patients after coronary stenting (Denollet et al. 2008; Davidson et al. 2010a).

Depression clearly adversely affects patients’ perceptions of their heart disease status and quality of life. Ruo et al. (2003) examined 1,024 patients with stable CAD to evaluate the contributions of depressive symptoms and objective measures of cardiac function to their health status. The patients who had depressive symptoms (20%) were more likely to report coronary disease symptom burden, physical limitations, diminished quality of life, and impaired health. In multivariate analyses, depression symptoms had significant independent association with these health status outcomes. In contrast, exercise capacity, left ventricular ejection fraction, and myocardial ischemia (measured by stress echocardiography) were not related to worse health status. These findings suggest that efforts to improve subjective health and functional status in coronary disease patients should address depression symptoms. A subsequent study (Ruo et al. 2006) in 2,675 postmenopausal women found that new or persistent depression had as powerful an impact on patients’ self-ratings of their health as recent acute coronary events, heart failure, and coronary bypass surgery. Somatic symptoms associated with depression have a stronger effect on CAD prognosis than cognitive-affective symptoms (Linke et al. 2009; Martens et al. 2010).

Mechanisms Linking Depression and Coronary Artery Disease

Candidate psychophysiological mechanisms linking depression to adverse coronary disease outcomes include platelet dysfunction, autonomic dysfunction, and abnormalities of inflammation, but there is not yet compelling evidence comprehensively demonstrating that any of these mechanisms account for depression-related effects on heart disease (R.M. Carney et al. 2002; York et al. 2009). Persons with depression have increased platelet reactivity to orthostatic challenge (Musselman et al. 1996) and heightened circulating levels of beta-thromboglobulin and platelet factor 4, two markers of platelet activation (Laghrissi-

Thode et al. 1997; Pollock et al. 2000). This implies that depressed patients have increased likelihood of thrombus formation in response to thrombogenic stimuli. Serotonin is stored in platelets, and serotonin release is a crucial intermediate step in platelet aggregation and thrombus formation. Serotonin storage in platelets is dependent on a serotonin transporter protein on the platelet cell membrane. Serotonin reuptake inhibitors may reduce the capacity of platelets to store serotonin, and thereby reduce their capacity to initiate thrombus formation. A large case-control study of first MI patients demonstrated that use of serotonergic antidepressants with high affinity for the serotonin transporter protein reduced the risk of MI in comparison with the risk for those using other antidepressant agents (Sauer et al. 2003).

Several measures of cardiac autonomic control, derived from time series or power spectral analyses of heart rate variability (HRV), are also deranged in depression. These measures indicate elevated sympathetic activation, suppression of vagal tone, and increased propensity to cardiac arrhythmias (R.M. Carney et al. 2001; Stein et al. 2000). Some studies have attributed this association primarily to antidepressant drug use (Licht et al. 2008). Similar changes in heart rate variability have been described as common in CAD patients and predict mortality after MI (Bigger et al. 1992, 1993). However, HRV measures were no different in depressed and nondepressed patients with stable CAD in a large patient cohort in the Heart and Soul Study, raising doubt about the importance of the autonomic derangements seen in depression in explaining subsequent cardiovascular events (Gehi et al. 2005b). Other HRV measures less specifically linked to sympathetic nervous system activation may account for a part of the mortality risk attributable to depression after MI (R.M. Carney et al. 2005).

Inflammation has been widely recognized as another process involved in the development of atherosclerosis and acute coronary events (Libby et al. 2002). Inflammatory cytokines are elevated in coronary disease patients, and the extent of elevation of specific markers such as interleukin-6 (IL-6), tumor necrosis factor- α , and C reactive protein (CRP), predicts coronary and cerebrovascular disease events and progression of heart failure (Cesari et al. 2003; Fisman et al. 2006). Depression has been shown to be associated with increased circulating levels of IL-6, CRP, and intercellular adhesion molecule 1 (ICAM-1) (Empana et al. 2005; Liukkonen et al. 2006; G.E. Miller et al. 2002; Vaccarino et al. 2007), but depression adds to risk of CAD incidence and events even after controlling for inflammation (Empana et al. 2005; Vaccarino et al. 2007).

It has also been suggested that antidepressant drugs are the cause of excess cardiovascular events and deaths in patients with depression. There are numerous reports of in-

creased risk of cardiac events and mortality in healthy subjects and coronary disease patients treated with tricyclic antidepressants (TCAs) and/or selective serotonin reuptake inhibitors (SSRIs) (Blanchette et al. 2008; H. W. Cohen et al. 2000; Krantz et al. 2009; Meier et al. 2001; Monster et al. 2004; Rosenberg et al. 2009; Tata et al. 2005; Xiong et al. 2006). None of these studies were randomized trials, however, and they cannot exclude the confounding effect of depression itself on outcomes (O'Connor et al. 2008).

Depression may also exert a negative effect on cardiovascular outcomes through its negative effects on adherence to treatment recommendations. Poor adherence to the medical regimen in CAD patients is associated with increased recurrent cardiac events and mortality (Gehi et al. 2007; J.N. Rasmussen et al. 2007). Demonstrated effects of depression in coronary disease patients include lower rates of smoking cessation, exercise, dietary modification, and adherence to medication regimen (Gehi et al. 2005a; Glassman 1993; Ziegelstein et al. 2000). In fact, differences in adherence behavior between nondepressed and depressed patients with coronary disease may be the most important factor underlying the variance in survival and morbidity associated with depression in coronary disease patients (Hamer et al. 2008; Kronish et al. 2006; Whooley et al. 2008). Improvement in depression symptoms is followed by improved adherence to the medical regimen in heart disease patients (Rieckmann et al. 2006). It remains to be demonstrated in an intervention trial that depression treatment changes any of these candidate mechanisms in a way that accounts for any part of the variance in any cardiovascular outcome.

Intervention Trials

If depression exerts a negative effect on cardiac outcomes in coronary disease, a natural and important question is whether treatment of depression improves coronary disease outcomes. Three large-scale randomized clinical trials have now investigated this question. In the first of these studies, the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART; Glassman et al. 2002), 369 patients with major depression after hospitalization for unstable angina or acute MI were randomized in a double-blind study to receive treatment with sertraline (50–200 mg/day) or placebo. The primary goal of the trial was to assess the safety of sertraline treatment, but a secondary goal was to obtain an estimate of the effect on cardiac outcomes. Although the trial was not powered to adequately test an effect on morbidity or mortality (i.e., only seven deaths occurred during the follow-up period), sertraline was superior in absolute numerical terms to placebo in the rate of recurrent MI, mortality, heart failure, and angina, suggesting that a larger study of treatment effects on mortality would be worthwhile. However, long-term follow-up (mean: 7

years) of the SADHART cohort showed that although more severe depression and failure to improve after short-term treatment were associated with increased mortality, treatment (antidepressant vs. placebo) had no effect on long-term survival (Glassman et al. 2009).

Concurrent with the SADHART, the Enhancing Recovery in Coronary Heart Disease (ENRICHED) trial was directed primarily at addressing the effects of treatment on mortality in post-MI patients (Writing Committee for the ENRICHED Investigators 2003). In ENRICHED, patients with low social support or depression after MI were enrolled in usual care or a cognitive-behavioral therapy (CBT) intervention group. Patients in the intervention group received 6–10 sessions of treatment over 6 months following acute MI. Mortality was assessed at 30-month follow-up. A confounding element of the trial was the use of antidepressants, primarily sertraline, in both arms of the trial in patients with more severe depressive symptoms. The CBT intervention was not effective in reducing mortality, and subgroup analyses did not demonstrate an effect of the intervention even in the depression subgroup. Although the use of sertraline was not randomized, it was notable that all-cause mortality in the sertraline-treated patients was only 7.4%, compared with 15.3% and 10.6% in patients who did not receive drug therapy and patients treated with TCAs, respectively. However, sertraline did not reduce the risk of recurrent nonfatal MI (Taylor et al. 2005).

Suggestive convergent evidence of a possible benefit of SSRI treatment of depression on cardiovascular disease outcomes in cardiovascular disease patients comes from a study of prophylaxis of depression after stroke (A. Rasmussen et al. 2003). In this study, 137 patients with acute ischemic stroke who were not depressed at screening assessment within 4 weeks of the index stroke were randomly assigned to placebo or sertraline treatment for 12 months. The study demonstrated a strong prophylactic effect of sertraline on the incidence of depression, and cardiovascular adverse events during the 12-month follow-up were reduced by two-thirds in the sertraline group compared with the patients receiving placebo.

Myocardial Infarction and Depression—Intervention Trial (MIND-IT), the third major clinical trial, compared a variety of depression interventions against usual care in patients with post-MI depression. A subsample of the MIND-IT patients participated in a randomized, placebo-controlled trial of mirtazapine, but other pharmacotherapy and psychotherapy interventions were also available for intervention group subjects, making this a complicated trial to understand. Although active treatment was modestly more effective than usual care for depression outcome, there was no effect of treatment on cardiac outcomes (Honig et al. 2007; van Melle et al. 2007).

It is notable that in all of these post-MI depression intervention trials, persistence of depression was associated with higher cardiac morbidity and mortality over long-term follow-up (R.M. Carney and Freedland 2009; R.M. Carney et al. 2004; de Jonge et al. 2007; Glassman et al. 2009). Recovery from depression was associated with better long-term cardiac prognosis, but treatment was not. A congruent effect was observed in an observational study of patients following coronary artery bypass surgery, in which patients whose depression improved in the 6 months after surgery had better cardiac prognosis than patients whose depression persisted or worsened (Blumenthal et al. 2003). Conversely, patients with new onset or worsening of depression in the months following myocardial infarction appear to have worse cardiac prognosis (Dickens et al. 2008; Parker et al. 2008).

Depression Effects on CHF Outcome

Depression arising *de novo* in patients after the diagnosis of coronary disease is associated with 1.5-fold increased risk of subsequent development of CHF, even after adjusting for confounding factors (May et al. 2009). Depression is associated with myocardial fibrosis, a characteristic finding in heart failure (Kop et al. 2010), and also appears to be associated with a two- to threefold increased mortality risk in patients hospitalized with CHF (Albert et al. 2009; Jiang et al. 2001; O'Connor et al. 2008; Sherwood et al. 2007). Depressed CHF patients in the hospital receive lower intensity of invasive interventions and referral to outpatient disease management programs, which may contribute to their risk of death (Albert et al. 2009). Prospective cohort studies in ambulatory CHF patients with 2–6 years of follow-up also demonstrate that depression is associated with substantially increased subsequent mortality and recurrent cardiac events (Faris et al. 2002; Junger et al. 2005; Murberg and Furze 2004; Sherwood et al. 2007).

A multicenter study of 460 outpatients with CHF showed that compared with nondepressed patients, patients with significant depression symptoms had both worse subjective health status at baseline (even after adjustment for objective measures of illness) and more deterioration in health status over short-term follow-up. Depression predicted worsening of heart failure symptoms, physical and social functioning, and quality of life. Depression symptoms were the strongest predictor of decline in health status (Rumsfeld et al. 2003).

Mechanisms like those postulated to underlie the relationship of depression and coronary disease have been proposed to account for the effect of depression on CHF outcomes (Joynt et al. 2004), but little pathophysiological research has been performed specifically in depressed patients with heart failure.

Anxiety and CAD Risk

The relationship of anxiety symptoms and disorders to CAD remains unsettled. Several recent reports demonstrate that anxiety symptoms increase risk of incident CAD (Eaker et al. 2005; Shen et al. 2008), and in middle-aged and older men without heart disease, anxiety is associated with incident MI even after controlling for demographic and metabolic risk factors, smoking, alcohol use, and blood pressure, and for depression, Type A behavior, anger, and treatments for hypertension, diabetes, and dyslipidemia during follow-up (Shen et al. 2008). But lifetime anxiety disorders were not associated with risk of CAD in a large epidemiological survey of older adults (Herbst et al. 2007). Anxiety symptoms and tension also modestly increase risk of incident atrial fibrillation (Eaker et al. 2005).

Large-scale prospective epidemiological studies do demonstrate an association of anxiety with sudden cardiac death. In a study involving 33,999 male, middle-aged health professionals with 2-year follow-up, there were 168 new cases of CAD, including 40 fatal and 128 nonfatal events. Fatal but not nonfatal cardiac events increased with the level of phobic anxiety; the excess risk was limited to cases of sudden cardiac death, with a sixfold increased risk associated with high anxiety (Kawachi et al. 1994a). The second study assessed 2,280 men free of chronic disease at baseline, with 32 years of follow-up. After adjustment for potential confounding variables, men with anxiety scores above the ninety-eighth percentile had a 4.46-fold increased risk of sudden cardiac death and a 1.94-fold increased risk of fatal CAD, but no excess risk for angina or nonfatal MI (Kawachi et al. 1994b). In patients with CAD, phobic anxiety is also associated with increased risk of ventricular arrhythmias, and the co-occurrence of anxiety and depression symptoms elevates this risk further (Watkins et al. 2006).

For patients with preexisting CAD, anxiety increases the risk of future events. In hospitalized acute MI patients, high anxiety symptoms are associated with a more than twofold increased risk of death during the hospitalization (Moser and Dracup 1996). In longer-term follow-up after MI, and in patients with stable CAD, anxiety confers increased risk of recurrent major cardiac events and mortality, independent of depression (Frasere-Smith and Lesperance 2008; Frasere-Smith et al. 1995b; Shibeshi et al. 2007; Strik et al. 2003). Preoperative anxiety symptoms have also been associated with a near-doubling of long-term mortality after CABG surgery, after adjustment for other prognostic factors (Tully et al. 2008).

Panic disorder was associated with increased cardiovascular morbidity (MI and stroke) in a large community sample (Weissman et al. 1990) and an anxiety disorders clinic sample (Coryell 1988; Coryell et al. 1986), but these early studies had significant methodological limitations. Newer

studies, however, have supported the finding. A very large prospective epidemiological cohort study found a nearly twofold increased incidence of CAD in panic disorder patients, controlling for tobacco use, comorbid depression, medications, and obesity (Gomez-Caminero et al. 2005), and in the Women's Health Initiative panic attacks were common in healthy postmenopausal women and were associated with risk of subsequent CAD, stroke, and all-cause mortality (Smoller et al. 2007).

Increased CHD incidence also occurs in association with elevated posttraumatic stress symptom severity (Kubzansky et al. 2007). PTSD in patients with established coronary disease is associated with physical symptom burden and impaired quality of life and has a stronger association with self-reported cardiovascular health status than objective measures of cardiac function (B.E. Cohen et al. 2009). Vietnam-era military combat veterans with PTSD have higher rates of heart disease and heart disease mortality than peer veterans without PTSD, and their risk increases in proportion to the severity of their PTSD symptoms (Boscarino 2008).

Anxiety in post-acute coronary syndrome (ACS) patients is associated with reduced adherence to smoking cessation and exercise (Kuhl et al. 2009).

Anger, Type A Behavior, and Hostility

Type A behavior pattern—characterized by anger, impatience, aggravation, and irritability—was linked to incident coronary disease in men in the 1970s. The Western Collaborative Group Study of more than 3,000 middle-aged men demonstrated that Type A behavior was associated with a more than twofold-increased risk of incident MI and of fatal coronary events (Rosenman et al. 1975). One of the few large-scale clinical trials in psychosomatic cardiology, the Recurrent Coronary Prevention Project, examined the effect of group counseling in reducing the impact of Type A behavior pattern on mortality and recurrent infarction. Patients were survivors of an acute MI and were randomly assigned to usual care or Type A behavior modification groups. Follow-up at 4.5 years demonstrated a significant reduction in recurrent infarction in those assigned to Type A counseling (M. Friedman et al. 1986). Subsequent studies of Type A behavior pattern and CAD have been inconclusive or negative, perhaps because of the difficulty in measuring Type A behavior or changes in cardiovascular therapeutics, especially the widespread use of beta-adrenergic blockers in patients with coronary disease (Booth-Kewley and Friedman 1987).

Anger and hostility, considered as “toxic components” within the Type A concept, have also been studied as risk factors for coronary disease but with mixed results in longitudinal observations (Barefoot et al. 1994, 1995). Low

hostility is protective against incident coronary disease (Shekelle et al. 1983); a majority of (but not all) studies find that high anger and high hostility are linked to increased cardiovascular risk (Krantz et al. 2006). In women with ischemic symptoms undergoing evaluation for coronary disease, high hostility was equally likely in those with and without angiographic CAD, but a tendency to overtly aggressive angry responding to angry feelings was associated with CAD, and over 3- to 6-year follow-up, high hostility was associated with more CAD events and lower likelihood of event-free survival (Krantz et al. 2006; Olson et al. 2005). In the Normative Aging Study analysis, anger predicted the incidence of a combined endpoint of coronary death, non-fatal MI, and angina, but it did not predict coronary death or nonfatal MI to a statistically significant degree (Kawachi et al. 1996).

Type D Personality

The combination of tendency to experience negative affects and to inhibit expression of negative emotions in social interactions has been coined Type D (for “distressed”) personality (Denollet 2005; Pelle et al. 2009). This construct, explored almost exclusively in European studies, has been repeatedly associated with increased coronary disease risk (Denollet et al. 1995, 1996, 2006). Type D personality interacts with anxiety to increase arrhythmia risk (Van den Broek et al. 2009).

Acute Mental Stress

George Engel, who championed the biopsychosocial model in medicine, provided vivid examples from the news media of acute mental stress preceding acute coronary events (Engel 1976), and epidemiological studies of disasters have helped to demonstrate the relationship of acute stress to risk for sudden cardiac death (Dimsdale 2008). Even sports events, such as World Cup soccer matches, can have an epidemiologically significant stress effect on the incidence of coronary events (Wilbert-Lampen et al. 2008). In animal models of sudden cardiac death, ventricular tachycardia and fibrillation can be provoked by classically conditioned emotionally aversive stimuli. Interestingly, this effect depends on the presence of myocardial ischemia and can be disrupted by the use of intracerebral beta-adrenergic blockade (DeSilva 1983, 1993; Lown 1990; Lown et al. 1980; Skinner 1985; Skinner and Reed 1981; Skinner et al. 1975). The Northridge, California, earthquake in 1994 caused a surge in sudden cardiac deaths over the subsequent 2 days in individuals who were not physically endangered by the earthquake but resided in the immediate area (Leor et al. 1996). Other earthquake events have provided serendipitous data demonstrating deleterious effects of sudden massive psychological stress on hemoconcentration and
